This is done for each month of the year. The solar energy contribution for the month is the product of \( f \) and the total heating load \( L \) for the month. Finally, the fraction \( F \) of the annual heating load supplied by solar energy is the sum of the monthly solar energy contributions divided by the annual load.

**Fig. 28 Solar Air Heating System**  
(Adapted from Beckman et al. 1977)
Solar Energy Use

![Chart for Air System](Adapted from Beckman et al. 1977)

**Example 6.** Calculating the heating performance of a residence, assume that a solar heating system is to be designed for use in Madison, WI, with two-cover collectors facing south, inclined 58° with respect to the horizontal. The air heating collectors have the characteristics $F_R U_L = 2.84\, W/(m^2 \cdot K)$ and $F_R X \tau_a = 0.49$. The $T_d$ is $-7^\circ C$, the total space and water heating load for January is calculated to be 36 GJ, and the solar radiation incident on the plane of the collector is calculated to be 13 MJ/(d·m²). Determine the fraction of the load supplied by solar energy with a system having a collector area of 50 m².

**Solution:** For air systems, there is no heat exchanger penalty factor and $F_R \tau_a = 1$. The value of $(\tau_a)/(\tau_a)_{no}$ is 0.94 for a two-cover collector in January. Therefore, the values of $X$ and $Y$ are

$$X = (2.84\, W/m^2 \cdot K) \times [100 - (-7)^\circ C] \times 31 \times 86\, 400\, s/d \times (50^2/36\, GJ) = 1.13$$

$$Y = (0.49)(1)(0.94)(13\, MJ/d \cdot m^2) \times (31\, d) \times (50^2/36\, GJ) = 0.26$$

Then the fraction $f$ of the energy supplied for January is 0.19. The total solar energy supplied by this system in January is

$$f L = 0.19 \times 36\, GJ = 6.84\, GJ$$

The annual system performance is obtained by summing the energy quantities for all months. The result is that 37% of the annual load is supplied by solar energy.

The collector heat removal factor $F_R$ that appears in $X$ and $Y$ is a function of the collector fluid flow rate. Because of the higher cost of power for moving fluid through air collectors than through liquid collectors, the capacitance rate used in air heaters is ordinarily much lower than that in liquid heaters. As a result, air heaters generally have a lower value of $F_R$. Values of $F_R$ corresponding to the expected airflow in the collector must be used to calculate $X$ and $Y$.

An increase in airflow rate tends to improve collector performance by increasing $F_R$, but it tends to decrease performance by reducing the degree of thermal stratification in the pebble bed (or water storage tank). The $f$-Chart for air systems is based on a collector airflow rate of 10 L/s per square metre of collector area. The performance with different collector airflow rates can be estimated by using the appropriate values of $F_R$ in both $X$ and $Y$. A further modification to the value of $X$ is required to account for the change in degree of stratification in the pebble bed.

Air system performance is less sensitive to storage capacity than that of liquid systems for two reasons: (1) air systems can operate with air delivered directly to the building in which storage is not used, and (2) pebble beds are highly stratified and additional capacity is effectively added to the cold end of the bed, which is seldom heated and cooled to the same extent as the hot end. The $f$-Chart for air systems is for a nominal storage capacity. Performance of systems with other storage capacities can be determined by modifying the dimensionless group $X$ as described in Beckman et al. (1977).

With modification, $f$-Charts can be used to estimate the performance of solar water heating operating in the range of 50 to 70°C. The main water supply temperature and the minimum acceptable hot water temperature (i.e., the desired delivery temperature) both affect the performance of solar water heating. The dimensionless group $X$, which is related to collector energy loss, can be redefined to include these effects. If monthly values of $X$ are multiplied by a correction factor, the $f$-Chart for liquid-based solar space and water heating systems can be used to estimate monthly values of $f$ for water heating. Experiments and analysis show that the load profile for a well-designed heater has little effect on long-term performance. Although the $f$-Chart was originally developed for two-tank systems, it may be applied to single- and double-tank domestic hot water systems with and without collector tank heat exchangers.

For industrial process heating, absorption air conditioning, or other processes for which the delivery temperature is outside the normal $f$-Chart range, modified $f$-Charts are applicable (Klein et al. 1976). The concept underlying these charts is that of solar usability, which is the fraction of the total solar energy that is useful in the given process. This fraction depends on the required delivery temperature as well as collector characteristics and solar radiation. The procedure allows the energy delivered to be calculated in a manner similar to that for $f$-Charts. An example of the application of this method to solar-assisted heat pumps is presented in Svard et al. (1981).

**Other Active Collector Methods**

The relative areas method, based on correlations of the $f$-Chart method, predicts annual rather than monthly active heating performance (Barley and Winn 1978). An hourly simulation program has been used to develop the **monthly solar-load ratio (SLR)** method, another simplified procedure for residential systems (Dickinson and Cheremisinoff 1980). Based on hour-by-hour simulations, a method was devised to estimate performance based on monthly values of horizontal solar radiation and heating kelvin-days. This SLR method has also been extended to nonresidential buildings for a range of design water temperatures (Dickinson and Cheremisinoff 1980; Schnurr et al. 1981).

**Passive Heating**

A widely accepted simplified passive space heating design tool is the solar-load ratio method (DOE 1980, 1982; ASHRAE 1984). It can be applied manually, although like the $f$-Chart, it is available on microcomputer software. The SLR method for passive systems is based on correlating results of multiple hour-by-hour computer simulations, the algorithms of which have been validated against test cell data for the following generic passive heating types: direct gain, thermal storage wall, and attached sunspace. Monthly and annual performance, as expressed by the auxiliary heating requirement, is predicted by this method. The method applies to single-zone, envelope-dominated buildings. A simplified, annual-basis distillation of SLR results, the **load collector ratio (LCR)** method, and several simple-to-use rules have grown out of the SLR method. Several hand-held calculator and microcomputer programs have been written using the method (Nordham 1981).

The SLR method uses a single dimensionless correlating parameter (SLR), which Balcomb et al. (1982) define as a particular ratio of solar energy gains to building heating load:

$$SLR = \frac{\text{Solar energy absorbed}}{\text{Building heating load}}$$

(36)
A correlation period of 1 month is used; thus the quantities in the SLR are calculated for a 1 month period.

The parameter that is correlated to the SLR, the solar savings fraction (SSF), is defined as

\[
SSF = 1 - \frac{\text{Auxiliary heat}}{\text{Net reference load}} \tag{37}
\]

The SSF measures the energy saving expected from the passive solar building, relative to a reference nonpassive solar building. In Equation (37) the net reference load is equal to the kelvin-day load DD of the nonsolar elements of the building:

\[
\text{Net reference load} = (\text{NLC})(\text{DD}) \tag{38}
\]

where NLC is the net load coefficient, which is a modified load DD of the nonsolar elements of the building. The nominal units are kJ/(K·day). The term DD is the temperature departure in kelvin-days computed for an appropriate base temperature. A building energy analysis based on the SLR correlations begins with a calculation of the monthly SSF values. The monthly auxiliary heating requirement is then calculated by

\[
\text{Auxiliary heat} = (\text{NLC})(\text{DD})(1 - \text{SSF}) \tag{39}
\]

Annual auxiliary heat is calculated by summing the monthly values.

By definition, SSF is the fraction of the heat load of the nonsolar portions of the building met by the solar element. If the solar elements of the building (south-facing walls and window in the northern hemisphere) were replaced by other elements so that the net annual flow of heat through these elements was zero, the annual heat consumption of the building would be the net reference load. The saving achieved by the solar elements would therefore be the net reference load minus the auxiliary heat in Equation (39), which gives

\[
\text{Solar saving} = (\text{NLC})(\text{DD})(\text{SSF}) \tag{40}
\]

Although simple, in many situations and climates, Equation (40) is only approximately true because a normal solar-facing wall with a normal complement of opaque walls and windows has a near-zero effect over the entire heating season. In any case, the auxiliary heat estimate is the primary result and does not depend on this assumption.

The hour-by-hour simulations used as the basis for the SLR correlations are done with a detailed model of the building in which all the design parameters are specified. The only parameter that remains a variable is the solar collector area, which can be expressed in terms of the load collector ratio (LCR):

\[
\text{LCR} = \frac{\text{NLC}}{A_p} = \frac{\text{Net load coefficient}}{\text{Projected collector area}} \tag{41}
\]

Performance variations are estimated from the correlations, which allow the user to account directly for thermostat set point, internal heat generation, glazing orientation, and configuration, shading, and other solar radiation modifiers. Major solar system characteristics are accounted for by selecting one of 94 reference designs. Other design parameters, such as thermal storage thickness and conductivity, and the spacing between glazings, are included in a series of sensitivity calculations obtained using hour-by-hour simulations. The results are generally presented in graphic form so that the designer can see the effect of changing a particular parameter.

Solar radiation correlations for the collector area have been determined using hour-by-hour simulation and typical meteorological year (TMY) weather data. These correlations are expressed as ratios of incident-to-horizontal radiation, transmitted-to-incident radiation, and absorbed-to-transmitted radiation as a function of the latitude minus mid-month solar declination and the atmospheric clearness index \(K_t\).

The performance predictions of the SLR method have been compared to predictions made by the detailed hour-by-hour simulations for a variety of climates in the United States. The standard error in the prediction of the annual SSF, compared to the hour-by-hour simulation, is typically 2 to 4%.

The annual solar savings fraction calculation involves summing the results of 12 monthly calculations. For a particular city, the resulting SSF depends only on the LCR of Equation (41), the type of system, and the temperature base used in calculating the temperature departure. Thus, tables that relate SSF to LCR for the various systems and for various kelvin-day base temperatures may be generated for a particular city. Such tables are easier for hand analysis than are the SLR correlations.

Annual SSF versus LCR tables have been developed for 209 locations in the United States and 14 cities in southern Canada for 94 reference designs and 12 base temperatures (ASHRAE 1984).

Example 7. Consider a small office building located in Denver, Colorado, with 279 \(m^2\) of usable space and a sunspace entry foyer that faces due south; the projected collector area \(A_p\) is 39 \(m^2\). A sketch and preliminary plan are shown in Figure 30. Distribution of solar heat to the offices is primarily by convection through the doorways from the sunspace. The principle thermal mass is in the common wall that separates the sunspace from the offices and in the sunspace floor. This example is abstracted from the detailed version given in Balcomb et al. (1982). Even though lighting and cooling are likely to have the greatest energy costs for this building, heating is a significant energy item and should be addressed by a design that integrates passive solar heating, cooling, and lighting.

Solution: Table 5 shows calculations of the net load coefficient. Then:

\[
\text{NLC} = 86400 \times 277.5 = 24.0 \text{ MJ/(K·d)}
\]

ASHRAE procedures are approximated with \(V = \text{volume, } m^3\); \(c = \text{heat capacity of Denver air, } kJ/(m^3·K)\); \(ACH = \text{air changehour}^{-1}\); equivalent \(UA = V/ACH\). In this case, \(V = 680 \text{ m}^3, c = 1.006 \text{ kJ/(m}^3·\text{K)}\), and \(ACH = 0.5\).

![Fig. 30 Commercial Building in Example 7](image-url)
Solar Energy Use

and the total load coefficient includes the solar aperture:

\[ \text{TLC} = 86400 \times 357 = 30.8 \text{ MJ/(K} \cdot \text{d)} \]

From Equation (43), the load collector ratio is

\[ \text{LCR} = 24.0/39 = 0.615 \text{ MJ/(m}^2 \cdot \text{K} \cdot \text{d)} \]

Suppose the daily internal heat is 135 MJ/day, and the average thermostat setting is 20°C. Then,

\[ T_{\text{base}} = 20 - 135/30.8 = 15.6°C \]

(Note that solar gains to the space are not included in the internal gain term as they customarily are for nonsolar buildings.)

In this example, the solar system is type SSD1, defined in ASHRAE (1984) and Balcomb et al. (1982). It is a semiclosed sunspace with a 300-mm masonry common wall between it and the heated space (offices). The aperture is double-glazed, with a 50° tilt and no night insulation. To achieve a projected area of 39 m², a sloped glazed area of 39/sin 50° = 51 m² is required.

The SLR correlation for solar system type SSD1 is shown in Figure 31. Values of the absorbed solar energy \( S \) and heating kelvin-days DD to base temperature 15.6°C are determined monthly. For \( S \), the solar radiation correlation presented in ASHRAE (1984) for tabulated Denver, CO, weather data are used. For January, the horizontal surface incident radiation is 9.54 MJ/(m²·d). The 15.6°C base kelvin-days are 518. Using the tabulated incident-to-absorbed coefficients found in ASHRAE (1984), \( S = 495.4 \text{ MJ/m}^2 \). Thus \( S/DD = 0.9564 \text{ MJ/(m}^2 \cdot \text{K} \cdot \text{d)} \). From Figure 31, at an LCR = 0.615 MJ/(m²·K·d), the SSF = 0.51. Therefore, for January

\[ \text{LCR} = 24.0/39 = 0.615 \text{ MJ/(m}^2 \cdot \text{K} \cdot \text{d)} \]

\[ \text{Auxiliary heat} = 12.43 – 6.34 = 6.09 \text{ GJ} \]

Repeating this calculation for each month and adding the results for the year yields an annual auxiliary heat of 21.0 GJ.

Other Passive Heating Methods

The concept of usability has been applied to passive buildings. In this approach, the energy requirements of zero- and infinite-capacity buildings are calculated. The amount of solar energy that enters the building and exceeds the instantaneous load of the zero-capacity building is then calculated. This excess energy must be dumped in the zero-capacity building, but it can be stored to offset heating loads in a finite-capacity building. Methods are provided to interpolate between the zero- and infinite-capacity limits for finite-capacity buildings. Equations and graphs for direct gain and collector-storage wall systems are given in Monsen et al. (1981, 1982).

INSTALLATION GUIDELINES

Most solar components are the same as those in HVAC and hot water systems (pumps, piping, valves, and controls), and their installation is not much different from a conventional installation. Solar collectors are the most unfamiliar component in a solar heater. They are located outdoors, which requires penetration of the building envelope. They also require a structural element to support them at the proper tilt and orientation toward the sun.

The site must taken into account. Collectors should be (1) located so that shading is minimized and (2) installed so that they are attractive both on and off site. They should also be located to minimize vandalism and to avoid a safety hazard.

Collectors should be placed near the storage tank to reduce piping cost and heat loss. The collector and piping must be installed so that they can be drained without trapping fluid in the system.

For best annual performance, collectors should be installed at a tilt angle above the horizontal that is appropriate for the local latitude. In the northern hemisphere they should be oriented toward true south, not magnetic south. Small variations in tilt (±10°) and orientation (±20°) do not reduce performance significantly.

Collector Mounting

Solar collectors are usually mounted on the ground or on flat or pitched roofs. A roof location necessitates penetration of the building envelope by mounting hardware, piping, and control wiring. Ground or flat roof-mounted collectors are generally rack-mounted.

Pitched roof mounting can be done several ways. Collectors can be mounted on structural standoffs, which support them at an angle other than that of the roof to optimize solar tilt. In another pitched roof-mounting technique known as direct mounting, collectors are placed on a waterproof membrane on top of the roof sheeting. The finished roof surface together with the necessary collector structural attachments and flashing are then built up around the collector. A weatherproof seal between the collector and the roof must be maintained to prevent leakage, mildew, and rotting.

Integral mounting can be done for new pitched roof construction. The collector is attached to and supported by the structural framing members. The top of the collector then serves as the finished roof surface. Weather tightness is crucial to avoid damage and mildew.

Collectors should support snow loads that occur on the roof area they cover. The collector tilt usually expedites snow sliding with only a small loss in efficiency. The roof structure should be free of objects that could impede snow sliding, and the collectors should be raised high enough to prevent snow buildup over them.

The mounting structure should be built to withstand winds of at least 160 km/h, which impose a wind load of 1.9 kPa on a vertical surface or an average of 1.2 kPa on a tilted roof (HUD 1977). Wind
load requirements may be higher, depending on local building codes. Flat-plate collectors mounted flush with the roof surface should be constructed to withstand the same wind loads.

The collector array becomes more vulnerable to wind gusts as the angle of the mount increases. This wind load, in addition to the equivalent roof area wind loads, should be determined according to accepted engineering procedures (ASCE Standards 7, 8, and 9).

Expansion and contraction of system components, material compatibility, and the use of dissimilar metals must be considered. Collector arrays and mounting hardware (bolts, screws, washers, and angles) must be well protected from corrosion. Steel-mounting hardware in contact with aluminum, and copper piping in contact with aluminum hardware are both examples of metal combinations that have a high potential for corrosion. Dissimilar metals can be separated by washers made of fluorocarbon polymer, phenolic, or neoprene rubber.

Freeze Protection

Freeze protection is extremely important and is often the determining factor when selecting a system in the United States. Freezing can occur at ambient temperatures as high as 6°C because of radiation to the night sky. Manual freeze protection should not be used for commercial installations.

One simple way of protecting against freezing is to drain the fluid from the collector array and interior piping when potential freezing conditions exist. The drainage may be automatic, as in draindown and drainback systems, or manual, as in direct thermosiphon systems. Automatic systems should be capable of fail-safe drainage operation—even in the event of pump failure or power outage. In some cases water may be designed to drain back through the pump, so the design must allow refilling without causing cavitation.

In areas where freezing is infrequent, recirculating water from storage to the collector array can be used as freeze protection. Freeze protection can also be provided by using fluids that resist freezing. Fluids such as water/glycol solutions, silicone oils, and hydrocarbon oils are circulated by pumps through the collector array and double wall heat exchanger. Draining the collector fluid is not required, because these fluids have freezing points well below the coldest anticipated outdoor temperature.

In mild climates where recirculation freeze protection is used, a second level of freeze protection should be provided by flushing the collector with cold supply water when the collector approaches near-freezing temperatures. This can be accomplished with a temperature-controlled valve that will automatically open a small port at a near-freezing temperature of about 4.5°C and then close at a slightly higher temperature.

Over-Temperature Protection

During periods of high insolation and low hot water demand, overheating can occur in the collectors or storage tanks. Protection against overheating must be considered for all portions of the solar hot water system. Liquid expansion or excessive pressure can burst piping or storage tanks. Steam or other gases within a system can restrict liquid flow, making the system inoperable.

The most common methods of overheat protection stop circulation in the collection loop until the storage temperature decreases, discharge the overheated water and replace it with cold makeup water, or use a heat exchanger as a means of heat rejection. Some freeze protection methods can also provide overheat protection.

For nonfreezing fluids such as glycol antifreezes, over-temperature protection is needed to limit fluid degradation at high temperatures during collector stagnation.

Safety

Safety precautions required for installing, operating, and servicing a solar domestic hot water heater are essentially the same as those required for a conventional domestic hot water heater. One major exception is that some solar systems use nonpotable heat transfer fluids. Local codes may require a double wall heat exchanger for potable water installations.

Pressure relief must be provided in all parts of the collector array that can be isolated by valves. The outlet of these relief valves should be piped to a container or drain, and not where people could be affected.

Start-Up Procedure

After completing the installation, certain tests must be performed before charging or filling the system. The system must be checked for leakage, and pumps, fans, valves, and sensors must be checked to see that they function. Testing procedures vary with system type.

Closed-loop systems should be hydrostatically tested. The system is filled and pressurized to 1.5 times the operating pressure for one hour and inspected for leaks and any appreciable pressure drop.

Drain-down systems should be tested to be sure that all water drains from the collectors and piping located outdoors. All lines should be checked for proper pitch so that gravity drains them completely. All valves should be verified to be in working order.

Drain-back systems should be tested to ensure that the collector fluid is draining back to the reservoir tank when circulation stops and that the system refills properly.

Air systems should be tested for leaks before insulation is applied by starting the fans and checking the ductwork for leaks.

Pumps and sensors should be inspected to verify that they are in proper working order. Proper cycling of the pumps can be checked by a running time meter. A sensor that is suspected of being faulty can be dipped alternately in hot and cold water to see if the pump starts or stops.

Following system testing and before filling or charging it with heat transfer fluid, the system should be flushed to remove debris.

Maintenance

All systems should be checked at least once a year in addition to any periodic maintenance that may be required for specific components. A log of all maintenance performed should be kept, along with an owner’s manual that describes system operational characteristics and maintenance requirements.

The collectors’ outer glazing should be hosed down periodically. Leaves, seeds, dirt, and other debris should be carefully swept from the collectors. Care should be taken not to damage plastic covers.

Without opening up a sealed collector panel, the absorber plate should be checked for surface coating damage caused by peeling, crazing, or scratching. Also, the collector tubing should be inspected to ensure that it contacts the absorber. If the tubing is loose, the manufacturer should be consulted for repair instructions.

Heat transfer fluids should be tested and replaced at intervals suggested by the manufacturer. Also, the solar energy storage tank should be drained about every six months to remove sediment.

Performance Monitoring / Minimum Instrumentation

Temperature sensors and temperature differential controllers are required to operate most solar systems. However, additional instruments should be installed for monitoring, checking, and troubleshooting.

Thermometers should be located on the collector supply and return lines so that the temperature difference in the lines can be determined visually.

A pressure gage should be inserted on the discharge side of the pump. The gage can be used to monitor the pressure that the pump must work against and to indicate if the flow passages are blocked.

Running time meters on pumps and fans may be installed to determine if the system is cycling properly.
DESIGN, INSTALLATION, AND OPERATION CHECKLIST

The following checklist is for designers of solar heating and cooling systems. Specific values have not been included because these vary for each application. The designer must decide whether design figures are within acceptable limits for any particular project (see DOE 1978a for further information). The review order listed does not reflect their precedence or importance during design.

Collectors

- Check flow rate for compliance with manufacturer’s recommendation.
- Check that collector area matches the application and claimed solar fraction of the load.
- Review collector instantaneous efficiency curve and check match between collector and system requirements.
- Relate collector construction to end use; two cover plates are not required for low-temperature collection in warm climates and may, in fact, be detrimental. Two cover plates are more efficient when the temperature difference between the absorber plate and outdoor air is high, such as in severe winter climates or when collecting at high temperatures for cooling. Radiation loss only become significant at relatively high absorber plate temperatures. Selective surfaces should be used in these cases. Flat black surfaces are acceptable and sometimes more desirable for low collection temperatures.
- Check match between collector tilt angle, latitude, and collector end use.
- Check collector azimuth.
- Check collector location for potential shading and exposure to vandalism or accidental damage.
- Review provisions made for high stagnation temperature. If not used, are liquid collectors drained or left filled in the summer?
- Check for snow hang-up and ice formation. Will casing vents become blocked?
- Review precautions, if any, against outgassing.
- Check access for cleaning covers.
- Check mounting for stability in high winds.
- Check for architectural integration. Do collectors on roof present rainwater drainage or condensation problems? Do roof penetrations present potential leak problems?
- Check collector construction for structural integrity and durability. Will materials deteriorate under operating conditions? Will any pieces fall off?
- Are liquid collector passages organized in such a way as to allow natural fill and drain? Does mounting configuration affect this?
- Does air collector duct connection promote a balanced airflow and an even heat transfer? Are connections potentially leaky?

Hydraulics

- Check that the flow rate through the collector array matches system parameters.
- If antifreeze is used, check that the flow rate has been modified to allow for the viscosity and specific heat.
- Review properties of proposed antifreeze. Some fluids are highly flammable. Check toxicity, vapor pressure, flash point, and boiling and freezing temperatures at atmospheric pressure.
- Check means of makeup into antifreeze system. An automatic water makeup system can result in freezing.
- Check that provisions are made for draining and filling the system. (Air vents at high points, drains at low points, pipes correctly graded in-between; drainback vented to storage or expansion tank.)
- If system uses drain-back freeze protection, check that
  1. Provision is made for drain-back volume and back venting
  2. Pipes are graded for drain back

3. Solar primary pump is sized for lift head
4. Pump is self-priming if tank is below pump
- Check that collector pressure drop for drainback is slightly higher than static pressure between the supply and return headers.
- Optimum pipe arrangement is reverse return with collectors in parallel. Series collectors reduce flow rate and increase head. A combination of parallel/series can sometimes be beneficial, but check that equipment has been sized and selected properly.
- Cross-connections under different operating modes sometimes result in pumps operating in opposition or tandem, causing severe hydraulic problems.
- If heat exchangers are used, check that approach temperature differential has been recognized in the calculations.
- Check that adequate provisions are made for water expansion and contraction. Use specific volume/temperature tables for calculation. Each unique circuit must have its own provision for expansion and contraction.
- Three-port valves tend to leak through the closed port. This, together with reversed flows in some modes, can cause potential hydraulic problems. As a general rule, simple circuits and controls are better.

Airflow

- Check that the flow rate through the collector array matches the system design values.
- Check temperature rise across collectors using air mass flow and specific heat.
- Check that duct velocities are within the design limits.
- Check that cold air or water cannot flow from collectors by gravity under “no-sun” conditions.
- Verify duct material and construction methods. Ductwork must be sealed to reduce loss.
- Check duct configuration for balanced flow through collector array.
- Check number of collectors in series. More than two collectors in series can reduce collection efficiency.

Thermal Storage

- Check that thermal storage capacity matches values of collector area, collection temperature, utilization temperature, and load.
- Verify that thermal inertia does not impede effective operation.
- Check provisions for promoting temperature stratification during both collection and use.
- Check that pipe and duct connections to storage are compatible with the control, ensuring that only the coolest air goes to the collectors and connections.
- If liquid storage is used for high temperature (above 90°C), check that tank material and construction can withstand the temperature and pressure.
- Check that storage location does not promote unwanted heat loss or gain and that adequate insulation is provided.
- Verify that liquid storage tanks are treated to resist corrosion. This is particularly important in tanks that are partially filled.
- Check that provision is made to protect liquid tanks from exposure to either an overpressure or vacuum.

Uses

Domestic Hot Water

- Characteristics of domestic hot water loads include short periods of high draw interspersed with long dormant periods. Check that domestic hot water storage matches solar heat input.
- Check that provisions have been made to prevent reverse heating of the solar thermal storage by the domestic hot water backup heater.
- Check that the design allows cold makeup water preheating on days of low solar input.
Verifying the anti-scald valve limits domestic hot water supply to a safe temperature during periods of high solar input.

Depending on total dissolved solids, city water heated above 65°C may precipitate a calcium carbonate scale. If collectors are used to heat water directly, check provisions for preventing scale formation in absorber plate waterways.

Check whether the heater is required to have a double wall heat exchanger and that it conforms to appropriate codes if the collector uses nonpotable fluids.

**Heating**

Warm air heating systems have the potential of using solar energy directly at moderate temperatures. Check that air volume is sufficient to meet the heating load at low supply temperatures and that the limit thermostat has been reset.

At times of low solar input, solar heat can still be used to meet part of the load by preheating return air. Check location of solar heating coil in system.

Baseboard heaters require relatively high supply temperatures for satisfactory operation. Their output varies as the 1.5 power of the log mean temperature difference and falls off drastically at low temperatures. If solar is combined with baseboard heating, check that supply temperature is compatible with heating load.

Heat exchangers imply an approach temperature difference that must be added to the system operating temperature to derive the minimum collection temperature. Verify calculations.

Water-to-air heat pumps rely on a constant solar water heat source for operation. When the heat source is depleted, the backup system must be used. Check that storage is adequate.

**Cooling**

Solar activated absorption cooling with fossil fuel backup is currently the only commercially available active cooling. Be assured of all design criteria and a large amount of solar participation. Verify calculations.

Storing both hot water and chilled water may make better use of available storage capacity.

**Controls**

Check that control design matches desired modes of operation.

Verify that collector loop controls recognize solar input, collector temperature, and storage temperature.

Verify that controls allow both the collector loop and the utilization loop to operate independently.

Check that control sequences are reversible and will always revert to the most economical mode.

Check that controls are as simple as possible within the system requirements. Complex controls increase the frequency and possibility of breakdowns.

Check that all controls are fail-safe.

**Performance**

Check building heating, cooling, and domestic hot water loads as applicable. Verify that building thermal characteristics are acceptable.

Check solar energy collected on a monthly basis. Compare with loads and verify solar participation.

**PHOTOVOLTAIC APPLICATIONS**

Photovoltaic (PV) devices, or cells, convert light directly into electricity. Chapter 33 of the 2000 ASHRAE Handbook—Systems and Equipment discusses the fundamentals of their operation. Photovoltaics are used to power communications, equipment in remote locations, remote monitoring, lighting, water pumping, battery charging, and cathodic protection.

**Communications.** Photovoltaics can provide reliable power with little maintenance for communications systems, especially those in remote areas (away from the power grid) with extreme weather conditions such as high winds, heavy snows, and ice. Examples include communication relay towers, travelers’ information transmitters, cellular telephones, mobile radio systems, emergency call boxes, and military test facilities. These systems range in size from a few watts for call boxes to several kilowatts for microwave repeater stations.

For larger systems at remote sites, an engine generator is often combined with the photovoltaic-battery system. These hybrid systems with two or more generators can achieve nearly 100% availability.

**Remote Site Electrification.** Photovoltaics are used to provide power to rural residences, visitor centers in parks, vacation cabins, island and villages, remote research facilities, and military test areas. The varied loads include lighting, small appliances, water pumps (including circulators on solar water heating systems), and communications equipment. The load demand varies from a few watts to tens of kilowatts.

**Remote Monitoring.** Photovoltaics provide power at remote sites to sensors, data loggers, and associated transmitters for meteorological monitoring, structural condition measurement, seismic recording, irrigation control, highway/traffic monitoring, and scientific research. Most of these applications require less than 200 W, and many can be powered by a single photovoltaic module. Vandalism may be a problem in some areas, so non-glass-covered modules are sometimes used. Mounting the modules on a tall pole or in an unobtrusive manner may also help avoid damage or theft. The batteries are often located in the same weather-resistant enclosure as the data acquisition/monitoring equipment. This enclosure is sometimes camouflaged or buried for protection. Some data loggers come with their own battery and charge regulator.

**Signs and Signals.** The most popular application for photovoltaics is warning signs. Typical devices that are powered include navigational beacons, audible signals such as sirens, highway warning signs, railroad signals, and aircraft warning beacons. Because these signals are critical to public safety, they must be operative at all times, and thus the reliability of the photovoltaic system is extremely important. High reliability can be achieved by using large-capacity batteries and no charge control. Many of these systems operate in harsh environments. For maritime applications, special modules are used that are resistant to corrosion from salt water.

**Water Pumping and Control.** Photovoltaics are used for intermediate-sized water pumping applications—those larger than hand pumps and smaller than large engine-powered pumps. The typical range of sizes for photovoltaic-powered pumps is a few hundred watts to a few kilowatts. Applications include domestic use, water for campgrounds, irrigation, village water supplies, and livestock watering. Photovoltaics for livestock watering can be more economical than maintaining a distribution line to a remote pump on a ranch. Most pumping systems do not use batteries but store the water in holding tanks. The photovoltaic modules are often mounted on tracking frames that maximize energy production by tracking the sun each day.

**Rest Room Facilities.** Highway rest stops, public beach facilities, outdoor recreation parks, and public campgrounds may have photovoltaics to operate air circulation and ventilation fans, interior and exterior lights, and auxiliary water pumps for sinks and showers. For most of these applications, the initial cost for photovoltaic power is the least expensive option.

**Charging Vehicle Batteries.** Vehicle batteries self-discharge over time if they are not being used. This is a problem for organizations that maintain a fleet of vehicles such as fire-fighting or snow removal equipment, some of which are infrequently used. Photovoltaic battery chargers can solve this problem by providing a trickle charging current that keeps the battery at a high state of charge. Often the PV module can be placed inside the windshield and plugged into the cigarette lighter, thus using existing wiring and...
protection circuits and providing a quick disconnect for the module. The modules are installed on the roof or engine hood of larger vehicles. An application under development is the use of PV modules to charge the batteries in electric vehicles.

THERMAL storage systems remove heat from or add heat to a storage medium for use at another time. Thermal storage for HVAC applications can involve storage at various temperatures associated with heating or cooling. High-temperature storage is typically associated with solar energy or high-temperature heating, and cool storage with air-conditioning, refrigeration, or cryogenic-temperature processes. Energy may be charged, stored, and discharged daily, weekly, annually, or in seasonal or rapid batch process cycles. The Design Guide for Cool Thermal Storage (Dorgan and Elleson 1993) covers cool storage issues and design parameters in more detail.

Thermal storage may be an economically attractive approach to meeting heating or cooling loads if one or more of the following conditions apply:

- Loads are of short duration
- Loads occur infrequently
- Loads are cyclical in nature
- Loads are not well matched to the availability of the energy source
- Energy costs are time-dependent (e.g., time-of-use energy rates or demand charges for peak energy consumption)
- Utility rebates, tax credits, or other economic incentives are provided for the use of load-shifting equipment
- Energy supply from the utility is limited, thus preventing the use of full-size nonstorage systems

Terminology

Heat storage. As used in this chapter, the storage of thermal energy at temperatures above the nominal temperature of the space or process.

Cool storage. As used in this chapter, the storage of thermal energy at temperatures below the nominal temperature of the space or process.

Mass storage. Storage of energy in building materials in the form of sensible heat.

Sensible energy storage (sensible heat storage). Heat storage or cool storage in which all of the energy stored is in the form of sensible heat associated with a temperature change in the storage medium.

Latent energy storage (latent heat storage). Heat storage or cool storage in which the energy stored is largely as latent heat (usually of fusion) associated with a phase change (usually between solid and liquid states) in the storage medium.

Off-peak air conditioning. An air-conditioning system that uses cool storage during peak periods that was produced during off-peak periods.

Off-peak heating. A heating system that uses heat storage.

The preparation of this chapter is assigned to TC 6.9, Thermal Storage.

Storage Media

A wide range of materials can be used as the storage medium. Desirable characteristics include the following:

- Commonly available
- Low cost
- Environmentally benign
- Nonflammable
- Nonexplosive
- Nontoxic
- Compatible with common HVAC materials
- Noncorrosive
- Inert
- Well-documented physical properties
- High density
- High specific heat (for sensible heat storage)
- High heat of fusion (for latent heat storage)
- High heat transfer characteristics
- Storage at ambient pressure
- Characteristics unchanged over long use

Common storage media for sensible heat storage include water, soil, rock, brick, ceramics, concrete, and various portions of the building structure (or process fluid) being heated or cooled. In HVAC applications such as air conditioning, space heating, and water heating, water is often the chosen thermal storage medium; it provides virtually all of the desirable characteristics when kept between its freezing and boiling points. In lower temperature applications, aqueous secondary coolants (typically glycol solutions) are often used as the heat transfer medium, enabling certain storage media to be used below their freezing or phase-change points. For high-temperature heat storage, the storage medium is often rock, brick, or ceramic materials for residential or small commercial applications and oil, oil-rock combinations, or molten salt for large industrial or solar energy power plant applications. Use of the building structure itself as passive thermal storage offers advantages under some circumstances (Morris et al. 1994).

Common storage media for latent heat storage include water-ice, aqueous brine-ice solutions, and other phase-change materials (PCMs) such as hydrated salts and polymers. Clathrates, carbon dioxide, and paraffin waxes are among the alternative storage media used for latent heat storage at various temperatures. For air-conditioning applications, water-ice is the most common storage medium; it provides virtually all of the previously listed desirable characteristics.

A challenge common to all latent heat storage methods is to find an efficient and economical means of achieving the heat transfer necessary to alternately freeze and thaw the storage medium. Various methods have been developed to limit or deal with the heat...
transfer approach temperatures associated with freezing and melting; however, leaving fluid temperatures (from storage during melting) must be higher than the freezing point, while entering fluid temperatures (to storage during freezing) must be lower than the freezing point. Ice storage can provide leaving temperatures well below those normally used for comfort and nonstorage air-conditioning applications. However, entering temperatures are also much lower than normal. Certain PCM storage systems can be charged using temperatures near those for comfort cooling, but they produce warmer leaving temperatures.

Benefits of Thermal Storage

The primary reasons for the use of thermal storage are economic. The following are some of the key benefits of storage:

**Reduced Equipment Size.** If thermal storage is used to meet all or a portion of peak heating or cooling loads, equipment sized to meet the peak load can be downsized to meet an average load.

**Capital Cost Savings.** Capital savings can result both from equipment downsizing and from certain utility cash incentive programs. Even in the absence of utility cash incentives, the savings from downsizing cooling equipment can offset the cost of the storage. Cool storage integrated with low-temperature air and water distribution systems can also provide an initial cost savings due to the use of smaller chillers, pumps, piping, ducts, and fans. Storage has the potential to provide capital savings for systems having heating or cooling peak loads of extremely short duration.

**Energy Cost Savings.** The significant reduction of time-dependent energy costs such as electric demand charges and on-peak time-of-use energy charges is a major economic incentive for the use of thermal storage.

**Energy Savings.** Although thermal storage is generally designed primarily to shift energy use rather than to conserve energy, storage often reduces energy consumption. Cool storage systems permit chillers to operate more at night when lower condensing temperatures improve equipment efficiency; and storage permits the operation of equipment at full-load, avoiding inefficient part-load performance. Documented examples include chilled water storage installations that reduce annual energy consumption for air conditioning by up to 12% (Fiorino 1994; ITSAC 1992).

**Improved HVAC Operation.** Storage adds an element of thermal capacitance to a heating or cooling system, allowing the decoupling of the thermal load profile from the operation of the equipment. This decoupling can be used to provide increased flexibility, reliability, or backup capacity for the control and operation of the system.

**Other Benefits.** Storage can bring about other beneficial synergies. As already noted, cool storage can be integrated with cold air distribution. Thermal storage can be configured to serve a secondary function such as fire protection, as is often the case with chilled water storage. Some cool storage can be configured for recharge via free cooling (Holness 1992; Hussain and Peters 1992; Meckler 1992).

**ECONOMICS**

Thermal storage is installed for two major reasons: (1) to lower initial cost and (2) to lower operating cost.

**Lower Initial Cost.** Applications such as churches and sports facilities, where the load is short in duration and there is a long time between load occurrences, generally have the lowest initial cost for thermal storage. These buildings have a relatively large space-conditioning load for fewer than 6 h per day and only a few days per week. The relatively small refrigeration plant for these applications would operate continuously for up to 100 h or more to recharge the thermal storage. The initial cost of such a design could be less than that of a standard cooling plant designed to meet the highest instantaneous cooling load.

Secondary capital costs may also be lower for thermal storage. For example, the electrical supply (kVAs) can sometimes be reduced because peak energy demand is lower. For cold air distribution systems, the volume of air is reduced, and smaller air-handling equipment and ducts may generally be used. The smaller air-handling unit sizes may reduce the mechanical room space required, providing more usable space. The smaller duct sizes may allow the floor-to-floor height of the building to be reduced; in some cases, an additional floor may be added without an increase in building height.

An example of reduction in equipment size is shown in Figure 1. The load profiles shown are for a 9000 m² commercial building. If the 22 GJ (6120 kWh) load is met by a nonstorage air-conditioning system, as shown in Figure 1A, a 660 kW chiller is required to meet the peak cooling demand.

If a load-leveling partial storage system is used, as shown in Figure 1B, an 255 kW chiller meets the demand. The design-day cooling load in excess of the chiller output (3060 kWh) is supplied by the storage. The cost of storage approximates the amount saved by downsizing the chiller, cooling tower, electrical service, etc., so load-leveling partial storage is often competitive with nonstorage systems on an initial cost basis.

If a full storage system is installed, as shown in Figure 1C, the entire peak load is shifted to the storage, and a 360 kW chiller is required. The size of the chiller equipment may be reduced, but the total equipment cost including the storage is usually higher for the full storage system than for nonstorage systems. Although the initial cost is higher than for the load-leveling system, Figure 1B, full storage offers substantially reduced operating costs because the entire chiller demand is shifted to the off-peak period.

In order to prepare a complete cost analysis, the initial cost must be determined. Equipment cost should be obtained from each of the manufacturers under consideration, and an estimate of installation cost should be made.

**Lower Operating Cost.** The other reason for installing thermal storage is to reduce operating cost. Most electric utilities charge less during the night or weekend off-peak hours than during the time of highest electrical demand, which often occur on hot summer afternoons due to air-conditioning use. Electric rates are normally divided into a demand charge and a consumption charge.

The monthly demand charge is based on the building’s highest recorded demand for electricity during the month and is measured over a brief period (usually 1 to 15 min). Ratchet billing, another form of demand charge, is based on the highest annual monthly demand. This charge is assessed each month, even if the maximum demand in the particular month is less than the annual peak.

The consumption charge is based on the total measured use of electricity in kilowatt-hours (kWh) over a longer period and are generally representative of the utility’s cost of fuel to operate its generation facilities. In some cases, the consumption charge is lower during off-peak hours because a higher proportion of the electricity is generated by baseload plants that are less expensive to operate. Rates that reflect this difference are known as time-of-use billing structures.

To compare the costs of different systems, the annual operating cost of each system being considered must be estimated, including both electrical demand and consumption costs. To determine demand cost, the monthly peak demand for each system is multiplied by the demand charge and totaled for the year; any necessary adjustments for ratchet billing must be made. The electrical consumption cost is determined by totaling the annual energy use for each system in kilowatt-hours and multiplying it by the cost per kilowatt-hour. For time-of-use billing, energy use must be classified by time-of-use period and multiplied by the corresponding rate.

The first step is to estimate the annual utility cost for nonstorage. For example, the peak demand in Figure 1A, which occurs at 3 P.M. (360 kW), is multiplied by the demand charge...
Thermal Storage

and, if necessary, adjusted for ratchet billing. The energy used during the off-peak period for the nonstorage system (corresponding to 2100 kWh of cooling) would be multiplied by the off-peak electrical rate. The energy used during the on-peak period (4020 kWh) is multiplied by the on-peak electrical rate. This procedure is repeated (1) for each day of each month to determine the energy charge and (2) for the peak day in each month to determine the demand charge.

Annual cost for a load-leveling partial thermal storage is calculated the same way. The peak demand in Figure 1B (255 kW) is multiplied by the demand charge and adjusted for any ratchet billing. This process is repeated for each month. The demand charge for the load-leveling system is lower than for a nonstorage system; the difference represents the demand savings. If time-of-use billing is used, the energy used during the off-peak period (2800 + 1530 = 4320 kWh) is multiplied by the off-peak electrical rate, and the energy consumed during the on-peak period (1780 kWh) is multiplied by the on-peak electrical rate. The total energy cost is lower because less energy is used during the on-peak hours.

The full storage system in Figure 1C eliminates all energy use during the on-peak hours, except energy used by the auxiliary equipment that transfers stored energy. The energy cost for the off-peak period (3960 + 2160 = 6120 kWh) is multiplied by the off-peak rate. This procedure should be repeated for each month to determine the annual energy cost.

The operating cost and the net capital cost should be analyzed using the life-cycle cost method or other suitable method to determine which design is best for the project. Other items to be considered are space requirements, reliability, and ease of interface to the planned delivery equipment. An optimal application of thermal energy storage balances the savings in utility charges against the initial cost of the installation needed to achieve the savings.

APPLICATIONS

Thermal storage can take many forms to suit a variety of applications. This section addresses several groups of thermal storage applications: off-peak air conditioning, retrofits, industrial/process cooling, off-peak heating, district heating and cooling, and other applications.

Thermal Storage Operation and Control

In general, thermal storage operation and control is more schedule-dependent than that for instantaneous systems. Because thermal storage systems separate the generation of heating or cooling from its use, control of each of these functions must be considered separately. Also, many thermal storage systems offer the ability to provide heating or cooling either directly or from storage. With this flexibility comes the need to define how loads will be met at any time. That is, the methods for providing this level of control are defined in terms of (1) the operating modes available to the system, (2) the control strategies used to implement the operating modes, and (3) the operating strategies that determine when the various operating modes and control strategies are selected.

Operating Modes

A complete thermal storage design includes a detailed description of the intended operating strategy and its associated control strategies and operating modes. This description should address control for the complete storage cycle under full-load and part-load operation, including seasonal variations.

The operating strategy defines the overall method of controlling the thermal storage in order to achieve the design intent. The operating strategy determines the logic that governs the selection of operating modes such as charging, meeting the load from chiller(s) only, or meeting the load from discharging storage. The operating
strategy also determines which control strategy is implemented within each mode.

A thermal storage control strategy defines how the system is controlled when it is in a specific operating mode. The control strategy defines the actions of individual control loops and the values of their setpoints in response to changes in load or other variables.

A thermal storage operating mode describes which of several possible functions the system is currently performing. The five basic operating modes are described in Table 1.

The available operating modes differ for individual thermal storage systems. Some systems may include fewer than the five basic modes. For example, the option to meet the load while charging may not be available. In some installations, operation to meet loads may be defined by a single operating mode that includes discharging only at one end of a continuum and direct equipment-only at the other. In fact, many systems operate with just two modes: daytime and nighttime operation.

Many systems also include other operating modes. Some examples include

- Charging cool storage from free cooling
- Charging cool storage while recovering condenser heat
- Charging heat storage with recovered condenser heat
- Discharging at distinct supply temperatures
- Discharging in conjunction with various combinations of available equipment

In general, the control system selects the current operating mode based on the time of day and the day of the week. Other variables that may also be considered include outdoor temperature, current load, or total facility demand at the billing meter.

In some cases, particularly large cool storage systems with multiple chillers and multiple loads, different operating modes or control strategies may be applied to different parts of a system at one time. For example, one chiller may operate in a charging-only mode, while another chiller operates to meet a load.

Control Strategies

A thermal storage control strategy defines how the system is controlled in a specific operating mode. The control strategy defines what equipment is running and the actions of individual control loops, including the values of their setpoints, in response to changes in load or other variables.

Charging the Storage. Control strategies for charging are generally easily defined. Typically the generation equipment operates at full capacity with a constant supply temperature setpoint and a constant flow through the storage. This operation continues until the storage is fully charged or the period available for charging has ended. Under this basic charging control strategy, the entire capacity of the equipment is applied to charging storage.

Charging Storage while Meeting Load. A control strategy for charging storage while meeting load may also operate the generation equipment at its maximum capacity. The capacity that is not needed to meet the load is applied to charging storage. Depending on the system design, the load may be piped either in series or parallel with storage under this operating mode. Some systems may have specific requirements for the operating strategy in this mode. For example, in an ice storage system with a heat exchanger between glycol and water loops, the control strategy may have to address freeze protection for the heat exchanger.

Meeting Load from Discharging Only. A control strategy by discharging only (full storage or load shifting operation) is also straightforward. The generating equipment does not operate and the entire load is met from storage.

Meeting Load from Discharging and Direct Equipment Operation. These strategies are more complex and must regulate what portion of the load at any time will be met from storage and what proportion will be met from direct generation. These partial storage strategies have been mostly developed for and applied to cool storage. While they could also be applied to heat storage, the following discussion is in terms of cool storage. Three common control strategies are chiller priority, storage priority, and constant proportion or proportional control.

Chiller priority control operates the chiller, up to its available capacity, to meet loads. Cooling loads in excess of the chiller capacity are met from storage. If a chiller demand limit is in place, the available capacity of the chiller is less than the maximum capacity.

Chiller priority control can be implemented with any storage configuration. However, it is most commonly applied with the chiller in series upstream of storage. A simple method of implementing chiller priority control is to set the chiller setpoint and the temperature downstream of storage to the desired chilled water supply temperature. When the load exceeds the chiller capacity, the supply temperature exceeds the setpoint, and some flow is diverted through storage to provide the required additional cooling. A potential problem with this method is that if the chiller is controlled by a separate temperature measurement than the storage, sensing errors may cause the storage to be used before the chiller has reached full capacity (i.e., unnecessarily).

A storage priority control strategy meets the load from storage up to its available discharge rate. If the load exceeds this discharge rate, the chiller operates to meet the remaining load. If a storage discharge rate limit is in place, the available discharge rate is less than the maximum discharge rate.

A storage priority strategy must ensure that storage is not depleted too early in the discharge cycle. Failure to properly limit the discharge rate could cause loss of control of the building or excessive demand charges or both. Load forecasting is required to maximize the benefits of storage-priority control. A method for forecasting diurnal energy requirements is described in Chapter 40. Simpler storage-priority strategies using constant discharge rates, predetermined discharge rate schedules or pseudo-predictive methods have been used.

</table>
A constant proportion or proportional control strategy divides the load between chiller and storage. The load may be divided equally or in some other proportion. The proportion may change with time in response to changing conditions. A limit on chiller demand or storage discharge may be applied.

Demand-limiting control may be applied to any of the above control strategies. This type of control attempts to limit the facility demand either by setting a maximum capacity above which the chiller is not allowed to operate or by modulating the chiller set-point. Because chiller demand may comprise 30% or more of the total demand, a large demand savings is possible. The demand limit may be a constant value or it may change with time in response to changing conditions. Demand limiting is most effective when the chiller capacity is controlled in response to the facility demand at the billing meter. In such cases, the chiller capacity is controlled to keep the total demand from exceeding a predetermined facility demand limit. A simpler approach, which generally achieves lower demand savings, is simply to limit chiller capacity or the chiller’s electric demand without considering the total facility demand.

The storage discharge rate may also be limited, similar to the chiller demand limit. The discharge limit establishes a maximum discharge rate that the storage is allowed to provide. Such a limit is typically used with storage priority control strategies to ensure that sufficient capacity will be available for the entire discharge cycle. The discharge rate limit may change with time in response to changing conditions. The discharge limit may be defined in terms of maximum instantaneous cooling capacity supplied from storage. Alternatively, it may be defined either in terms of the maximum flow through storage, or the minimum mixed temperature leaving the storage and its bypass.

Operating strategies that seek to optimize system operation often recalculate the demand limit and discharge limit on a regular basis during the discharge period.

Nearly any partial storage control strategy can be described by specifying (1) whether it is chiller priority, storage priority, or constant proportion, and (2) by specifying the applicable chiller demand limit and storage discharge rate limit.

Applicable utility rates and system efficiency in various operating modes determine the selection of a control strategy. If on-peak energy cost is significantly higher than off-peak energy cost, the use of stored energy should be maximized and a storage priority strategy is appropriate. If on-peak energy is not significantly more expensive than off-peak energy, a chiller priority strategy is more appropriate. If demand charges are high, some type of demand-limiting control should be implemented.

Operating Strategies

It is important to distinguish between the operating strategy, which defines the higher-level logic by which a system will be operated, and the various control strategies, which implement the operating strategy through specific control actions. The operating strategy defines the overall method of controlling the thermal storage system in order to achieve the design intent. The operating strategy determines the logic that governs when each operating mode is selected, as well as what control strategy is implemented within each mode.

Dorgan and Elleson (1993) use the term operating strategy to refer to full storage and partial storage operation. This chapter focuses on design day operation and does not discuss operation under all conditions. For example, a system that is designed for partial storage operation on the design day may operate with a full-storage strategy during many times of the year.

Operating strategies that use sophisticated routines to optimize the use of storage have been investigated (Drees 1994). The cost-saving benefits of such optimal strategies are often small in comparison to well-designed logic that makes full and appropriate use of the principles described previously.

Characterizing Operating and Control Strategies

State diagrams are an effective tool for modeling operating strategy. Rumbaugh et al. (1991) describe the use of state diagrams for modeling systems while Ruchti et al. (1996) describes the application of state diagrams to cool storage control. Figure 3 shows an example of a state diagram of a cool storage system. With structured state diagrams, operating strategies are modeling as a nested hierarchy of supersets and subsets. For example, a simple cool storage system may have just three supersets at the highest level in the hierarchy: charging, discharging, and idle. Each of these three supersets may have multiple subsets. For example, there may be two strategies of discharging: chiller priority and storage priority. In some cases, particularly large systems with multiple chillers and multiple loads, different operating modes or control strategies may be applied to different parts of a system at one time. For example, one chiller may operate in a charging-only mode, while another chiller operates to meet a load.

Common Mistakes

Poorly designed control logic may induce higher costs than if storage had not been used. The following logic should be avoided.

1. Locking out storage during off-peak periods. Doing so may cause overheating and unnecessary service calls to answer complaints that the building is too hot when the load is higher than the chiller capacity during off-peak periods.

2. Charging an external melt system to full capacity every night. External melt systems should only be charged to the minimum required capacity for the next day.

OFF-PEAK AIR CONDITIONING

Refrigeration Design

Packaged compression or absorption equipment is available for most of the cool storage technologies discussed in this chapter. The maximum cooling load that can be satisfied with a single package and the number of packages that must be installed in parallel to yield the required capacity depend on the specific technology. Individual components such as ice builders, chiller bundles, falling-film chillers, ice makers, compressors, and condensers can be used and interconnected on-site.

For the most part, chillers in chilled water storage systems operate at conditions similar to those for nonstorage applications. However, a greater percentage of the operating hours occur at lower ambient temperatures; special consideration should thus be given to providing a condensing temperature that maintains compressor differential.

The lower suction temperature necessary for making ice imposes a higher compression ratio on the refrigeration equipment. Positive displacement compressors (e.g., reciprocating, screw, and scroll compressors) are usually better suited to these higher compression ratios than centrifugal compressors.

Ice storage systems must operate over a wider range of conditions than nonstorage systems. Care should be taken in design and installation to ensure proper operation at all operating points. The following general categorization of refrigeration equipment applies to ice storage systems:

- Direct-expansion systems feed refrigerant to the heat exchanger through expansion valves. The wide range of operating loads requires careful selection and control of expansion valves.
- Flooded or overfeed systems circulate liquid refrigerant from a large low-pressure receiver to the ice-making heat exchangers. Chapter 1 of the 1998 ASHRAE Handbook—Refrigeration covers liquid overfeed systems.
- Secondary coolant systems chill and circulate low-temperature secondary coolant to the ice-producing and storage equipment.
The corrosion properties of the coolant should be considered; a solution containing corrosion inhibitors is normally added. The chiller must also be properly derated both for the lower heat transfer properties of the secondary coolant and for the lower than normal operating temperatures. Secondary coolant systems may use direct-expansion, flooded, or liquid overfeed refrigeration systems.

The following steps should be considered for all ice thermal storage refrigeration:

- **Design for part-load operation.** Refrigerant flow rates, pressure drops, and velocities are reduced during part-load operation. Components and piping must be designed so that control of the system can be maintained and oil can be returned to the compressors at all load conditions.

- **Design for pull-down load.** Because ice-making equipment is designed to operate at water temperatures approaching 0°C, a higher load is imposed on the refrigeration system during the initial start-up, when the inlet water is warmest. The components must be sized to handle this higher load.

- **Plan for chilling versus ice making.** Most ice-making equipment has a much higher instantaneous water/air chilling capacity than ice-making capacity. This higher chilling capacity can be used advantageously if the refrigeration equipment and interconnecting piping are properly sized and selected to handle it.

- **Protect compressors from liquid slugging.** Ice builders and ice harvesters tend to contain more refrigerant than chillers of similar capacity used for nonstorage systems. This provides more opportunity for compressor liquid slugging. Care should be taken to oversize suction accumulators and equip them with high-level compressor cutouts and suction heat exchangers to evaporate any remaining liquid.

- **Oversize the receivers.** Every opportunity should be taken to make the system easy to maintain and service. Maintenance flexibility may be provided in a liquid overfeed system by oversizing the low-pressure receiver and in a direct-expansion system by oversizing the high-pressure receiver.

- **Prevent oil trapping.** Refrigerant lines should be arranged to prevent the trapping of large amounts of oil and to ensure its return to compressors under all operating conditions, especially during periods of low compressor loads. All suction lines should slope toward the suction line accumulators, and all discharge lines should pitch toward the oil separators. Oil tends to collect in the evaporator because that is the location at the lowest temperature and pressure. Because refrigerant accumulators trap oil as well as liquid refrigerant, the larger accumulators needed for ice storage systems require special provisions to ensure adequate oil return to the compressors.

It is very important to fully analyze design trade-offs; equivalent comparisons should be made when comparing cool storage to other available cost- and energy-saving opportunities. For example, if energy-efficient motors are assumed for a cool storage design, they should be assumed for the nonstorage system being compared. Current designs, whether based on HCFC, HFC, ammonia, or on any of the proven refrigeration techniques (e.g., direct-expansion, flooded, or liquid overfeed), should be used.
Cold Air Distribution

Reducing the temperature of the distribution air is attractive because smaller air-handling units, ducts, pumps, and piping can be used, resulting in a lower initial cost. In addition, the reduced ceiling space required for ductwork can significantly reduce building height, particularly in high-rise construction. These cost reductions can make thermal storage competitive with nonstorage on an initial cost basis (Landry and Noble 1991).

The optimum supply air temperature should be determined through an analysis of initial and operating cost for the various design options. Depending on the load, the additional latent energy removed at the lower discharge air temperature may be offset by the reduction in fan energy associated with the lower air flow.

The minimum achievable supply air temperature is determined by the chilled water temperature and the temperature rise between the cooling plant and the terminal units. With some ice storage systems, the fluid temperature may rise during discharge; the supply temperatures normally achievable with various types of ice storage plants must therefore be carefully investigated with the equipment supplier.

A heat exchanger, which is sometimes required with storage tanks that operate at atmospheric pressure or between a secondary coolant and chilled water system, adds at least 1 K to the final chilled water supply temperature. The rise in chilled water temperature between the cooling plant discharge and the chilled water coil depends on the length of piping and the amount of insulation; the difference could be up to 0.3 K over long exposed runs.

The difference between the temperature of the chilled water entering the cooling coil and the temperature of the air leaving the coil is generally between 3 and 5 K. A closer approach (smaller temperature differential) can be achieved with more rows or a larger face area on the cooling coil; but extra heat transfer surface to provide a closer approach is often uneconomical. A 1.5 K temperature rise due to heat gain in the duct between the cooling coil and the terminal units can be assumed for preliminary design analysis. With careful design and adequate insulation, this rise can be reduced to as little as 0.5 K.

A blow-through configuration provides the lowest supply air temperature and the minimum supply air volume. The lowest temperature rise achievable with a draw-through configuration is about 1.5 K because heat from the fan is added to the air. A draw-through configuration should be used if space for flow straightening between the fan and coil is limited. A blow-through unit should not be used with a lined duct because air with high relative humidity enters the duct.

Face velocity determines the size of the coil for a given supply air volume. The coil size determines the size of the air-handling unit. A lower face velocity generates a lower supply air temperature, whereas a higher face velocity results in smaller equipment and lower first costs. The face velocity is limited by moisture carryover from the coil. The face velocity for cold air distribution should be 1.8 to 2.3 m/s, with an upper limit of 2.8 m/s.

Cold primary air can be tempered with room air or plenum return air by using fan-powered mixing boxes or induction boxes. The primary air should be tempered before it is supplied to the conditioned space. The energy use of fan-powered mixing boxes is significant and negates the savings from downsizing central supply fans (Hittle and Smith 1994; Elleson 1993). Diffusers designed for cold air distribution can provide supply air directly to the space without causing drafts, thereby eliminating the need for fan-powered boxes.

If the supply airflow rate to occupied spaces is expected to be below 2 L/s per square metre, fan-powered or induction boxes should be used to boost the air circulation rate. At supply air rates of 2 to 3 L/s per square metre, a diffuser with a high ratio of induced room air to supply air should be used to ensure adequate dispersion of ventilation air throughout the space. A diffuser that relies on turbulent mixing rather than induction to temper the primary air may not be effective at this flow rate.

Cold air distribution systems normally maintain space humidity between 30 and 45% rh, as opposed to the 50 to 60% rh generally maintained by other systems. At this lower humidity level, equivalent comfort conditions are provided at a higher dry-bulb temperature. The increased dry-bulb set point generally results in decreased energy consumption.

The surfaces of any equipment that may be cooled below the ambient dew point, including air-handling units, ducts, and terminal boxes, should be insulated. All vapor barrier penetrations should be sealed to prevent migration of moisture into the insulation. Prefabricated, insulated round ducts should be insulated externally at joints where internal insulation is not continuous. If ducts are internally insulated, access doors should also be insulated.

Duct leakage is undesirable because it represents cooling capacity that is not delivered to the conditioned space. In cold air distribution, leaking air can cool nearby surfaces to the point that condensation forms. Designers should specify acceptable methods of sealing ducts and air-handling units and establish allowable leakage rates and test procedures. These specifications must be followed up with on-site supervision and inspection during construction.

A thorough commissioning process is important for the optimal operation of any large space-conditioning system, particularly thermal storage and cold air distribution systems. Reductions in initial and operating costs are major selling points for cold air distribution, but the commitment to provide a successful system must not be compromised by the desire to reduce first cost. While a commissioning procedure may appear to involve additional expense, it actually decreases cost by reducing future malfunctions and troubleshooting expense and provides increased value by ensuring optimal operation. The commissioning process is discussed in greater detail in the section on Implementation and Commissioning.

Storage of Heat in Cool Storage Units

Some cool storage installations may be used to provide storage for heating duty and/or heat reclaim. Many commercial buildings have areas that require cooling even during the winter, and the refrigeration plant may be in operation year-round. When cool storage is charged during the off-peak period, the rejected heat may be directed to the heating system or to storage rather than to a cooling tower. Depending on the building loads, the chilled water or ice could be considered a byproduct of heating. One potential use of the heat may be to provide morning warm-up on the following day.

Heating with a cool storage system can be achieved using heat pumps or heat-reclaim equipment such as double bundle condensers, two condensers in series on the refrigeration side, or a heat exchanger in the condenser water circuit. Cooling is withdrawn from storage as needed; when heat is required, the cool storage is recharged and used as the heat source for the heat pump. If needed, additional heat must be obtained from another source because this type of system can supply usable heating energy only when the heat pump or heat-recovery equipment is running. Possible secondary heat sources include a heat storage system, solar collectors, or waste heat recovery from exhaust air. When more cooling than heating is required, excess energy can be rejected through a cooling tower.

Individual storage units may be alternated between heat storage and cool storage service. The stored heat can meet the building’s heating requirements, which may include morning warm-up and/or evening heating, and the stored cooling can provide midday cooling. If both the chiller and storage are large enough, all compressor and boiler operation during the on-peak period can be avoided, and the heating or cooling requirements can be satisfied from storage. This method of operation replaces the air-side economizer cycle that involves the use of outside air to cool the building when the enthalpy of the outside air is lower than that of the return air.
The extra cost of equipping a chilled water storage facility for heat storage is small. The necessary plant additions include a partition in the storage tank to convert a portion to warm water storage, some additional controls, and a chiller equipped for heat reclaim. The additional cost may be offset by savings in heating energy. In fact, adding heat storage may increase the economic advantage of cool storage.

Care should be taken to avoid thermal shock in cast-in-place concrete tanks. Tamblyn (1985) showed that the seasonal change from heat storage to cool storage caused sizable leaks to develop if the cool-down period was fewer than five days. Raising the temperature of a concrete tank causes no problems because it generates compressive stresses, which concrete can sustain. Cool-down, on the other hand, causes tensile stresses, under which concrete has low strength.

STORAGE FOR RETROFIT APPLICATIONS

Because latent heat storage (ice and other phase-change materials) has a smaller volume, it is preferable to water storage for retrofit installations where space is limited. Latent heat storage is also preferred for building sites where rock or a high water table make deep excavation for an underground tank expensive. The relatively small size of ice-on-coil units is an advantage in cases where access to the equipment room is limited or where the storage units can be distributed throughout the building and located near the cooling coils.

Existing installations that already contain chilled water piping and chillers are more easily retrofitted to accept chilled water storage than latent heat storage. The requirement for secondary coolant in some ice storage systems may complicate pumping and heat exchange for existing equipment. A secondary coolant temperature colder than the chilled water temperature in the original design typically offsets the reduction in heat transfer.

INDUSTRIAL/PROCESS COOLING

Refrigeration and process cooling typically require lower temperatures than air conditioning. Applications such as vegetable hydrocooling, milk cooling, carcass spray-cooling, and storage room dehumidification can use cold water from an ice storage system. Lower temperatures for freezing food, storing frozen food, and so forth can be obtained by using either a low-temperature hydrated salt phase-change material (PCM) charged and discharged by a secondary coolant or a nonaqueous PCM such as CO₂.

Refrigeration applications have traditionally used heavy-duty industrial refrigeration equipment. The size of the loads has often required custom-engineered, field-erected systems, while the occupancy has often allowed the use of ammonia. Cool storage systems for these applications can be optimized by the choice of refrigerant (halocarbon or ammonia) and the choice of refrigerant feed control (direct-expansion, flooded, mechanically pumped, or gas-pumped).

Some of the advantages of cool storage may be particularly important for refrigeration and process cooling applications. Cool storage can provide a steady supply temperature regardless of large, rapid changes in cooling load or return temperature. Charging equipment and discharging pumps can be placed on a separate electrical service to economically provide cooling during a power blackout or to take advantage of low, intermittent electrical rates. Storage tanks can be oversized to provide water for emergency cooling or fire fighting as well. Cooling can be extracted very quickly from harvested ice storage or chilled water storage to satisfy a very large load and then be discharged slowly using a small charging system. System design may be simplified when the load profile is determined by production scheduling rather than occupancy and outdoor temperatures.

An industrial application for cool storage is the precooling of inlet air for combustion turbines. Oil- or gas-fired combustion turbines typically generate full rated output at an inlet air temperature of 15°C. At higher inlet air temperatures, the mass flow of air is reduced, as are the shaft power and fuel efficiency. The capacity and efficiency can be increased by precooling the inlet combustion air with chilled water coils or direct contact cooling. The optimum inlet air temperature is typically in the range of 5 to 10°C, depending on the turbine model.

On a 38°C summer day, a combustion turbine driving a generator may lose up to 25% of its rated output. This drop in generator output occurs at the most inopportune time, when an electrical utility or industrial user is most in need of the additional electrical output available from combined cycle or peaking turbines. This loss in capacity can be regained if the inlet air is artificially cooled (MacCracken 1994; Mackie 1994; Ebeling et al. 1994; Andrepont 1994). Storage systems using chilled water or ice are well suited to this application because the cooling is generated and stored during off-peak periods, and maximum net increase in generator capacity is obtained by turning off the refrigeration compressor during peak demand periods. While instantaneous cooling is also used for inlet air precooling, they often use 25% to 50% of the increase in power output to drive the refrigeration compressors. Evaporative coolers are a simple and well-established technology for inlet air precooling, but they cannot deliver the low air temperatures available from refrigeration.

OFF-PEAK HEATING

Service Water Heating

The tank-equipped service water heater, which is the standard water heater in North America, is a thermal storage device; some electric utilities provide incentives for off-peak water heating. The heater is equipped with a control system that is activated by a clock or by the electric utility to curtail power use during peak demand. An off-peak water heater generally requires a larger tank than a conventional heater.

An alternate system of off-peak water heating consists of two tanks connected in series, with the hot water outlet of the first tank supplying water to the second tank (ORNL 1985). This arrangement minimizes the mixing of hot and cold water in the second tank. Tests performed on this configuration show that it can supply 80 to 85% of rated capacity at suitable temperatures, compared to 70% for a single-tank configuration. The wiring for the heating elements in the two tanks must be modified to accommodate the dual-tank configuration.

Solar Space and Water Heating

Rock beds, water tanks, or PCMs can be used for solar space and water heating, depending on the type of solar system employed. Various applications are described in Chapter 32.

Space Heating

Thermal storage for space heating can be carried out by radiant floor heating, brick storage heaters (electric thermal storage or ETS heaters), water storage heaters, or PCMs. Radiant floor heating is generally applied to single-story buildings. The choice between the other storage methods depends on the type of heating system. Air heaters use brick, while water heaters may use water or a PCM. Water heaters can be charged either electrically or thermally.

Insulation is more important for heat storage than for cool storage because the difference between storage and ambient temperatures is greater. Methods of determining the cost-effective thickness of insulation are given in Chapter 23 of the 1997 ASHRAE Handbook—Fundamentals.

A rational design procedure requires an hourly simulation of the design heat load and discharge capacity of the storage device. The first criterion for satisfactory performance is that the discharge rate be no less than the design heating load at any hour. During the off-peak period, energy is added to storage at the rate determined by the
room units, heat pump boosters, and central furnaces. The section of off-peak periods, they must store the total daily heating requirement.

Electrically charged room storage heaters are energized only during discharge corresponds to Curves 3 and 4. Since the heating elements heat, the internal fan starts operating. The resulting faster dynamic performance. In reality, radiation and convection from the exterior surface of the device continually supplies heat to the room during charging. Curve 2 shows this static discharge. When the thermostat calls for heat, the internal fan starts operating. The resulting faster dynamic discharge corresponds to Curves 3 and 4. Since the heating elements of electrically charged room storage heaters are energized only during off-peak periods, they must store the total daily heating requirement.

The three types of brick storage heaters currently available are room units, heat pump boosters, and central furnaces. The section on Electrically Charged Heat Storage Devices later in this chapter explains the various types of brick storage heaters.

Water Storage Heaters. Electrically charged pressurized water storage tanks, in most applications, must be able to recharge the full daily heating requirement during the off-peak period, while simultaneously supplying heat during the off-peak period. The heat exchanger design allows a constant discharge and does not decrease near the end of the cycle.

Thermally charged hot water storage tanks are similar in design to the cool storage tanks described in the section on Off-Peak Air Conditioning. Many are also used for cooling. Unlike off-peak cooling, off-peak heating seldom permits a reduction in the size of the heating plant. The size of a storage tank used for both heating and cooling is based more on cooling than on heating for lowest life-cycle cost, except in some residential applications.

District Heating and Cooling. These systems distribute thermal energy (steam, hot and chilled water) from a central energy source (plant) to residential, commercial, and industrial consumers via a distribution system (piping) for use in comfort heating/cooling, service water heating, and process heating/cooling. Thermal energy storage has operated successfully in such district heating and cooling (DHC) applications as off-peak air conditioning, industrial/process cooling, etc. Because most storages tanks are open, attention should be given to system hydraulics when connecting several plants to a common distribution network where storage tank water levels are at different elevations.

The distribution system in DHC is a large percentage of the total system cost. As a result, the higher temperature differential available from thermal storage media lowers life-cycle cost because it allows the use of smaller pipes, valves, pumps, motors, starters, etc. Furthermore, thermal storage may be used to increase the available cooling capacity of an existing chilled water distribution system by providing cooler supply water. This modification would have little impact to the distribution system itself (i.e., pumping and piping) because the existing system flow rates and pressure drops are not changed.

**OTHER APPLICATIONS**

Storage in Aquifers

Aquifers can be used to store large quantities of thermal energy. Aquifers are underground, water-yielding geological formations, either unconsolidated (gravel and sand) or consolidated (rocks). In general, the natural aquifer water temperature is slightly warmer than the local mean annual air temperature. Aquifer thermal energy...
storage has been used for process cooling, space cooling, space heating, and ventilation air preheating (Jenne 1992). Aquifers can be used as heat pump sinks or sources and to store energy from ambient winter air, waste heat, and renewable sources.

The thickness and porosity of the aquifer determine the storage volume. Two separate wells are normally used to charge and discharge aquifer storage. A well pair may be pumped either (1) constantly in one direction or (2) alternatively from one well to the other, especially when both heating and cooling are provided. Backflushing is recommended to maintain well efficiency.

The length of the storage period depends on local climate and on the type of building or process being supplied with cooling or heating. Aquifer thermal energy storage may be used on a short-term or long-term basis, as the sole source of energy or as partial storage, and at a temperature useful for direct application or needing upgrade. It may also be used in combination with a dehumidification system such as desiccant cooling. The cost-effectiveness of aquifer thermal energy storage is based on the avoidance of equipment capital cost and on lower operating cost.

The incorporation of aquifer thermal energy storage into a building system may be accomplished in a variety of ways, depending on the other components present and the intentions of the designer (Hall 1993b; CSA 1993). Control is simplified by separate hot and cold wells that operate on the basis that the last water in is the first water out. This principle ensures that the hottest or coldest water is always available when needed.

Seasonal storage has a large saving potential and began as an environmentally sensitive improvement on the large-scale mining of groundwater (Hall 1993a). The current method reinjects all pumped water to attempt annual thermal balancing (Morofsky 1994; Public Works Canada 1991, 1992; Snijders 1992). Rock caverns have also been used successfully in a manner similar to aquifers to store energy. For example, Oulu, Finland, stores hot water in a cavern for district heating.

**STORAGE TECHNOLOGIES**

**WATER STORAGE**

Water is well suited for both hot and cold storage applications, in part because it has the highest specific heat of all common materials [4.18 kJ/(kg·K)]. ASHRAE Standard 94.3 covers procedures for measuring the thermal performance of sensible heat storage. Tanks are available in many shapes; however, vertical cylinders are the most common. Tanks can be located above ground, partially buried, or completely buried. They are usually atmospheric, unpressurized tanks and may have clear-span spherical dome roofs or column-supported flat roofs.

Water thermal storage vessels must keep cool and warm water volumes separate. This chapter focuses on chilled water storage because it is the most common storage in use. However, the same techniques apply to hot water.

**Temperature Range and Storage Size**

The cooling capacity of a chilled water storage vessel is proportional to the volume of water stored and the temperature differential (Δt) between the stored cool water and the returning warm water. For economical storage, the cooling coils should provide as large a Δt as practical. For example, chillers that cool water in storage to 5°C and coils that return water to storage at 15°C provide a Δt of 10 K. The cost of the extra coil surface required to provide this range can be offset by savings in pipe size, insulation, and pumping energy. Storage is likely to be uneconomical if the temperature differential is less than about 5 K because the tank must be so large (Caldwell and Bahnfleth 1997).

The initial cost of chilled water storage benefits from a dramatic economy of scale; that is, large installations can compare favorably with ice storage as well as with equivalent nonstorage chilled water plants (Andrepont 1992).

**Techniques for Separating Cool and Warm Water Volumes**

The following methods have all been applied in chilled water storage. Thermal stratification has become the dominant method due to its simplicity, reliability, efficiency, and low cost. The other methods are described only for reference.

**Thermal Stratification.** In thermal stratified storage, the warmer, less dense returning water floats on top of the stored chilled water. The water from storage is supplied and withdrawn in low velocity, horizontal flow so that buoyancy forces dominate inertial effects. Pure water is most dense at 4°C; therefore, it can not be stratified below this temperature.

When the stratified storage tank is charged, chilled supply water, typically between 4 and 6.7°C, enters through the diffuser at the bottom of the tank [Figure 5] and return water exits to the chiller through the diffuser at the top of the tank. Typically, the incoming water mixes with the water in the tank to form a 0.3 to 0.9-m thick thermocline, which is a region with vertical temperature and density gradients [Figure 6]. The thermocline prevents further mixing of the water above it with that below it. The thermocline rises as recharging continues and subsequently falls during discharging. It thickens somewhat during charging and discharging due to heat conduction through the water and heat transfer to and from the walls of the tank. The storage tank may have any cross-section, but the walls are usually vertical. Horizontal cylindrical tanks are generally not good candidates for stratified storage.

**Flexible Diaphragm.** A flexible diaphragm (normally horizontal) is used in a tank to separate the cold water from the warm water.

**Multiple Compartments.** Multiple compartments in a single tank or a series of two or more tanks can also be used. Pumping is scheduled so that one compartment is always at least partially empty; water returning from the system during the occupied period and from the chiller during storage regeneration is then received into the empty tank. Water at the different temperatures is thus stored in separate compartments, minimizing blending.

**Labyrinth Tank.** This tank has both horizontal and vertical traverses. The design commonly takes the form of successive cubicles with high and low ports. Strings of cylindrical tanks and tanks with successive vertical weirs may also be used.

**Performance of Chilled Water Storage**

A perfect storage tank would deliver water at the same temperature at which it was stored. It would also require that the water returning to storage neither mix nor exchange heat with the stored water or the tank. In practice, however, both types of heat exchange occur.
Typical temperature profiles of water entering and leaving a storage tank are shown in Figure 7. Tran et al. (1989) tested several large chilled water storage systems and developed the figure of merit, which is used as a measure of the amount of cooling available from the tank.

Well-designed storage tanks have figures of merit of 90% or higher for daily complete charge/discharge cycles and between 80 and 90% for partial charge/discharge cycles.

**Design of Stratification Diffusers**

Stratification diffusers must be designed and constructed to produce and maintain stratification at the maximum flow through storage. The *Design Guide for Cool Thermal Storage* (Dorgan and Elleson 1993) discusses these design parameters. Wildin (1990) gives more information concerning the design of stratified storage hardware.

Inlet and outlet streams must be kept at sufficiently low velocities, so that buoyancy forces predominate over inertia forces in order to produce a gravity current (density current) across the bottom or top of the tank. Designers typically select a diffuser dimension to create an inlet Froude number of 1.0 or less. However, values up to 2.0 have been successfully applied (Yoo et al. 1986). The inlet Froude number Fr is defined as

$$Fr = \frac{Q}{\sqrt{gh \cdot (\Delta \rho / \rho)}}$$

where
- Q = volume flow rate per unit length of diffuser, m³/(s·m)
- g = gravitational acceleration, m/s²
- h = inlet opening height, m
- ρ = inlet water density, kg/m³
- Δρ = difference in density between stored water and incoming or outflowing water, kg/m³

The density difference Δρ can be obtained from Table 2. The inlet Reynolds number is defined as follows:

$$Re = \frac{Q}{\nu}$$

where ν = kinematic viscosity, m²/s.

Experimental evidence indicates that the intensity of mixing near the inlet diffuser is influenced by the inlet Reynolds number. In short tanks, in which the inlet diffuser affects a large portion of the tank volume, the inlet Reynolds number may significantly affect thermal performance. Also, tanks with sloping sidewalls, such as inverted truncated pyramids, may benefit from using lower inlet Reynolds numbers.

Wildin and Truman (1989), observing results from a 1.5-m deep, 6.1-m diameter vertical cylindrical tank, found that reduction of the inlet Reynolds number from 850 (using a radial disk diffuser) to 240 (using a diffuser comprised of pipes in an octagonal array) reduced mixing to negligible proportions. This is consistent with subsequent results obtained by Wildin (1991) in a 0.9 m deep scale model tank, which indicated negligible mixing at Reynolds numbers below approximately 450.

For tall tanks with water depths of 12 m or more, the inlet Reynolds number is less important. Field measurements indicate that inlet mixing does not significantly affect the thermocline when it is more than about 3 m away from the inlet diffuser. Bahnfleth and Joyce (1994) and Musser and Bahnfleth (1998) documented successful operation of tanks with water depths greater than 13.7 m for design inlet Reynolds numbers as high as 6000. However, improvement in the thermal performance of these systems was observed at lower inlet Reynolds numbers. Some consider values of 1000 to 2000 typical for large tanks.

**Storage Tank Insulation**

Exposed tank surfaces should be insulated to help maintain the temperature differential in the tank. Insulation is especially important for smaller storage tanks because the ratio of surface area to stored volume is relatively high. Heat transfer between the stored water and the tank contact surfaces (including divider walls) is a primary source of capacity loss. Not only does the stored fluid lose heat to (or gain heat from) the ambient by conduction through the floor and wall, but heat flows vertically along the tank walls from the
warmer to the cooler region. Exterior insulation of the tank walls does not inhibit this heat transfer.

Other Factors
The cost of chemicals for water treatment may be significant, especially if the tank is filled more than once during its life. A filter system helps keep the stored water clean. Exposure of the stored water to the atmosphere may require the occasional addition of biocides. While tanks should be designed to prohibit leakage, the designer should understand the potential effect of leakage on the selection of chemical water treatment.

The storage circulating pumps should be installed below the minimum operating water level to assure flooded suction. The required net positive suction pressure (NPSH) must be maintained to avoid subatmospheric conditions at the pumps.

ICE STORAGE AND OTHER PHASE-CHANGE MATERIALS

Thermal energy can be stored in the latent heat of fusion of water (ice) or other materials. Water has the highest latent heat of fusion of all common materials—334 kJ/kg at the melting or freezing point of 0°C. The PCM other than water most commonly used for thermal storage is a hydrated salt with a latent heat of fusion of 95.4 kJ/kg and a melting or freezing point of 8.3°C. The volume required to store energy in the form of latent heat is considerably less than that stored as sensible heat, which contributes to lower capital cost.

External Melt Ice-on-Coil Storage
The oldest type of ice storage is the refrigerant-fed ice builder, which consists of refrigerant coils inside a storage tank filled with water [Figure 8]. A compressor and evaporative condenser freeze the tank water on the outside of the coils to a thickness of up to 65 mm. Ice is melted from the outside of the formation (hence the term external melt) by circulating the return water through the tank, whereby it again becomes chilled. Air bubbled through the tank agitates the water to promote uniform ice buildup and melting.

Instead of refrigerant, a secondary coolant (e.g., 25% ethylene glycol and 75% water) is cooled by a liquid chiller and circulated through the coils to freeze the water in the tank. The thickness of ice on the coils and the percentage of the water in the tank that is frozen depend on the coil configuration and on the type of system. During discharge, the reduced heat transfer surface.

Regardless of the refrigeration method (direct-expansion, pumped liquid overfeed, or secondary coolant), the compressor is controlled by (1) a time clock, which restricts operation to the periods dictated by the utility rate structure, and (2) an ice-thickness override control, which stops the compressor(s) at a predetermined ice thickness. At least one ice-thickness device should be installed per ice bank; the devices should be connected in series. If there are multiple refrigeration circuits per ice bank, one ice-thickness control per circuit should be installed. Placement of the ice-thickness device(s) should be determined by the ice-bank manufacturer, based on circuit geometry and flow pressure drop, to minimize bridging.

Ice-thickness controls are either mechanically or electrically operated. A mechanical control typically consists of a fluid-filled probe positioned at the desired distance from the coil. As ice builds, it encapsulates the probe, causing the fluid to freeze and apply pressure. The pressure signal controls the refrigeration system via a pneumatic-electric (P/E) switch. Electric controls sense the three times greater electrical conductivity of ice as compared to water. Multiple probes are installed at the desired thickness, and the change in current flow between probes provides a control signal. Consistent water treatment is essential to maintaining constant conductivity and thus accurate control.

Because energy use is related to ice thickness on the coil, a partial-load ice inventory management system should be considered. This system maintains the ice inventory at the minimum level needed to supply immediate future cooling needs, rather than topping off the inventory after each discharge cycle. This method also helps prevent bridging by ensuring that the tank is completely discharged at regular intervals, thereby allowing ice to build evenly.

The most common method of measuring ice inventory is based on the fact that ice has a greater volume than water; thus, a sensed change in water level can be taken to indicate a change in the amount of stored ice. Water level can be measured by either an electrical probe or a pressure-sensing transducer.

Other methods such as metering of all temperatures and fluid flows (energy) on both sides of the coil (glycol and water) combined with strain gauges on the individual ice coils can be used for calibrating inventory.

Internal Melt Ice-on-Coil Storage
In this type of storage device, coils or tubing are placed inside a water tank [Figure 9]. The coils occupy approximately 10% of the tank volume; another 10% of the volume is left empty to allow for the expansion of the water upon freezing; and the rest is filled with water. A secondary coolant solution (e.g., 25% ethylene glycol and 75% water) is cooled by a liquid chiller and circulated through the coils to freeze the water in the tank. The thickness of ice on the coils and the percentage of the water in the tank that is frozen depend on the coil configuration and on the type of system. During discharge,
the secondary coolant circulates to the system load and returns to the tank to be cooled again by the coils submerged in ice.

A standard chiller can provide the refrigeration for these systems. During the charging cycle for a typical system, the chilled secondary coolant exits from the chiller at a constant −3.5°C and returns at −0.5°C. When the tanks are 90% charged, the chiller inlet and outlet temperatures fall rapidly because there is little water left to freeze. When the chiller exit temperature reaches approximately −5.5°C, the chiller is shut down and locked off for the night so that it does not short-cycle or recirculate due to convection flow through the pipes. The chiller remains fully loaded through the entire cycle and keeps the system running at its maximum efficiency because the exit-temperature thermostat is set at −5.5°C. The temperatures for a given system may vary from this example.

Because the same heat transfer surface freezes and melts the water, the coolant may freeze the water completely every night, minimizing loss in efficiency. A temperature-modulating valve at the outlet of the tanks keeps a constant flow of liquid to the load (see Figure 15). Under a full storage control strategy, the chiller is kept off during discharge, and the modulating valve allows some fluid to bypass the tanks to supply the load as needed. If a partial storage control strategy is followed, the chiller thermostat is reset from the −5.5°C setting up to the design temperature of the cooling coils (e.g., 6.7°C) during the discharge cycle. If the load on the building is low, the chiller operates to meet the 6.7°C setting without depleting the storage. If the load is greater than the chiller’s capacity, the exiting temperature of the secondary coolant rises, and the temperature-modulating valve automatically opens to maintain the design temperature to the coils (Kirshenbaum 1991).

Because water increases 9% in volume when it turns to ice, the water level varies directly with the amount of ice in the tank as long as all of the ice remains submerged. This water displaced by the ice must not be frozen, or it will trap ice above the original water level. Therefore, no heat exchange surface area can be above the original water level.

The change in water level in the tank due to freezing and thawing is typically 150 mm. This change can be measured with either a pressure gage or a standard electrical transducer. On projects with multiple tanks, reverse-return piping ensures uniform flow through all the tanks, so measuring the level on one tank is sufficient to determine the proportion of ice remaining.

Encapsulated Ice

This type of thermal storage relies on plastic containers filled with deionized water and an ice-nucleating agent. Commercially available systems have either spherical containers of approximately 100 mm diameter (Figure 10) or rectangular containers approximately 35 mm by 300 mm by 760 mm (Figure 14). These primary containers are placed in storage tanks, which may be either steel pressure vessels, open concrete tanks, or suitable fiberglass or polyethylene tanks. In tanks with spherical containers, water flows vertically through the tank, and in tanks with rectangular containers, water flows horizontally. The type, size, and shape of the storage tank is limited only by its ability to achieve even flow of heat transfer fluid between the containers. Refrigeration may be any type of liquid chiller rated for the lower temperatures required.

A secondary coolant (e.g., 25% ethylene glycol or propylene glycol and 75% water) is cooled to about −4°C by a liquid chiller and circulates through the tank and over the outside surface of the plastic containers, causing ice to form inside the containers. As for the internal melt ice-on-coil storage, the temperature at the end of the charge cycle is lower (e.g., −5.5°C), and the chiller must be capable of operating at this reduced temperature. The plastic containers must be flexible to allow for change of shape during ice formation; the spherical type has preformed dimples in the surface, and the rectangular type is designed for direct flexure of the walls. During discharge, coolant flows either directly to the load or to a heat exchanger, thereby removing heat from the load and melting the ice within the plastic containers. As the ice melts, the plastic containers return to their original shape.

Ice inventory is measured and controlled by an inventory/expansion tank normally located at the high point in the assembly and connected directly to the main storage tank. As ice forms, the flexible plastic containers force the surrounding secondary coolant into the inventory tank. The liquid level in the inventory tank may be monitored to account for the ice available at any point during the charge or discharge cycle.

Ice-Harvesting

Ice-harvesting systems separate the ice formation from storage. Ice is typically formed on both sides of a hollow, flat plate or on the outside or inside (or both) of a cylindrical evaporator surface. The evaporators are arranged in vertical banks above the storage tank. Ice is formed to thicknesses between 6 and 10 mm. This ice is then harvested, often by introducing hot refrigerant gas into the evaporator. The gas warms the evaporator, which breaks the bond between the ice and the evaporator surface and allows the ice to drop into the storage tank below. Other types of ice harvesters use a mechanical means of separating the ice from the evaporator surface. Figure 11 shows a typical ice-harvesting schematic.

Ice is generated by circulating 0°C water from the storage tank over the evaporators for a 10- to 30-min. build cycle. The defrost time is a function of the amount of energy required to warm the system and break the bond between the ice and the evaporator surface. Depending on the control method, the evaporator configuration, and the discharge conditions of the compressor, defrost can be accomplished in 20 to 90 s. Typically, the evaporators are grouped in sections that are defrosted individually such that the heat of rejection from the active sections provides the energy for defrost. Knebel (1991) showed that the net available capacity from an ice harvester is the compressor gross capacity minus the fraction of time spent in defrost times the total heat of rejection from the compressor.

Tests done by Stovall (1991) indicate that for a four-section plate ice harvester, all of the total heat of rejection is introduced into the evaporator during the defrost cycle. To maximize ice production, harvest time must be kept to a minimum.

In Figure 11 chilled water is pumped from the storage tank to the load and returned to the ice generator. A low-pressure recirculation pump is used to provide minimum flow for wetting the evaporator in the ice-making mode. The system may be applied to load-leveling or load-shifting applications.
In load-leveling applications, ice is generated and the storage tank charged when there is no building load. When a building load is present, the return chilled water flows directly over the evaporator surface, and the ice generator functions either as a chiller or as both an ice generator and a chiller. Cooling capacity as a chiller is a function of the water velocity on the evaporator surface and the entering water temperature. The defrost cycle must be energized any time the exit water temperature is above a temperature that will permit ice generation.

Positive displacement compressors are usually used with ice harvesters, and saturated suction temperatures are usually between −7.8 to −5.5°C. The condensing temperature should be kept as low as possible to reduce energy consumption. The minimum allowable condensing temperature depends on the type of refrigeration used and the defrost characteristics of the system. Several systems operating with evaporative cooled condensers have operated with a compressor-specific power consumption of 0.25 to 0.28 kW/kW (Knebel 1986, 1988a; Knebel and Houston 1989).

Fig. 11 Ice-Harvesting Schematic

Ice-harvesting systems can melt the stored ice very quickly. Individual ice fragments are characteristically less than 150 mm by 150 mm by 6 mm and provide at least 1 m³ of surface area per megajoule (4 m²/kWh) of ice stored. When properly wetted, a 24 h charge of ice can be melted in less than 30 min for emergency cooling demands.

During the ice generation mode, the system is energized if the ice is below the high ice level. A partial storage system is energized only when the entering water is at or above a temperature that will permit chilling during the discharge mode; otherwise, the system is off, and the ice tank is discharged during the on-peak period to meet the load. The high ice level sensor can be mechanical, optical, or electronic. The entering water temperature thermostat is usually electronic.

When ice is floating in the tank, the water level will always be constant, so it is impossible to measure ice inventory by measuring water level. The following methods are generally used to determine the ice inventory:

Water Conductivity Method. As water freezes, dissolved solids are forced out of the ice into the liquid water, thus increasing their concentration in the water. Accurate ice inventory information can be maintained by measuring conductivity and recalibrating daily from the high ice level indicator.

Heat Balance Method. The cooling effect obtained from a system may be determined by measuring the power input to, and heat of rejection from, the compressor. The cooling load on the system is determined by measuring coolant flow and temperature. This may be accomplished by measuring the ice inventory and knowing the time to recharge the storage. The ice inventory is then determined by integrating cooling input minus load and calibrating daily from the high ice level sensor. A variant of the heat balance method is determined by running a heat balance on the compressor only, using performance data from the compressor manufacturer and measured load data (Knebel 1988b).

Optimal performance of ice-harvesting may be achieved by recharging the ice storage tank over a maximum amount of time with minimum compressor capacity. Ice inventory measurement and the known recharge time are used to accomplish this goal. Knebel and Houston (1989) demonstrated that efficiency can be dramatically increased with proper selection of multiple compressors and unloading controls.

Design of the storage tank is important to the operation of the system. The amount of ice stored in a storage tank depends on the shape of the storage, the location of the ice entrance to the tank, the angle of repose of the ice (between 15 and 30°, depending on the shape of the ice fragments), and the water level in the tank. If the water level is high, voids occur under the water due to the buoyancy of the ice. Ice-water slurries have been reported to have a porosity of 0.50 and typical storage densities of 6.53 m³/GJ (0.0235 m³/kWh). Gute et al. (1995), and Stewart et al. (1995a, 1995b) describe models for determining the amount of ice that can be stored in rectangular tanks and the discharge characteristics of various tank configurations. Dorgan and Elleson (1993) provide further information.

Ice Slurry Systems

Simply defined, an ice slurry is a suspension of ice crystals in liquid. In general, the working fluid’s liquid state consists of a solvent (water) and a solute such as glycol, ethanol, or calcium carbonate. Depending on the specific slurry technology, the initial solute concentration varies from 2% to over 10% by mass. The solute depresses the freezing point of the solvent and buffers the production of ice crystals.

Slurry generation begins by lowering the working fluid to its initial freezing point. Extracting additional energy from the working fluid initiates the process of solidification. As solidification proceeds, solute is rejected to the solid-liquid interface (only the water is frozen). The solute-rich interface is eventually incorporated into the bulk fluid by convection and diffusion. As freezing progresses, the solute in the bulk field increases and the freezing point needed to sustain ice crystal production decreases.
Assuming that none of the solute is incorporated into the solid, a relationship between the solute concentration and the ice fraction can be established by the following equation:

\[ f_{\text{ice}} = \frac{C - C_0}{C} \]  

(4)

where \( C \) is the concentration of the solute in the system, \( C_0 \) is the initial solute concentration and \( f_{\text{ice}} \) represents the ice fraction in the system. Thus the ice fraction can be estimated by knowing the initial solute concentration and the solute concentration at any time during slurry production or consumption. The equilibrium solute concentration can be related back to temperature through freezing point curves. A relation between ice fraction and solution temperature is shown in Figure 13, based on an 8% initial concentration of CMA in water.

Thus, by monitoring the liquid temperature during slurry production and slurry consumption, the fraction of ice in a given system can be estimated by knowing the initial solute concentration and the freezing point characteristic of the working fluid. The success of this technique relies on an assumption that all of the solute is being rejected to the liquid phase upon solidification and minimal dilution of the working fluid over time (e.g., due to condensation of moisture from the air in the storage vessel).

Other Phase-Change Materials

Like ice and chilled water storage, hydrated salts have been in use for many decades. PCMs with various phase-change points have been developed. To date, the hydrated salt most commonly used for cool storage applications changes phase at 8.3°C; it is often encapsulated in plastic containers, as described in the section on Encapsulated Ice. This material is a mixture of inorganic salts, water, and nucleating and stabilizing agents. It has a latent heat of fusion of 95.4 kJ/kg and a density of 1490 kg/m³. The PCM’s latent heat of fusion requires a capacity of about 0.044 m³/kWh for the entire tank assembly, including piping headers and water in the tank.

Another option is an internal melt ice-on-coil system in which the water is replaced by salts or polymers that change phase at -11°C or -2°C. The hydrated salts typically have a latent heat of fusion of 267 to 314 kJ/kg and a density of 1040 to 1130 kg/m³.

Typically, 5°C chilled water is used to charge the storage tank of systems using the 8.3°C PCM. The leaving temperature remains a relatively constant 8.3°C until the hydrated salts complete the phase-change process, at which point the temperature of the water leaving the tank begins to approach that of the entering water. It is usually preferable to charge the last 10% to 20% of the tank’s capacity while there is a cooling load because of the low (2 K) temperature difference across the tank.

During discharge, the exit temperature begins at 5.5°C and rises to 9 to 10°C. The usable storage capacity is determined by the highest discharge temperature that can be used by the system.

Any new or existing centrifugal, screw, or reciprocating chiller can be used to charge the storage because conditions are comparable to those for standard air conditioning. As a result, this technology is particularly appropriate for retrofit applications.

As shown in Figure 14, the PCM is sealed inside self-stacking plastic containers measuring approximately 600 mm by 200 mm by 45 mm. The containers are designed to provide space for water to pass between them in a meandering flow pattern. The containers are placed in an open tank, typically of below-grade concrete or sprayed-on concrete. The containers displace about two-thirds of the volume of the tank, so that one-third of the tank is occupied by the water used as the heat transfer medium. The containers do not float or expand when the PCM changes phase, so the container spacing arrangement is maintained throughout the phase-change cycle. The top of the tank can be landscaped or designed for traffic or use as a parking lot.

Precoolers with partial storage provide some storage and a colder water temperature to the load. The 8.3°C PCM can be used with the chiller downstream of the storage to supply water at 6.7°C or lower to the load.

Circuits for Ice Storage

Piping for ice storage can be configured in a variety of ways. Numerous studies have been conducted to determine optimum configurations and control schemes for a variety of designs (Simmonds 1994). The optimum configuration depends on the type of system; the operation, performance, and temperature requirements; and the configuration of the building loop. The chiller may be located upstream or downstream of the building loop, and the cooling plant may also be decoupled from the building load.

An example of a basic piping schematic for ice storage providing partial storage is shown in Figure 15. During off-peak periods, the loop supplying the building load is bypassed, and the chiller charges the ice storage unit. When cooling is required during

Fig. 13 Ice Fraction Versus Temperature for 8% CMA Solution

\[ f_{\text{ice}} = \frac{C - C_0}{C} \]  

Fig. 14 Container for Phase-Change Material
peratures of about 8°C, the same insulation practices apply.

**Storage Tank Insulation**

Because of the low temperature associated with ice storage, insulation is a high priority. In retrofit applications, the current insulation must be evaluated to ensure there is no condensation or excessive heat loss. All ice storage tanks located above ground should be insulated to limit standby losses. For external melt ice-on-coil systems and some internal melt ice-on-coil systems, the insulation and vapor barrier are part of the factory-supplied containers; most other storage tanks require that insulation and a vapor barrier by applied in the field. Below-ground tanks used with ice harvesters may not need insulation below the first metre. Because the tank temperature does not drop below 0°C at any time, there is no danger of freezing and thawing groundwater.

All below-ground tanks using fluids below 0°C during the charge cycle should have a well designed and properly installed insulation and vapor barrier, generally on the exterior. Interior insulation is susceptible to damage from the ice and should be avoided. Because a hydrated salt solution operates at chilled water temperatures of about 8°C, the same insulation practices apply.

**ELECTRICALLY CHARGED HEAT STORAGE DEVICES**

Thermal energy can also be stored in electrically-charged, thermally-discharged storage devices. For devices that use a solid mass as the storage medium, equipment size is typically specified by the nominal power rating (to the nearest kilowatt) of the internal heating elements. The nominal storage capacity is taken as the amount of energy supplied during an 8 h charge period. For example, a 5 kW heater would have a nominal storage capacity of 144 MJ (40 kWh). ASHRAE Standard 94.2 describes methods for testing these devices. If multiple charge/off-peak periods are available during a 24 h period, an alternative method yields a more accurate estimate of equipment size. The method considers not only the nominal power rating, but also fan discharge rate and storage capacity. The equipment manufacturer should have more information on calculating capacity.

**Room Storage Heaters (Room Units)**

Room storage heaters (commonly called room units) have magnetite or magnesite brick cores encased in shallow metal cabinets. The core can be heated to 760°C during off-peak hours by resistance heating elements located throughout the cabinet. Room units are generally small heaters that are placed into a particular area or room. These heaters have well-insulated storage cavities, which help retain the heat in the brick cavity. Even though the brick inside the units get very hot, the outside of the heater is relatively cool with surface temperatures generally below 80°C. Storage heaters are discharged by natural convection, radiation, and conduction (static heaters) or by a fan. The air flowing through the core is mixed with room air to limit the outlet air temperature to a comfortable range.

Storage capacities range from 49 to 216 MJ (13.5 to 60 kWh). Inputs range from 0.8 to 9.0 kW. In the United States, 120 V, 208 V, 240 V, and 277 V units are commonly available. The 120 V model is useful for heating smaller areas or in geographical areas with moderate heating days. Room storage heaters are for residential, motel, hotel, apartment, and office applications.

Operation is relatively simple. When a room thermostat calls for heat, fans (on dynamic units) located in the lower section of the room unit discharge air through the ceramic brick core and into the room. Depending on the charge level of the brick core, a small amount of radiant heat may also be delivered from the room unit. The amount of heat stored in the brick core of the unit can be regulated either manually or automatically in relation to the outside temperature.

These units fully charge in about 7 h and they can be fully depleted in as little as 6 h. The equipment retains heat for up to 72 h (3 days) if it has no fan discharge.

Choosing the appropriate size of room unit(s) depends on control strategy of the power company (on-peak versus off-peak hours), outside design climate, and heat loss of the area or space. The manufacturer of the equipment may provide assistance in determining the heat loss for the area requiring heat. Based on the control strategy of the power company, the following two concepts can be used for sizing of the equipment:

**Whole House Concept.** Under this strategy, room units are placed throughout the home. A room by room heat loss calculation must be performed. This method is used in areas where the power company has long hours of consecutive control (on-peak hours), generally 10 h or more.
Warm Room Concept. Under this strategy, one or two room units are generally used as the primary heating source during the control (on-peak) periods. The units are placed in the area most often occupied (main area). Adjacent areas generally are kept cooler and have no operable heat during the control (on-peak) time; however, some heat migrates from the main area.

When determining the heat loss of the main area, an additional sizing factor of approximately 25% should be added to allow for migration of heat to adjacent areas. Under the warm room concept, sizing factors vary depending upon the control strategy of the power company and the performance of the equipment under those control strategies. The designer should consult the manufacturer of the equipment for specific sizing information.

The warm room concept is the most common method used by power companies for their load management and off-peak marketing programs. It is successful in areas that have a small number of consecutive hours of control (generally 10 hours or less), or have a mid-day block of off-peak time during which the equipment can recharge. The advantage of the warm room concept is that it requires smaller sizes and quantity of equipment than the whole house concept.

Heat Pump Booster

Air-to-air heat pumps generally perform well when outside temperatures are relatively warm. However, as outside temperature drops, the efficiency, output capacity, and temperature from a heat pump also declines. When the output of the heat pump drops below the heat loss of the structure, supplemental heat (typically from an electric resistance unit) must be added to maintain comfort. To eliminate the use of electric resistance heat during peak periods, storage heaters such as the heat pump booster (HPB) can be used to supplement the output of a heat pump. The HPB can also be used as a booster for stand-alone furnaces or to back up electric or fossil fuel equipment in dual-fuel programs.

Core charging of the HPB is regulated automatically based on outdoor temperature. The brick storage core is well insulated so that radiant or static heat discharge is small. Equipment input power ratings range from 11 to 22 kW. Storage capacities range from 270 to 490 MJ (75 to 135 kWh).

Central Furnace

The central storage furnace is a centrally-ducted, heat-storage product for residential and small commercial and industrial applications. These units are available with input ratings ranging from 28.8 to 38.4 kW. Storage capacities range from 650 to 860 MJ (180 to 240 kWh).

Pressurized Water Storage Heaters

This storage device consists of an insulated cylindrical steel tank containing immersion electrical resistance elements near the bottom of the tank and a water-to-water heat exchanger near the top. During off-peak periods, the resistance elements are sequentially energized until the storage water reaches a maximum temperature of 138°C, corresponding to 240 kPa (gage). The ASME Boiler Code considers such vessels unfired pressure vessels, so they are not required to meet the provisions for fired vessels. The heaters are controlled by a pressure sensor, which eliminates problems that could be caused by unequal temperature distributions. A thermal controller gives high-limit temperature protection. Heat is withdrawn from storage by running service water through the heat exchangers and a tempering device that controls the output temperature to a predetermined level. The storage capacity of the device is the sensible heat of water between 5 K above the desired output water temperature and 138°C. The output water can be used for space heating or service hot water. The water in the storage tank is permanently treated and sealed, requires no makeup, and does not interact with the service water.
**Underfloor Heat Storage**

This storage method typically uses electric resistance cables buried in a bed of sand 300 to 900 mm below the floor of a building. It is suitable for single-story buildings, such as residences, churches, offices, factories, and warehouses. An underfloor storage heater acts as a flywheel; while it is charged only during the nightly off-peak, it maintains the top of the floor slab at a constant temperature slightly higher than the desired space temperature. Because the cables spread heat in all directions, they do not have to cover the entire slab area. For most buildings, a cable location of 450 mm below the floor elevation is optimum. The sand bed should be insulated along its perimeter with 50 mm of rigid, closed-cell foam insulation to a depth of 1200 mm (see Figure 20). Even with a well-designed and well-constructed underfloor storage, 10% or more of the input heat may be lost to the ground.

**Building Mass Effects**

The thermal storage capabilities inherent in building mass can have a significant effect on the temperature within the space as well as on the performance and operation of the HVAC system. Effective use of structural mass for thermal storage reduces building energy consumption and reduces and delays peak heating and cooling loads (Braun 1990). In some cases, it improves comfort (Simmonds 1991; Morris et al. 1994). Perhaps the best-known use of thermal mass to reduce energy consumption is in buildings that include passive solar techniques (Balcomb 1983).

Cooling energy can be reduced by precooling the structure at night using ventilation air. Braun (1990), Rund et al. (1990), and Andresen and Brandemuehl (1992) suggested that mechanical precooling of a building can reduce and delay peak cooling demand; Simmonds (1991) suggested that the correct building configuration may even eliminate the need for a cooling plant. Mechanical precooling may require more energy use; however, the reduction in electrical demand costs may give lower overall energy costs. Moreover, the installed capacity of air-conditioning equipment may also be reduced, providing lower installation costs.

The effective use of thermal mass can be considered incidental and be allowed for in the heating or cooling design, or it may be considered intentional and form an integral part of the design. The effective use of building structural mass for thermal energy storage depends on such factors as (1) the physical characteristics of the structure, (2) the dynamic nature of the building loads, (3) the coupling between the mass and zone air (Akbabi et al. 1986), and (4) the strategies for charging and discharging the stored thermal energy. Some buildings, such as frame buildings with no interior mass, are inappropriate for thermal storage. Many other physical characteristics of a building or an individual zone, such as carpeting, ceiling plenums, interior partitions, and furnishings, affect thermal storage and the coupling of the building with zone air.

**Incidental Thermal Mass Effects.** A greater amount of thermal energy must be removed or added to bring a room in a massive building to a suitable condition before occupancy than for a similar light building. Therefore, the system must either start conditioning the spaces earlier or operate at a greater output. During the occupied period, a massive building requires a lower output, as a higher proportion of heat gains or losses are absorbed by the thermal mass.

Advantage can be taken of these effects if low-cost electrical energy is available during the night; the air-conditioning system can be operated during this period to precool the building. This can reduce both the peak and total energy required during the following day (Braun 1990; Andresen and Brandemuehl 1992) but may not always be energy-efficient.

**Intentional Thermal Mass Effects.** To make best use of thermal mass, the building should be designed with this objective in mind. Intentional use of the thermal mass can be either passive or active. Passive solar heating is a common application that applies the thermal mass of the building to provide warmth outside the sunlit period. This effect is discussed in further detail in Chapter 32. Passive cooling applies the same principles to limit the temperature rise during the day. The spaces can be naturally ventilated overnight to absorb surplus heat from the building mass. This technique works well in moderate climates with a wide diurnal temperature swing and low relative humidities, but it is limited by the lack of control over the cooling rate.

Active systems overcome some of the disadvantages of passive systems by using (1) mechanical power to help heat and cool the building and (2) appropriate controls to limit the output during the release or discharge period.

**Systems.**

Both night ventilation and precooling have limitations. The amount of heat stored in a slab equals the product of mass, specific heat, and low relative humidities, but it is limited by the lack of control over the cooling rate.

Active systems overcome some of the disadvantages of passive systems by using (1) mechanical power to help heat and cool the building and (2) appropriate controls to limit the output during the release or discharge period.
Effective Storage Capacity. The total heat capacity (THC) (Ruud et al. 1990) is the maximum amount of thermal energy stored or released due to a uniform change in temperature $\Delta t$ of the material and is given by

$$\text{THC} = \rho c_p V \Delta t$$

(6)

The diurnal heat capacity (DHC) is a measure of the thermal capacity of a building component exposed to periodically varying temperature.

Many factors must be considered when an energy source is time-dependent. The minimum temperature occurs around dawn, which may be at the end of the off-peak tariff; the optimum charge period may run into the working day. Beginning the charge earlier may be less expensive but also less energy-efficient. In addition, the energy stored in the building mass is neither isolated nor insulated, so some energy is lost during charging; and the amount of available free energy varies and must be balanced against the energy cost of mechanical power. As a result, there is a trade-off that varies with time between the amount of free energy that can be stored and the power necessary for charging.

As the cooling capacity is, in effect, embedded in the building thermal mass, conventional techniques of assessing the peak load cannot be used. Detailed weather records that show peaks over 3- to 5-day periods, as well as data on either side of the peaks, should be examined to ensure that (1) the temperature at which the building fabric is assumed to be before the peak period is realistic and (2) the consequences of running with an exhausted storage after peak are considered. This level of analysis can only be carried out effectively using a dynamic simulation program. Experience has shown that these programs should be used with a degree of caution, and the results should be compared with both experience and intuition.

Storage Charging and Discharging

The building mass can be charged (cooled or warmed) either indirectly or directly. Indirect charging is usually accomplished by heating or cooling either the bounded space or an adjacent void. Almost all passive and some active cooling systems are charged by cooling the space overnight (Arnold 1978). Most indirect active systems charge the store by ventilating the void beneath a raised floor (Herman 1980; Crane 1991). Where this is an intermediate floor, cooling can be radiated into the space below and convected from the floor void the following day. By varying the rate of ventilation through the floor void, the rate of discharge can be controlled. Proprietary floor slabs are commonly of the hollow-core type (Anderson et al. 1979; Willis and Wilkins 1993). The cores are continuous, but when used for thermal storage, they are plugged at each end, and holes are drilled to provide the proper airflow. Charging is carried out by circulating cool or warm air through the hollow cores and exhausting it to the room. Discharge can be controlled by a ducted switching unit that directs air through the slab or straight into the space.

A directly charged slab, used commonly for heating and occasionally for cooling, can be constructed with an embedded hydronic coil. The temperature of the slab is only cycled 2 to 3 K to either side of the daily mean temperature of the slab. Consequently the technique can use very low grade free cooling (approximately 19°C) (Meierhans 1993) or low-grade heat rejected from condensers (approximately 28°C). In cooling applications the slab is used as a cool radiant ceiling, and for warming it is usually a heated floor. Little control is necessary due to the small temperature differences and the high heat capacity of the slab.

INSTALLATION, OPERATION, AND MAINTENANCE

The design professional must consider that almost all thermal storage systems require more space than nonstorage systems. Having selected a system, the designer must decide on the physical location; the piping interface to the air-conditioning equipment; and the water treatment, control, and optimization strategies to transfer theoretical benefits into realized benefits. The design must also be documented, the operators trained, and the performance verified (i.e., the system must be properly commissioned). Finally, the system must be properly maintained over its projected service life. For further information on operation and maintenance management, see Chapter 37.

SPECIAL REQUIREMENTS

The location and space required by a thermal storage system are functions of the type of storage and the architecture of the building and site. Building or site constraints often shift the selection from one option to another.

Chilled Water Systems

Chilled water systems are associated with large volume. As a result, many stratified chilled water storage systems are located outdoors (such as in industrial plants or suburban campus locations). A tall tank is desirable for stratification, but a buried tank may be required for architectural or zoning reasons. Tanks are traditionally constructed of steel or prestressed concrete. A supplier who assumes full responsibility for the complete performance often constructs the tank at the site and installs the entire distribution system.

Ice-on-Coil Systems (External and Internal Melt)

Ice-on-coil systems are available in many configurations with differing space and installation requirements. Because of the wide variety available, these often best meet the unique requirements of many types of buildings.

Bare coils are available for installation in concrete cells, which are a part of the building structure. The bare steel coil concept can be used with direct cooling, in which the refrigerant is circulated through the coils, and the water is circulated over the coils to be chilled or frozen. This external melt system has very stringent installation requirements. Coil manufacturers do not normally design or furnish the tank, but they do provide design assistance, which covers distribution and air agitation design as well as side and end clearance requirements. These recommendations must be followed exactly to ensure success.

The bare coil concept can also be used with a secondary coolant to provide the cooling necessary to build the ice. In an internal melt configuration, the ice and water, which remains in the tank and is not circulated to the cooling system, cools the secondary coolant during discharge. This indirect chilling can also be used with an external melt discharge if it is not desirable to circulate the secondary coolant to the cooling load. Indirect chilling can use either steel or plastic tubes in the ice builder.

Coils with factory-furnished containers come in a variety of sizes and shapes. A suitable style can usually be found to fit the available space. Round plastic containers with plastic coils are available in several sizes. These are offered only in an internal melt configuration and can be above ground or partially or completely buried. Rectangular steel tanks are available with both steel and plastic pipe in a wide variety of sizes and capacities. Steel coil modules have the option of either internal or external melt. These steel tank systems are not normally buried. Each system comes prepackaged; installation requires only placement of the tank and proper piping connections. Any special support or insulation requirements of the manufacturer must be strictly followed.
Encapsulated Ice

Cylindrical steel containers with encapsulated water modules are also available. These offer yet another shape to fit available space. With proper precautions, these containers can be installed below grade. Standards and recommendations for corrosion protection published by the Steel Pipe Institute and the National Association of Corrosion Engineers should be followed, as should the manufacturer’s instructions. These systems are not shipped assembled. The containers must be placed in the shell at the job site in a way that channels the secondary coolant through passages where the desired heat transfer will be achieved.

Ice-Harvesting

Field-built concrete ice tanks are generally used with ice harvesting. The ice harvester manufacturer may furnish assistance in tank design and piping distribution in the tank. The tank may be completely or partially buried or installed above ground. Where the ground is dry and free of moving water, tanks have been buried without insulation. In this situation the ground temperature eventually stabilizes, and the heat loss becomes minimal. However, a minimum of 50 mm of closed cell insulation should be applied to the external surface. Because the shifting ice creates strong dynamic forces, internal insulation should not be used except on the underside of the tank cover. In fact, only very rugged components should be placed in the tank; exit water distribution headers should be of stainless steel or rugged plastic suitable for the cold temperatures encountered. PVC is not an acceptable material due to its extreme brittleness at the ice water temperature. An underfloor system that is a part of the concrete structure is preferred.

As with the chilled water and hydrated salt PCM tanks, close attention to the design and construction is critical to prevent leakage. Unlike a system where the manufacturer builds the tank and assumes responsibility for its integrity, an ice-harvesting system needs an on-site engineer familiar with concrete construction requirements to monitor each pour and to check all water stops and pipe seals. Unlined tanks that do not leak can be built. If liners are used, the ice equipment suppliers will provide assistance in determining a suitable type; the liner should be installed only by a qualified installer trained in the proper methods of installation by the liner maker.

The sizing and location of the ice openings is critical; the tank design engineer should check all framed openings against the certified drawings before the concrete is poured.

An ice harvester is generally installed by setting in place a pre-packaged unit that includes the ice-making surface, the refrigerant piping, the refrigeration equipment, and, in some cases, the heat rejection equipment and the prewired control. To ensure proper ice harvest, the unit must be properly positioned with respect to the drop opening. As the internal piping is not normally insulated, the drop opening should extend under the piping so that condensate drops into the tank. A grating below the piping is desirable. To prevent air or water leakage, gasketing between the unit frame and caulking must be installed in accordance with the manufacturer’s instructions. External piping and power and control wiring complete the installation.

Other PCM Systems

Coolant normally flows horizontally in salt and polymeric systems, so the tanks tend to be shallower than the ideal chilled water storage tank. As in chilled water systems, the chilled water supply to and return from the tank must be designed to distribute water uniformly through the tank without channeling. Tanks are traditionally of concrete. The system supplier normally designs the tank and its distribution system, builds the tank, and installs the salt solution containers.

SYSTEM INTERFACE

Open Systems

Chilled water; salt and polymeric PCMs; external melt ice-on-coil; and ice-harvesting systems are all open chilled water piping systems. Drain-down must be prevented by isolation valves, pressure-sustaining valves, or heat exchangers. Due to the potential for drain-down, the open nature of the system, and the fact that the water being pumped may be saturated with air, the construction contractor must follow the piping details carefully to prevent pumping or piping problems.

Closed Systems

Closed systems normally circulate an aqueous secondary coolant (25 to 30% glycol solution) either directly to the cooling coils or to a heat exchanger interface to the chilled water system. A domestic water makeup system should not be the automatic makeup to the secondary coolant system. An automatic makeup unit that pumps a premixed solution into the system is recommended, along with an alarm signal to the building automation system to indicate makeup operation. The secondary coolant must be an industrial solution (not automotive antifreeze) with inhibitors to protect the steel and copper found in the piping. The water should be deionized; as portable deionizers can be rented, the solution can be mixed on-site. A calculation, backed up by metering the water as it is charged into the piping system for flushing, is needed to determine the specified concentration. Premixed coolant made with deionized water is also available, and tank truck delivery with direct pumping into the system is recommended on large systems. An accurate estimate of volume is required.

INSULATION

Because the chilled water, secondary coolant, or refrigerant temperatures are generally 6 to 11 K below those found in nonstorage systems, special care must be taken to prevent damage. Although fiberglass or other open-cell insulation is theoretically suitable when supplied with an adequate vapor barrier, experience has shown that its success is highly dependent upon workmanship. Therefore, a two-layer closed-cell material with staggered joints and carefully sealed joints is recommended. A thickness of 40 to 50 mm is normally adequate to prevent condensation in a normal room. Provisions must be made to ensure that the relative humidity in the equipment room is less than 80%. This can be done with heating or with cooling and dehumidification.

Special attention must be paid to pump and heat exchanger insulation covers. Valve stem, gage, and thermometer penetrations and extensions should be carefully sealed and insulated to prevent condensation. PVC covers over all insulation in the mechanical room improve appearance, provide limited protection, and are easily replaced if damaged. Insulation located outdoors should be protected by an aluminum jacket.

REFRIGERATION EQUIPMENT

The refrigeration system may be packaged chillers, field-built refrigeration, or refrigeration equipment furnished as a part of a package. The refrigeration system must be installed in accordance with the manufacturer’s recommendations. Due to the high cost of refrigerant, refrigerant vapor detectors are suggested even for Class A1 refrigerants. Equipment rooms must be designed and installed to meet ASHRAE Standard 15. Relief valve lines should be monitored to detect valve weeping; any condensate that collects in the relief lines must be diverted and trapped so that it does not flow to the relief valve and eventually damage the seal.
**Thermal Storage**

**WATER TREATMENT**

**Open Systems**

Water treatment must be given close scrutiny in open systems. While the evaporation and concentration of solids associated with cooling towers does not occur, the water may be saturated with air, so the corrosion potential is greater than in a closed system. Treatment against algae, scale, and corrosion must be provided. No matter what type of treatment is chosen (i.e., traditional chemical or nontraditional treatment), some type of filtration that is effective at least down to 24 µm should be provided. To prevent damage, water treatment must be operational immediately following the completion of the cleaning procedure. Corrosion coupon assemblies should be included to monitor the effectiveness of the treatment. Water testing and service should be performed at least once a month by the water treatment supplier.

**Closed Systems**

The secondary coolant should be pretreated by the supplier. A complete analysis should be done annually. Monthly checks on the solution concentration should be made using a refractive indicator. Automotive-type testers are not suitable. For normal use, the solution should be good for many years without needing new inhibitors. However, provision should be made for the injection of new inhibitors through a shot feeder if recommended by the manufacturer. The need for filtering, whether it be the inclusion of a filtering system or filtering the water or solution before it enters the system, should be carefully considered. Combination filter feeders and corrosion coupon assemblies may be needed for monitoring the effect of the solution on copper and steel.

**CONTROLS**

A direct digital control to monitor and control all of the equipment associated with the central plant is preferred. Monitoring of electrical use by all primary plant components, individually if possible but at least as a group, is strongly recommended. Monitoring of the refrigeration capacity produced by the refrigeration equipment, by direct measurement where possible or by manufacturer’s capacity ratings related to suction and condensing pressures, should be incorporated. This ensures that a performance rating can be calculated for use in the commissioning process and reevaluated on an ongoing basis as a management tool to gage performance.

**Optimization Software**

Optimization software should be installed to obtain the best performance from the system. This software must be able to predict, monitor, and adjust to meet the load, as well as adapt to daily or weekly storage, full or partial storage, chiller or ice priority, and a wide variety of rate schedules.

**IMPLEMENTATION AND COMMISSIONING**

Elleson (1996) identified the following key steps to designing a cool storage system:

- Calculate an accurate load profile.
- Use an hourly operating profile to size and select equipment.
- Develop a detailed description of the control strategy.
- Produce a schematic diagram.
- Produce a statement of design intent.
- Use safety factors with care.
- Plan for performance monitoring.
- Produce complete design documents.
- Retain an experienced cool storage engineer to review design.

ENERGY conservation is the more efficient or effective use of energy. As fuel costs rise and environmental concerns grow, more-efficient energy conversion and utilization technologies become cost-effective. However, technology alone cannot produce sufficient results without a continuing management effort. Energy management begins with the commitment and support of an organization’s management team.

Suggestions for developing an energy management program are shown in Figure 1. First, a team with the right skills is selected to manage and execute the program. This team establishes objectives, priorities, and a time frame, sometimes with the help of outside consultants. A historic database can help to evaluate future energy conservation opportunities (ECOs). A monitoring system can be set up to obtain detailed use data (see Chapter 39, Building Energy Monitoring). Then, a detailed energy audit, which is discussed later in this chapter, should be performed. After the ECOs and the estimated savings have been determined, the team issues a report and adjusts or fine-tunes the objectives and priorities. A few lower-cost conservation measures that result in substantial savings can be implemented first to show progress. At this stage, it is critical to monitor and collect data, because energy management programs with written proof of progress are often the most successful. Metering can be installed to monitor energy consumption for each major piece of equipment and for each consumption area. Charts showing the progress of everyone in the facility increase awareness of energy conservation. The program requires regular reports and readjustments of the objectives and priorities, and the implemented ECOs need to be maintained.

**ORGANIZATION**

Because energy management is performed in existing facilities, most of this chapter is devoted to these facilities. Information on energy conservation in new design can be found in all volumes of the ASHRAE Handbook and in ASHRAE Standards 90.1 and 90.2. The area most likely to be overlooked in new design is the ability to measure and monitor energy consumption and trends for each energy use category given in Chapter 39.

To be effective, energy management must be given the same emphasis as management of any other cost/profit center. In this regard, the functions of top management are as follows:

- Establish the energy cost/profit center.
- Assign management responsibility for the program.
- Hire or assign an energy manager.
- Allocate resources.
- Ensure that the energy management program is clearly communicated to all departments to provide necessary support for achieving effective results.
- Monitor the cost-effectiveness of the program.
- Clearly set the program goals.
- Encourage ownership of the program at the lowest possible level in the organization.
- Set up an ongoing reporting and analysis procedure to monitor the energy management program.

An effective energy management program requires that the manager (supported by a suitable budget) act and be held accountable for those actions. It is common for a facility to allocate 3 to 10% of the annual energy cost for the administration of an energy management program. The budget should include funds for additional personnel as needed and for continuing education of the energy manager and staff.

If it is not possible to add a full-time, first-line manager to the staff, an existing employee, preferably with a technical background, should be considered for either a full- or part-time position. This person must be trained to organize an energy management program. Energy management should not be an alternate or collateral duty of an employee who is already fully occupied.
Planning and purchasing functions include the following:
1. Monitoring energy supplies and costs to take advantage of fuel-switching and load management opportunities
2. Ensuring that systems and equipment are purchased based on economics (not simply on the lowest initial cost), their energy requirements, and their ability to perform the required functions
3. Maintaining a current understanding of energy conservation, grant programs, and demand side management (DSM) programs offered by utilities and agencies
4. Negotiating or advising on major utility contracts
5. Developing contingency plans for supply interruptions or shortages
6. Forecasting the organization’s short- and long-term energy requirements and costs
7. Developing short- and long-term energy conservation plans and budgets
8. Reporting periodically to upper management

Public relations functions include the following:
1. Educating fellow employees on the benefits of efficient energy use
2. Establishing a system to elicit and evaluate energy conservation suggestions from employees
3. Recognizing successful energy conservation projects with awards to plants or employees
4. Setting up a formal system for reporting to upper management
5. Establishing an energy communications network within the organization, including bulletins, manuals, and conferences
6. Increasing community awareness of the organization’s energy conservation achievements with press releases and appearances at civic group meetings

General qualifications of the staff energy manager include (1) a technical background, preferably in engineering, with experience in energy-efficient design of building systems and processes; (2) practical, hands-on experience with systems and equipment; (3) a goal-oriented management style; (4) the ability to work with people at all levels, from operations and maintenance personnel to top management; and (5) technical report writing and verbal communications skills.

Desirable educational and professional qualifications of the staff energy manager include the following:
1. Bachelor of Science or Engineering degree from an accredited four-year college, preferably in mechanical, electrical, industrial, or chemical engineering
2. Thorough knowledge of the principles and practices of energy resource planning and conservation
3. Familiarity with the administrative governing organization
4. Ability to analyze and compile technical and statistical information and reports with particular regard to energy usage
5. Knowledge of resources and information relating to energy conservation and planning
6. Ability to motivate people and develop and establish effective working relationships with other employees
7. Ability to interpret plans and specifications for building facilities
8. Knowledge of the basic types of automatic controls and systems instrumentation
9. Knowledge of energy-related metering equipment and practices (see Chapter 39)
10. Knowledge of the organization’s manufacturing processes
11. Knowledge of building systems design and operation and/or maintenance
12. Interest in and enthusiasm for efficient energy use
13. Ability to present ideas to all levels in the organization

Another option is to hire a professional energy management consultant to design, implement, and maintain energy efficiency improvements. Some energy services companies (ESCOs) and other firms provide energy management services as part of a contract, with payments based on realized savings.

Figure 2 shows the organizational relationship of effective energy management. The solid lines indicate normal reporting relationships within the organization; the dotted lines indicate new relationships created by energy management. The arrows indicate the primary directions in which initiatives related to energy conservation normally flow. This chart shows the ideal organization. In actuality, the functions shown may overlap, especially in smaller organizations. For example, the assistant principal of a high school may also serve as energy manager and physical plant director. However, it is important that all functions be covered.

Energy Manager

The general functions of an energy manager fall into four categories: technical, policy-related, planning and purchasing, and public relations. The energy manager will need assistance with some of the tasks in the following lists. A list of the specific tasks and plans for their implementation must be clearly documented.

Technical functions include the following:
1. Conducting energy audits and identifying energy conservation opportunities (ECOs)
2. Establishing a baseline from which energy-saving improvements can be measured
3. Acting as an in-house technical consultant on new energy technologies, alternative fuel sources, and energy-efficient practices
4. Evaluating the energy efficiency of proposed new construction, building expansion, remodeling, and new equipment purchases
5. Setting performance standards for efficient operation and maintenance of machinery and facilities
6. Reviewing state-of-the-art energy management hardware
7. Selecting the most appropriate technology
8. Reviewing operation and maintenance
9. Implementing ECOs
10. Establishing an energy accounting program for continuing analysis of energy usage and the results of ECOs
11. Maintaining the effectiveness of ECOs
12. Measuring energy use in the field whenever possible to verify design and operation conditions

Policy-related functions include the following:
1. Fulfilling the energy policy established by upper management
2. Monitoring federal and state legislation and regulatory activities, and recommending policy/response on such issues
3. Representing the organization in energy associations
4. Administering government-mandated reporting programs

1999 ASHRAE Applications Handbook (SI)
Energy Consultant

In many instances, an energy manager needs outside assistance to conduct the energy management program. An energy consultant may be called on to assist with any of the energy manager’s functions and, in addition, may be responsible for training the energy management, operations, and maintenance staffs. In some cases, the energy consultant may be responsible for implementing and monitoring the energy management program.

The basic qualifications of an energy consultant should be similar to those of an energy manager. The consultant should be an objective party with no connections to the sale of equipment or systems. Energy service companies (ESCOs) and other contracting firms provide energy management services. Often these companies are compensated by a percentage of realized savings based on measured energy usage before and after the improvements. It is vital that the compensation methods be clearly specified and include provisions to adjust for changes in building use, production levels, and other factors.

Optimum energy conservation in a comprehensive and integrated energy management program can be accomplished only if system interaction is thoroughly understood and accounted for by the energy consultant and manager. For example, a lighting retrofit could reduce lighting energy while simultaneously causing the heating system that interacts with the lighting system to increase energy consumption.

Motivation

The success of an energy management program depends on the interests and motivation of the people implementing it (Turner 1993). Participation and communication are key points. Employees can be motivated to support an energy management program through awareness of the following:

- Amount of energy they use
- Cost of the energy
- Critical role of energy in the continued viability of their jobs
- Meaning of energy saving in their operations
- Relationship between production rate and energy consumption
- Benefits of participation, such as greater comfort and improved air quality

Energy management activities can be made a part of each supervisor’s performance or job standards. If the supervisor knows that top management is solidly behind the energy management program, and the overall performance rating depends, to some extent, on the energy savings that the department or group achieves, the supervisor will motivate employee interest and cooperation.

FINANCING A PROGRAM

Several financing options exist for energy management programs.

**Internal financing.** The building owner, manager, or occupant makes a decision to finance the modifications internally, taking advantage of all the savings and assuming all the risk.

**Shared savings contracts.** Typically, independent contractors install energy-related modifications at their expense. The building owner then pays a prearranged fee, which is usually related to the savings achieved. The term of these contracts runs from several years to as many as 20 years. The terms and conditions of the contract must be well documented in advance. In particular, methods of determining energy savings and of accounting for other influences on energy consumption must be carefully and precisely described.

**Guaranteed savings contracts.** These are similar to shared savings contracts, except that the costs of the modifications are specified up front. The owner can pay for the retrofit at the beginning of the contract, finance it over a period of years, or have the contractor finance it with repayment out of the savings. The owner should enter into these agreements carefully, with an understanding of the financial liability if the savings do not materialize and the contractor is unable to make good on the guarantee. Energy savings are guaranteed, usually on an annual basis. If greater savings are achieved, some contracts require that a bonus be paid to the contractor. If less than the guaranteed savings is realized, the owner is reimbursed for the difference. Insurance policies should be examined carefully. With this type of contract, the performance record of the contractor and insurance company and policy should be checked.

**Demand side management.** Demand side management (DSM) programs are offered by utilities and most often subsidize the installation of energy modifications. These programs usually take the form of rebates to contractors or building owners for the installation of specified equipment, and they are often carried out by subcontractors or unregulated subsidiaries of utilities. The purpose of these programs is to reduce demand or consumption of the form of energy supplied by the utility.

**Utility consultants.** Utility consultants review utility bills for building owners, checking for billing errors and proper rates and riders. Usually, no consideration is given to the quantity of energy consumed. Contracts are on a contingent fee basis, frequently with payment being half the savings for five years.

**Government programs.** There are some federal, state, and local government programs that provide subsidies or tax credits for certain energy modifications.

**Tariff analysis.** Most utilities offer a variety of rates. The customer selects the rates and riders, provided they meet their criteria. Because rates change frequently, it is often advantageous to examine the applicability of other utility rates that may lower costs.

**Tax exemption.** Many states exempt certain uses of energy from sales tax. As a general rule, utilities charge sales tax to all customers, unless they are advised that the customer is exempt. Typical exemptions include those for nonprofit organizations, research and development, and some types of manufacturing.

IMPLEMENTING A PROGRAM

There are six basic stages in implementing an energy management program:

1. Develop a thorough understanding of how energy is used.
2. Conduct a planned, comprehensive search to identify all potential opportunities for energy conservation. Contact utility companies to find out about applicable rates and to learn about any DSM program offerings.
3. Determine and clearly specify the energy and cost-savings analysis methods to be used. See Chapter 35, Owning and Operating Costs; MacDonald and Wasserman (1989); and PNL (1990).
4. Identify, acquire, allocate, and prioritize the resources necessary to implement energy conservation opportunities (ECOs).
5. Implement the ECOs in a rational order. This is usually a series of independent activities that take place over several years.
6. Monitor and maintain energy conservation measures taken. Reevaluate them as building functions change over time.

For existing buildings, ASHRAE Standard 100 was developed to provide criteria that will result in conservation of nonrenewable energy resources. These standards are directed toward upgrading existing building thermal performance; increasing system energy efficiency; and providing procedures and programs essential to the operation, maintenance, and monitoring of energy conservation measures.

Energy efficiency and/or energy conservation efforts should not be equated with discomfort, nor should they interfere with the primary function of the organization or facility. Energy conservation activities that disrupt or impede the normal functions of workers and/or processes and adversely affect productivity constitute false economies.
Databases

The compilation of a database of past energy usage and cost is important in developing an energy management program. Any reliable utility data that is applicable should be examined. Utilities can usually provide demand metered data on computer disks, often with measurement intervals as short as 15 min. This is preferable to monthly data because anomalies are more apparent. High consumption at certain times may reveal opportunities for conservation (Haberl and Komar 1990). If monthly data are used, they should be analyzed over several years. A base year should be established as a reference point for future energy conservation and energy cost avoidance activities. In tabulating such data, the actual dates of meter readings should be recorded so that energy use can be normalized for differences in the number of days in a period. Any periods during which consumption was estimated rather than measured should be noted.

If energy is available for more than one building and/or department under the authority of the energy manager, each of these should be tabulated separately. Initial tabulations should include both energy and cost per unit area. (In an industrial facility, this may be energy and cost per unit of goods produced.) Available information on variables that may have affected past energy use should also be tabulated. These might include heating or cooling degree-days, percent occupancy for a hotel, quantity of goods produced in a production facility, or average daily weather conditions, which can be obtained from the National Oceanic and Atmospheric Administration (NOAA), National Climatic Data Center Federal Building, Asheville, NC. Because such variables may not be directly proportional to energy use, it is best to plot information separately or to superimpose one plot over another, rather than develop such units as kilojoules per square metre per degree day. As such data are tabulated, ongoing energy accounting procedures should be developed for regular data collection and future uses.

Comparing a building’s energy use with that of many different buildings is a valuable way to check its relative efficiency. Data on buildings in all sectors are summarized in DOE/EIA-0246 and DOE/EIA-0318 for nonresidential buildings and in DOE/EIA-0321/1 for households. The following tables present the DOE/EIA data in a combined format. Table 1 lists physical characteristics of the buildings surveyed. Table 2 lists measured demand and energy consumption. Table 3 lists various residential end uses. The EIA also collects data on household energy consumption, which is summarized in Table 4.

When an energy management program for a new building is established, the energy use database may consist solely of typical energy use data for similar buildings, as illustrated in Table 2. This may be supplemented by energy simulation data for the specific building if such data were developed during the design of the building. In addition, a new building and its systems should be properly commissioned upon completion of construction to ensure proper operation of all systems, including any energy conservation features. Refer to ASHRAE Guideline 1, The HVAC Commissioning Process.

All the data presented in these tables are derived from detailed reports of consumption patterns in buildings. Before using the data, however, it is important to understand how it was derived. For example, all the household energy consumption data presented in Table 4 are average data, and they may not reflect variations in appliances or fuel situations for different buildings. Therefore, when using the data, verify the correct use of it with the original EIA documents. Because these surveys are performed regularly, there may be newer data.

ASHRAE Standard 105, Standard Methods of Measuring and Expressing Building Energy Performance, contains information that allows uniform, consistent expressions of energy consumption in both proposed and existing buildings. Its use is recommended. However, the data collected by EIA and presented here are not in accordance with this standard.

Mazzucchi (1992) lists data elements useful for normalizing and comparing utility billing information. Metered energy consumption and cost data are also gathered and published by trade associations that represent building owners. Some trade associations include the Building Owners and Managers Association International (BOMA), the National Restaurant Association (NRA), and the American Hotel and Motel Association (AH&MA).

The quality of published energy consumption data for buildings varies because the data are collected for different purposes by people with different levels of technical knowledge of buildings. The data presented here are primarily national data. In some cases, local energy consumption data may be available from local utility companies or state or provincial energy offices.

At this point in the development of an energy management program, it is useful to compile a list of previously accomplished energy conservation measures and the actual energy and/or cost savings of such measures. Energy and cost savings analysis methods (MacDonald and Wasserman 1989, Section 2) can be used to calculate savings. These measures and savings should be studied during subsequent energy audits to determine their effectiveness and the effort(s) necessary to maintain and/or improve them.

Since most energy management activities are dictated by economics, the energy manager must understand the utility rates that apply to each facility. Special rates are commonly applied for such variables as time of day, interruptible service, on peak/off peak, summer/winter, and peak demand. There are more than 1000 electric rate variations in the United States. The energy manager should work with local utility companies to develop the most cost-effective methods of metering and billing and enable energy cost avoidance to be calculated effectively.

It is common for electric utilities to meter both electric consumption and demand. Demand is the peak rate of consumption, typically integrated over a 15 or 30 min period. Electric utilities may also establish a ratchet billing procedure for demand. In a simplified version of ratchet demand billing, the billing demand is established as either the actual demand for the month in question or a percentage of the highest demand during the previous 11 months, whichever is greater. Figure 3 illustrates a gas-heated, electrically cooled building with the highest electric demands

**Note:** Consumption shown is on an annual basis. Source: DOE/EIA 0246(95) 1998
occuring in the summer, and shows actual demand versus billing demand under an 85% ratchet. The winter demand is approximately 700 kW each month, with chiller operation causing the August demand to peak at 1000 kW. Since an 85% ratchet applies, all months following August with actual demand below 850 kW are billed at 850 kW. Therefore, the following can be concluded about this building:

1. ECOs that reduce winter demand would not reduce the billed cost of demand unless they also reduced summer demand; and if such measures were implemented in September, they would not produce savings in demand billings for the first 11 months.
2. ECOs that reduce peak demand in each of the summer months (for example, 50 kW reduction in chiller peaks) may produce savings in demand billings throughout the year.

A billing method called real time pricing (RTP) is used by some utility companies. With this method, the utility calculates the marginal cost of power per hour for the next day, determines the customer price, and sends this hourly price (for the next day) to the customer. The customer can then determine the amount of power to be consumed at different times of the day.

There are many variations of the above billing methods, and it is important to understand the applicable rates. Caution is advised in designing or installing energy management and energy retrofit systems that take advantage of utility rate provisions, because these provisions can change. The structure or provisions of utility rates cannot be guaranteed for the life of the ECOs. Some provisions that change include on-peak times, declining block rates, and demand ratchets.

**Priorities**

Having established a database, the energy manager should assign priorities to future work efforts. If there is more than one building or department under the energy manager’s care, their energy use and cost databases should be compared overall and on the basis of energy use and cost per unit area, of cost per unit of production, or of some other index that demonstrates an acceptable level of accuracy. Comparisons should also be made with realistic energy targets, if they are known. Using such comparisons, it is often possible to set priorities that allocate the available resources most effectively.

One approach to comparing that is used in England is called Monitoring and Targeting. Monitoring involves collecting short-term metered data and analyzing it with respect to occupancy, weather prediction, and other variables. This permits a better understanding of the factors that influence energy consumption so that improvements can be made. Targeting involves comparisons with other similar buildings. When the building being monitored uses more energy than the norm for similar buildings, it is likely that reductions can be achieved.

At this point, a report should be prepared for top management outlining the data collected, the priorities assigned, plans for continued development of the energy management program, and projected budgetary needs. This should be the beginning of a regular monthly, quarterly, or semiannual reporting procedure.

**Energy Audits**

Three levels of energy audits or analysis have been defined (Mazzuchii 1992). Depending on the physical and energy use characteristics of a building and the needs and resources of the owner, these steps require different levels of effort. Following a preliminary energy use evaluation, an energy analysis can generally be classified into the following three categories:

**Level I—Walk-Through Assessment.** This level involves the assessment of a building’s energy cost and efficiency through the analysis of energy bills and a brief survey of the building. A Level I energy analysis will identify and provide a savings and cost analysis of low-cost/no-cost measures. It also provides a listing of potential capital improvements that merit further consideration, along with an initial judgment of potential costs and savings. The level of detail depends on the experience of the person performing the audit or on the specifications of the client paying for the audit.

**Level II—Energy Survey and Analysis.** This level includes a more detailed building survey and energy analysis. A breakdown of energy use within the building is provided. A Level II energy analysis identifies and provides the savings and cost analysis of all practical measures that meet the owner’s constraints and economic criteria, along with a discussion of any effect on operation and maintenance procedures. It also provides a listing of potential capital-intensive improvements that require more thorough data collection and analysis, along with an initial judgment of potential costs and savings. This level of analysis will be adequate for most buildings and measures.

**Level III—Detailed Analysis of Capital-Intensive Modifications.** This level focuses on potential capital-intensive projects identified during Level II and involves more detailed field data gathering and engineering analysis. It provides detailed project cost and savings information with a high level of confidence sufficient for major capital investment decisions.

The levels of energy audits do not have sharp boundaries between them. They are general categories for identifying the type of information that can be expected and an indication of the level of confidence in the results; that is, various measures may be subjected

</table>
In conducting an energy audit, a thorough systems approach produces the best results. This approach has been described as starting at the end rather than at the beginning. As an example of this approach, consider a factory with steam boilers in constant operation. An expedient (and often cost-effective) approach would be to measure the combustion efficiency of each boiler and to improve boiler efficiency. Beginning at the end would require observing all or most of the end uses of steam in the plant. It is possible that this would result in the discovery of considerable quantities of steam being wasted by venting to the atmosphere, venting through defective steam traps, uninsulated lines, and passing through unused heat exchangers. Elimination of such end-use waste could produce greater savings than those easily and quickly developed by improving boiler efficiency. When using this approach, care must be taken to make cost-effective use of the energy auditor’s time. It may not be cost-effective to track down every end use.

When conducting an energy audit, it is important to become familiar with operating and maintenance procedures and personnel. The energy manager can then recommend, through the appropriate departmental channels, energy-saving operating and maintenance procedures. The energy manager should determine, through continued personal observation, the effectiveness of the recommendations.

Stewart et al. (1984) tabulated 139 different energy audit input procedures and forms for 10 different building types, each using 62 factors. They discuss features of selected audit forms that can help in developing or obtaining an audit procedure.

To calculate the energy cost avoidance of various energy conservation opportunities, it is helpful to develop an energy cost distribution chart similar to that shown for a hospital in Figure 5. Preliminary information of this nature can be developed from monthly utility data by calculating end-use energy profiles (Spievol 1984).

Analysis of electrical operating costs starts with the recording of data from the bills on a form similar to that in Table 5. By dividing the consumption by the days between readings, the average daily consumption can be calculated. This consumption should be plotted to detect errors in meter readings or reading dates and to detect consumption variances (see Figure 6). For this example, 312 kwh/day is chosen as the “base electrical consumption” to cover year-round electrical needs such as lighting, business machines, domestic hot water, terminal reheat, security, and safety lighting. At this point, consumptions or spans that appear to be in error should be reexamined and corrected as necessary. If the reading date for the 10Nov bill in Table 5 was 05Nov, the curve in Figure 6 would be more continuous. On the basis of a 05Nov reading, the minimum daily consumption of 312 kwh on the continuous curve Figure 6 occurred in the February billing.

To start the analysis, the monthly base consumption is calculated (base daily consumption times billing days) and is subtracted from
each monthly total to obtain the difference. These differences fall under either summer excess or winter excess, depending on the season. Excess consumption in the summer is primarily due to the air-conditioning load. A similar analysis is made of the actual monthly demand. In Table 5, the base demand is 33.0 kW, and it is usually found in the same or adjacent months as the month with the base consumption. Substantial errors may arise if missing bills are not accounted for.

The base consumption can be further analyzed by calculating the electrical load factor (ELF) associated with this consumption. If the base demand had operated 24 h per day, then base consumption would be

\[
\frac{33.0 \text{ kW} \times 24 \text{ h/day}}{792 \text{ kWh/day}} = 312 \text{ kWh/day}
\]

But if the daily base consumption is 312 kWh/day, then the electrical load factor is

\[
\text{ELF} = \frac{312 \text{ kWh/day}}{792 \text{ kWh/day}} = 0.394 \text{ or } 39.4\%
\]

In this example, the electrical load factor (39.4%) is higher than the occupancy factor (29.8%).

One reason for this difference may be that the lights are left energized beyond the occupied hours.

Because of the air-conditioning demand, summer demand is 46.8 kW. If this additional demand of 13.8 kW had operated 24 h each day, the summer extra would equal \(13.8 \times 24\) or 331.2 kWh/day. The ratio of each summer month’s excess as a percent of 331.2 kWh yields the summer electrical load factor. Summer ELFs higher than the occupancy factor indicate that air conditioning is not shut off as early as possible in the evening. Winter excess demand and consumption are analyzed in the same way to yield winter monthly ELFs.

Base load energy use is the amount of energy consumed independent of weather. When a building has electric cooling and no electric heating, the base load energy use is normally the energy consumed during the winter months. The opposite is true for heating. The annual estimated base load energy consumption can be obtained by establishing the average monthly consumption during the nonheating or noncooling months and multiplying by 12. For many buildings, subtracting the base load energy consumption from the total annual energy consumption yields an accurate estimate of the heating or cooling energy consumption. This approach is not valid when building use differs from summer to winter; when there is cooling in operation 12 months of the year; or when space heating is used during the summer months, as for reheat. In many cases, the base load energy use analysis can be improved by using hourly load data that may be available from the utility company. ELFs and occupancy factors can also be used instead of hourly energy profiles (Haberl and Komor 1990).

Although it is difficult to relate heating and cooling energy used in commercial buildings directly to the severity of the weather, several authors, including Spielvogel (1984) and Fels (1986), suggest that this is possible using a curve-fitting method to calculate the balance point of a building (the balance point of a building is discussed in Chapter 30 of the 1997 ASHRAE Handbook—Fundamentals). The pitfalls of such an analysis are (1) estimated rather than actual utility usage data are used, (2) the actual dates of the metered information must be used, together with average billing period weather data, and (3) building use and/or operation are not regular.

A more detailed breakdown of energy usage requires that some metered data be collected on a daily basis (winter days versus summer days, weekdays versus weekends) and that some hourly information be collected to develop profiles for night (unoccupied), morning warmup, day (occupied), and the shutdown period. This discussion presumes that submetering is not installed within the building. Individual metering of the various energy end uses

*aEstimated from corrected monthly consumption from Figure 6.

*bBase electrical consumption = 312 kWh/day.

References
provides the energy manager with the information to apply energy management principles optimally. Ideally, each energy end use in the building should be metered separately. See also Chapter 39, Building Energy Monitoring.

**Energy Conservation Opportunities**

It is possible to quantitatively evaluate various energy conservation opportunities (ECOs) from end-use energy profiles. Important considerations in this process are as follows:

- System interaction
- Utility rate structure
- Payback
- Installation requirements
- Life of the measure
- Maintainability
- Impact on building operation and appearance

Accurate energy savings calculations can be made only if system interaction is allowed for and fully understood. Annual simulation models may be necessary to accurately estimate the interactions between various ECOs. The calculated remaining energy use should be verified against a separately calculated zero-based energy target.

Further, the actual energy cost avoidance may not be proportional to the energy saved, depending on the method of billing for energy used. Using average costs per unit of energy in calculating the energy cost avoidance of a particular measure is likely to result in incorrect values.

Figure 7 is a list of potential ECOs. A discussion of 118 ECOs can be found in PNL (1990).

In addition, previously implemented energy conservation measures should be evaluated—first, to ensure that they have remained effective, and second, to consider revising them to reflect changes in technology, building use, and/or energy cost.

**Prioritize Resources**

Once a list of ECOs is established, it should be evaluated, prioritized, and implemented. In establishing priorities, the capital cost, cost-effectiveness, and resources available must be considered. Factors involved in evaluating the desirability of a particular energy conservation retrofit measure are as follows:

- Rate of return (simple payback, life-cycle cost)
- Total savings (energy, cost avoidance)
- Initial cost (required investment)
- Other benefits (safety, comfort, improved system reliability, and improved productivity)
- Liabilities (increased maintenance costs and potential obsolescence)
- Risk of failure (confidence in predicted savings, rate of increase in energy costs, maintenance complications, and success of others with the same measures)

To reduce the risk of failure, documented performance of ECOs in similar situations should be obtained and evaluated. One common problem is that energy consumption for individual end uses is overestimated, and the predicted savings are not achieved. When doubt exists about the energy consumption, temporary measurements should be made and evaluated. Also, some owners are reluctant to implement ECOs because of past experiences with energy projects. The causes of past failures should be analyzed carefully to minimize the possibility of their reoccurrence.

The resources available to accomplish an energy conservation retrofit opportunity should include the following:

- Management attention, commitment, and follow-through
- Skills
- Manpower
- Investment capital

**ECOs may be financed with the following:**

- Profit/investment
- Loans
- Rearrangement of budget priorities
- Energy savings
- Shared savings plans with outside firms and investors
- Utility incentives
- Grant programs
- Tax credits, deductions, etc.
- Donations

When all of these considerations are weighed and a prioritized list of recommendations is developed, a report should be prepared for management. Each recommendation should include the following:

- Present condition of the system or equipment to be modified
- Recommended action
- Who should accomplish the action
- Necessary documentation or follow-up required
- Potential interferences to successful completion of the recommendation
Energy Accounting

The energy manager continues the meter reading, monitoring, and tabulation of facility energy use and profiles. These tabulations indicate the cost of energy management efforts and the resulting energy cost avoidance. In conjunction with this effort, the energy manager periodically reviews pertinent utility rates, rate structures, and their trends as they affect the facility. Many utilities maintain free mailing lists for changes in their rate tariffs. The energy manager provides periodic reports of the energy management efforts to top management, summarizing the work accomplished, the cost-effectiveness of the work, the plans and suggested budget for future work, and projections of future utility costs. If energy conservation measures are to retain their cost-effectiveness, continued monitoring and periodic reauditing are necessary, because many energy conservation measures become less effective if they are not carefully monitored and maintained.

BUILDING EMERGENCY ENERGY USE REDUCTION

The need for occasional reductions in energy use during specific periods has become more common due to rising energy costs and supply reductions (which may be voluntary or mandatory) or equipment failures. Emergency periods include short-term shortages of a particular energy source(s) brought about by natural disasters, extreme weather conditions, utility system equipment disruptions, labor strikes, failures in building systems or equipment, self-imposed cut-backs in energy use, world political activities, or other forces beyond the control of the building owner and operator. This section provides information to help building owners and operators maintain near-normal operation of facilities during energy emergencies.

The following terms are applicable to such programs:

Energy Emergency. A period in which energy supply reductions and/or climatic and natural forces or equipment failures preclude the normal operation of a building and necessitate a reduction in building energy use.

Level of Energy Emergency. A measure of the severity of the emergency that calls for the implementation of various energy use reduction measures. Typical levels include the following:

- **Green (Normal)** — All occupant or building functions maintained and systems operating under the normal operating circumstances for the building
- **Blue** — All or most of the occupant or building functions maintained, with reductions in building system output that may result in borderline occupancy comfort
- **Yellow** — A minor reduction of occupant or building functions with reductions in output
- **Red** — A major reduction of occupant or building functions and systems that barely sustains building occupancy capability
- **Black** — The orderly shutdown of systems and occupancy that maintains the minimum building conditions needed to protect the building and its systems

Implementation of Energy Reductions

Each building owner, lessor, and operator should use the energy team approach and identify an individual with the necessary authority to review and fit recommendations into a plan for the particular building. For each class of emergency, the responsible party recommends a specific plan to reduce building energy use that still maintains the best building environment under the given circumstances. Implementation of the particular recommendations should then be coordinated through the building operator with assistance from the responsible party and the building occupants, as necessary. The plan should be tested occasionally.

Depending on the type of building, its use, the energy source(s) for each function, and local conditions such as climate and availability of other similar buildings, the following steps should be taken in developing a building energy plan:

1. Develop a list of measures that are applicable to the building.
2. Estimate the amount and type of energy savings for each measure and appropriate combination of measures (e.g., account for air-conditioning savings resulting from reduced lighting and other internal loads). Tabulate demand and usage savings separately for response to different types of emergencies.
3. For the various levels of energy emergency, develop a plan that would maintain the best building environment under the circumstances. Include both short- and long-term measures in the plan. Operational changes may be implemented quickly and prove adequate for short-term emergencies.
4. Experiment with the plan developed, record energy consumption and demand reduction data, and revise the plan as necessary. Much of the experimentation may be done on weekends to minimize disruptive effects.

5. Meet with the local utility company(s) to review the plan.

In the emergency planning process, some measures can be implemented permanently. Depending on the level of energy emergency and the building priority, the following actions may be considered in developing the plan for emergency energy reduction in the building:

- Change operating hours
- Move personnel into other building areas (consolidation)
- Shut off nonessential equipment

**Thermal Envelope**

- Use all existing blinds, draperies, and window coverings during summer
- Install interior window insulation
- Caulk and seal around unused exterior doors and windows
- Install solar shading devices in summer
- Seal all unused vents and ducts to outside

**Heating, Ventilating, and Air-Conditioning Systems and Equipment**

- Modify controls or control set points to raise and lower temperature and humidity as necessary
- Shut off or isolate all nonessential equipment
- Tune up equipment
- Lower thermostat set points in winter
- Raise chilled water temperature
- Lower hot water temperature (Note: Keep hot water temperature higher than 63°C if a gas boiler is used.)
- Reduce the level of reheat or eliminate it in winter
- Reduce or eliminate ventilation and exhaust airflow
- Raise thermostat set points in summer
- Reduce the amount of recooling in summer

**Lighting Systems**

- Remove lamps or reduce lamp wattage
- Use task lighting where appropriate
- Move building functions to exterior or daylight areas
- Turn off electric lights in areas with adequate natural light
- Lower luminaire height where appropriate
- Wash all lamps and luminaires
- Replace fluorescent ballasts with high-efficiency or multilevel ballasts

- Revise building cleaning and security procedures to minimize lighting periods
- Consolidate parking and turn off unused parking security lighting

**Special Equipment**

- Take transformers off-line during periods of nonuse
- Shut off or regulate the use of vertical transportation systems
- Shut off unused or unnecessary equipment, such as photocopiers, music systems, and computers
- Reduce or turn off hot water supply

**Building Operation Demand Reduction**

- Sequence or interlock heating or air-conditioning systems
- Disconnect or turn off all nonessential loads
- Turn off some lights
- Preheat or precool prior to the emergency period

**REFERENCES**

OWNING and operating cost information for the HVAC system should be part of the investment plan of a facility. This information can be used for preparing annual budgets, managing assets, and selecting design options. [Table 1] shows a representative form that summarizes these costs.

A properly engineered system must also be economical. Economics are difficult to assess because of the complexities surrounding the effective management of money and the inherent difficulty of predicting future operating and maintenance expenses. Complex tax structures and the time value of money can affect the final engineering decision. This does not imply the use of either the cheapest or the most expensive system; instead, it demands an intelligent analysis of the financial objectives and requirements of the owner.

Certain tangible and intangible costs or benefits must also be considered when assessing owning and operating costs. Local codes may require highly skilled or certified operators for specific types of equipment. This could be a significant cost over the life of the system. Similarly, such intangible items as aesthetics, acoustics, comfort, safety, security, flexibility, and environmental impact may be important to a particular building or facility.

### OWNING COSTS

The following elements must be established to calculate annual owning costs: (1) initial cost, (2) analysis or study period, (3) interest or discount rate, and (4) other periodic costs such as insurance, property taxes, refurbishment, or disposal fees. Once established, these elements are coupled with operating costs to develop an economic analysis, which may be a simple payback evaluation or an in-depth analysis such as outlined in the section on [Economic Analysis](#).

#### Initial Cost

Major decisions affecting annual owning and operating costs for the life of the building must generally be made prior to the completion of contract drawings and specifications. To achieve the best performance and economics, comparisons between alternate methods of solving the engineering problems peculiar to each project must be made in the early stages of design. Oversimplified estimates can lead to substantial errors in evaluating the system.

A thorough understanding of the installation costs and accessory requirements must be established. Detailed lists of materials, controls, space and structural requirements, services, installation labor, and so forth can be prepared to increase the accuracy in preliminary cost estimates. A reasonable estimate of the capital cost of components may be derived from cost records of recent installations of comparable design or from quotations submitted by manufacturers and contractors. [Table 2] shows a representative checklist for initial costs.

---

The preparation of this chapter is assigned to TC 1.8, Owning and Operating Costs.
The time frame over which an economic analysis is performed greatly affects the results of the analysis. The analysis period is usually determined by specific analysis objectives, such as length of planned ownership or loan repayment period. The chosen analysis period is often unrelated to the equipment depreciation period or service life, although these factors may be important in the analysis. Table 3 lists representative estimates of the service life of various system components. Service life as used here is the time during which a particular system or component remains in its original service application. Replacement may be for any reason, including, but not limited to failure, general obsolescence, reduced reliability, excessive maintenance cost, and changed system requirements due to such influences as building characteristics, energy prices, or environmental considerations. Depreciation periods are usually set by federal, state, or local tax laws, which change periodically. Applicable tax laws should be consulted for more information on depreciation.

### Analysis Period

The time frame over which an economic analysis is performed greatly affects the results of the analysis. The analysis period is usually determined by specific analysis objectives, such as length of planned ownership or loan repayment period. The chosen analysis period is often unrelated to the equipment depreciation period or service life, although these factors may be important in the analysis. Table 3 lists representative estimates of the service life of various system components. Service life as used here is the time during which a particular system or component remains in its original service application. Replacement may be for any reason, including, but not limited to failure, general obsolescence, reduced reliability, excessive maintenance cost, and changed system requirements due to such influences as building characteristics, energy prices, or environmental considerations.

### Operating Costs

Operating costs are those incurred by the actual operation of the system. They include costs of fuel and electricity, wages, supplies, water, material, and maintenance parts and services. Chapter 30 of the 1997 ASHRAE Handbook—Fundamentals outlines how fuel and electrical requirements are estimated. Note that total energy consumption cannot generally be multiplied by a per unit energy cost to arrive at annual utility cost.

### Periodic Costs

Regularly or periodically recurring costs include insurance, property taxes, income taxes, rent, refurbishment expenses, disposal fees (e.g., refrigerant recycling costs), occasional major repair costs, and decommissioning expenses.

**Insurance.** Insurance reimburses a property owner for a financial loss so that equipment can be repaired or replaced. Insurance often indemnifies the owner from liability as well. Financial recovery may include replacing income, rents, or profits lost due to property damage.

Some of the principal factors that influence the total annual insurance premium are building size, construction materials, amount and size of mechanical equipment, geographic location, and policy deductibles. Some regulations set minimum required insurance coverages and premiums that may be charged for various forms of insurable property.

**Property Taxes.** Property taxes differ widely and may be collected by one or more agencies, such as state, county, or local governments or special assessment districts. Furthermore, property taxes may apply to both real (land, buildings) and personal (everything else) property. Property taxes are most often calculated as a percentage of assessed value but are also determined in other ways, such as fixed fees, license fees, registration fees, etc. Moreover, definitions of assessed value vary widely in different geographic areas. Tax experts should be consulted for applicable practices in a given area.

**Income Taxes.** Taxes are generally imposed in proportion to net income, after allowance for expenses, depreciation, and numerous other factors. Special tax treatment is often granted to encourage certain investments. Income tax experts can provide up-to-date information on income tax treatments.

**Additional Periodic Costs.** Examples of additional costs include changes in regulations that require unscheduled equipment refurbishment to eliminate use of hazardous substances, and disposal costs for such substances. Moreover, at the end of the equipment’s useful life there may be negative salvage value (i.e., removal, disposal, or decommissioning costs).

### Interest or Discount Rate

Most major economic analyses consider the opportunity cost of borrowing money, inflation, and the time value of money. **Opportunity cost** of money reflects the earnings that investing (or loaning) the money can produce. **Inflation** (price escalation) decreases
Owning and Operating Costs

Source: Data obtained from a survey of the United States by ASHRAE Technical Committee TC 1.8 (Akalin 1978).

Electrical Energy

Fundamental changes in the purchase of electrical energy are occurring in the United States, which is opening access to and eventually deregulating the electric energy industry. Individual electric utility rates and regulations may vary widely during this period of deregulation. Consequently, electrical energy providers and brokers or marketers need to be contacted to determine the most competitive supplier. Contract conditions need to be reviewed carefully to be sure that the service will suit the purchaser’s requirements.

The total cost of electrical energy is usually a combination of several components: energy consumption charges, fuel adjustment charges, special allowances or other adjustments, and demand charges.

#### Energy Consumption Charges

Most utility rates have step rate schedules for consumption, and the cost of the last unit of energy consumed may be substantially different from that of the first. The last unit may be cheaper than the first because the fixed costs to the utility may already have been recovered from earlier consumption costs. Alternatively, the last unit of energy may be sold at a higher rate to encourage conservation.

To reflect time-varying operating costs, some utilities charge different rates for consumption according to the time of use and season; typically, costs rise toward the peak period of use. This may justify the cost of shifting the load to off-peak periods.

#### Fuel Adjustment Charge

Due to substantial variations in fuel prices, electric utilities may apply a fuel adjustment charge to recover costs. This adjustment may not be reflected in the rate schedule. The fuel adjustment is usually a charge per unit of energy and may be positive or negative depending on how much of the actual fuel cost is recovered in the energy consumption rate.

Power plants with multiple generating units that use different fuels typically have the greatest effect on this charge (especially during peak periods, when more expensive units must be brought on-line). Although this fuel adjustment charge can vary monthly, the utility should be able to estimate an average annual or seasonal fuel adjustment for calculations.

#### Allowances or Adjustments

Special allowances may be available for customers who can receive power at higher voltages or for those who own transformers or similar equipment. Special rates may be available for specific interruptible loads such as domestic water heaters.

Certain facility electrical systems may produce a low power factor, which means that the utility must supply more current on an intermittent basis, thus increasing their costs. These costs may be passed on as an adjustment to the utility bill if the power factor is below a level established by the utility. The power factor is the ratio of active (real) kilowatt power to apparent (reactive) kVA power.

When calculating power bills, utilities should be asked to provide detailed cost estimates for various consumption levels. The final calculation should include any applicable special rates, allowances, taxes, and fuel adjustment charges.

#### Demand Charges

Electric rates may also have demand charges based on the customer’s peak kilowatt demand. While consumption charges typically cover the utility’s operating costs, demand charges typically cover the owning costs.

Demand charges may be formulated in a variety of ways:

1. **Straight charge**—cost per kilowatt per month, charged for the peak demand of the month.
2. **Excess charge**—cost per kilowatt above a base demand (e.g., 50 kW), which may be established each month.
3. Maximum demand (ratchet)—cost per kilowatt for the maximum annual demand, which may be reset only once a year. This established demand may either benefit or penalize the owner.

4. Combination demand—cost per hour of operation of the demand. In addition to a basic demand charge, utilities may include further demand charges as demand-related consumption charges.

The actual demand represents the peak energy use averaged over a specific period, usually 15, 30, or 60 min. Accordingly, high electrical loads of only a few minutes’ duration may never be recorded at the full instantaneous value. Alternatively, peak demand is recorded as the average of several consecutive short periods (i.e., 5 min out of each hour).

The particular method of demand metering and billing is important when load shedding or shifting devices are considered. The portion of the total bill attributed to demand may vary greatly, from 0% to as high as 70%.

Natural Gas

Rates. Conventional natural gas rates are usually a combination of two main components: (1) utility rate for gas consumption and (2) purchased gas adjustment (PGA) charges.

Although gas is usually metered by volume, it is often sold by energy content. The utility rate is the amount the local distribution company charges per unit of energy to deliver the gas to a particular location. This rate may be graduated in steps; the first 10 GJ of gas consumed may not be the same price as the last 10 GJ. The PGA is an adjustment for the cost of the gas per unit of energy to the local utility. It is similar to the electric fuel adjustment charge. The total cost per unit of energy is then the sum of the appropriate utility rate and the PGA, plus taxes and other adjustments.

Interruptible Gas Rates and Contract/Transport Gas. Large industrial plants usually have the ability to burn alternate fuels at the plant and can qualify for special interruptible gas rates. During peak periods of severe cold weather, these customers may be curtailed by the gas utility and may have to switch to propane, fuel oil, or some other backup fuel. The utility rate and PGA are usually considerably cheaper for these interruptible customers than they are for firm rate (noninterruptible) customers.

Deregulation of the natural gas industry allows end users to negotiate for gas supplies on the open market. The customer actually contracts with a gas producer or broker and pays for the gas at the source. Transport fees must be negotiated with the pipeline companies carrying the gas to the customer’s local gas utility. This can be a very complicated administrative process and is usually economically feasible for large gas users only. Some local utilities have special rates for delivering contract gas volumes through their system; others simply charge a standard utility fee (PGA is not applied because the customer has already negotiated with the supplier for the cost of the fuel itself).

When calculating natural gas bills, be sure to determine which utility rate and PGA and/or contract gas price is appropriate for the particular interruptible or firm rate customer. As with electric bills, the final calculation should include any taxes, prompt payment discounts, or other applicable adjustments.

Other Fossil Fuels

Propane, fuel oil, and diesel are examples of other fossil fuels in widespread use. Calculating the cost of these fuels is usually much simpler than calculating typical utility rates. When these fuels are used, other items that can affect owning or operating costs must be considered.

The cost of the fuel itself is usually a simple charge per unit volume or mass. The customer is free to negotiate for the best price. However, trucking or delivery fees must also be included in final calculations. Some customers may have their own transport trucks, while most shop around for the best delivered price. If storage tanks are not customer-owned, rental fees must be considered. Periodic replacement of diesel-type fuels may be necessary due to storage or shelf-life limitations and must also be considered. The final fuel cost calculation should include any of these costs that are applicable, as well as the appropriate taxes.

MAINTENANCE COSTS

The quality of maintenance and maintenance supervision can be a major factor in the energy cost of a building. Chapter 37 covers the maintenance, maintainability, and reliability of systems. Dohrmann and Alereza (1986) obtained maintenance costs and HVAC system information from 342 buildings located in 35 states in the United States. In 1983 U.S. dollars, data collected showed a mean HVAC system maintenance cost of $3.40/m² per year, with a median cost of $2.60/m² per year. The age of the building has a statistically significant but minor effect on HVAC maintenance costs. When analyzed by geographic location, the data revealed that location does not significantly affect maintenance costs. Analysis also indicated that building size is not statistically significant in explaining cost variation.

The type of maintenance program or service agency that the building management contracts for can also have a significant effect on total HVAC maintenance costs. While extensive or thorough routine and preventive maintenance programs cost more to administer, they usually produce benefits such as extended equipment life, improved reliability, and less system downtime.

Estimating Maintenance cost

Total HVAC maintenance cost for existing buildings with various types of equipment can be estimated using data from Table 4 and the method described below. For equipment types not included in Table 4 or as an alternate estimating method, contact equipment manufacturers or firms that provide maintenance contracts on buildings with similar equipment.

Several important limitations of the data presented here should be noted:

- Only selected data from Table 12 of the report by Dohrmann and Alereza (1986) are presented here.
- Data were collected for office buildings only.

*These results pertain to buildings with older, single-stage absorption chillers. The data from the survey are not sufficient to draw inferences about the costs of HVAC maintenance in buildings equipped with new absorption chillers.
Owning and Operating Costs

1.5

• Data measure total HVAC building maintenance costs, not the costs associated with maintaining particular items or individual pieces of equipment.
• The cost data are not intended for use in selecting new HVAC equipment or systems. This information is for equipment and systems already in place and may not be representative of the maintenance costs expected with newer equipment.

This method assumes that the base HVAC system in the building consists of fire-tube boilers for heating equipment, centrifugal chillers for cooling equipment, and VAV distribution systems. The total annual building HVAC maintenance cost for this system is $3.59/m². Adjustment factors from Table 4 are then applied to this base cost to account for building age and variations in type of HVAC equipment as follows:

\[ C = \frac{C_p}{(CPI)} - 0.431 - 0.948 + d \]

Example 1. Estimate the total annual building HVAC maintenance cost per square metre for a building that is 10 years old and has an electric boiler, a reciprocating chiller, and a constant volume distribution system.

\[ C = 3.59 + 0.019(10) - 0.287 - 0.431 + 0.948 \]
\[ C = $4.01/m^2 \text{ in 1983 dollars} \]

This estimate can be adjusted to current dollars by multiplying the maintenance cost estimate by the current Consumer Price Index (CPI) divided by the CPI in July 1983. In July 1983, the CPI was 100.1. Monthly CPI statistics are recorded in Survey of Current Business (U.S. Department of Commerce). This estimating method is limited to one equipment variable per situation. That is, the method can estimate maintenance costs for a building having either a centrifugal chiller or a reciprocating chiller, but not both. Assessing the effects of combining two or more types of equipment within a single category requires a more complex statistical analysis.

**IMPACT OF REFRIGERANT PHASEOUTS**

The production phaseout of many commonly used refrigerants has presented building owners with decisions regarding the replacement of existing equipment versus retrofit to alternative refrigerant compatibility. Several factors must be considered, including

• **Initial Cost.** New equipment may have a significantly higher installed cost than the retrofit of existing equipment. For example, the retrofit of an existing centrifugal chiller to operate on R-123 may cost 50% of the cost for a new chiller. The cost of rigging a new unit may significantly raise the installed cost, improving the first cost advantage of conversion.
• **Operating Costs.** The overall efficiency of new equipment is often substantially better than that of existing equipment, depending on age, usage, and level of maintenance performed over the life of the existing unit. In addition, conversion to alternative refrigerants may reduce capacity and/or efficiency.
• **Maintenance Costs.** The maintenance cost for new equipment is generally lower than that for existing equipment. The level of retrofit required to attain compatibility often includes replacement or remanufacture of major unit components, which can bring the maintenance and repair costs in line with those expected of new equipment.
• **Equipment Useful Life.** The impact of a retrofit on equipment useful life is determined by the extent of modification required.

The complete remanufacture of a unit should extend the remaining useful life to a level comparable to that of new equipment.

Decisions regarding the replacement of existing equipment or the conversion to alternative refrigerants offer opportunities to improve overall system efficiency. Reduced capacity requirements and the introduction of new technologies such as variable-speed drives and microprocessor-based controllers can substantially reduce annual operating costs and significantly improve a project’s economic benefit.

Information should be gathered to complete Table 1 for each alternative. The techniques described in the section on Economic Analysis Techniques may then be applied to compare the relative values of each option.

**OTHER ISSUES**

**Financing Alternatives**

Alternative financing is commonly used in the third-party funding of projects, particularly retrofit projects, and is variously called privatization, third-party financing, energy services, outsourcing, performance contracting, energy savings performance contracting (ESPC), or innovative financing. In these programs, an outside party performs an energy study to identify or quantify attractive energy-saving retrofit projects and then (to varying degrees) designs, builds, and finances the retrofit program on behalf of the owner or host facility. These contracts range in complexity from simple projects such as lighting upgrades to more detailed projects involving all aspects of energy consumption and facility operation.

Alternative financing can be used to accomplish any or all of the following objectives:

• Upgrade capital equipment
• Provide for maintenance of existing facilities
• Speed project implementation
• Conserve or defer capital outlay
• Save energy
• Save money

The benefits of alternative financing are not free. In general terms, these financing agreements transfer the risk of attaining future savings from the owner to the contractor. The contractor will want to be paid for assuming this risk. In addition, these innovative owning and operating cost reduction approaches have important tax consequences that should be investigated on a case-by-case basis.

There are many variations of the basic arrangements and nearly as many terms to define them. Common nomenclature includes guaranteed savings (performance-based), shared savings, paid from savings, guaranteed savings loans, capital leases, municipal leases, and operating leases. For more information, refer to the U.S. Department of Energy’s Web page and to the DOE-sponsored document entitled “International Performance Measurement and Verification Protocol.”

A few examples of alternative financing techniques follow.

**Leasing.** Among the most common methods of alternative financing is the lease arrangement. In a true lease or lease-purchase arrangement, outside financing provides capital for the construction of a facility. The institution then leases the facility at a fixed monthly charge and assumes responsibility for fuel and personnel costs associated with its operation.

Leasing is also commonly available for individual pieces of equipment or retrofit systems and often includes all design and installation costs. Equipment suppliers or independent third parties retain ownership of new equipment and lease it to the user.

**Outsourcing.** For a cogeneration, steam, or chilled water plant, either a lease or an energy output contract can be used. An energy output contract enables a private company to provide all the capital
and operating costs, such as personnel and fuel, while the host facility purchases energy from the operating company at a variable monthly charge.

**Energy Savings.** Retrofit projects that lower energy usage create an income stream that can be used to amortize the investment. In **paid-from-savings** programs, utility payments remain constant over a period of years while the contractor is paid out of savings until the project is amortized. In **shared savings** programs, the institution receives a percentage of savings over a longer period of years until the project becomes its property. In a **guaranteed savings** program, the owner retains all the savings and is guaranteed that a certain level of savings will be attained. A portion of the savings is used to amortize the project. In any type of energy savings project, building operation and utilization can have a major impact on the amount of savings actually realized.

**Low-Interest Financing.** In this arrangement, the supplier offers the equipment with special financing arrangements at below-market interest rates.

**Cost Sharing.** Several variations of cost-sharing programs exist. In some instances, two or more groups jointly purchase and share new equipment or facilities, thereby increasing utilization of the equipment and improving the economic benefits for both parties. In other cases, equipment suppliers or independent third parties (such as utilities) who receive an indirect benefit may share part of the equipment or project cost to establish a market foothold for the product.

**District Energy Service**

District energy service is increasingly available to building owners; district heating and cooling eliminates most on-site heating and cooling equipment. A third party produces treated water or steam and pipes it from a central plant directly to the building. The building owner then pays a metered rate for the energy that is used.

A cost comparison of district energy service versus on-site generation requires careful examination of numerous, often site-specific, factors extending beyond demand and energy charges for fuel. District heating and cooling eliminates or minimizes most costs associated with the installation, maintenance, administration, repair and operation of on-site heating and cooling equipment. Specifically, the costs associated with providing water, water treatment, specialized maintenance services, insurance, staff time, space to house on-site equipment, and structural additions needed to support equipment should be considered. Costs associated with auxiliary equipment, which represent 20 to 30% of the total plant annual operating costs, should also be included.

Any analysis that fails to include all the associated costs does not give a clear picture of the building owner’s heating and cooling alternatives. In addition to the tangible costs, there are a number of other factors that should be considered, such as convenience, risk, environmental issues, flexibility, and backup.

**On-Site Electric Generation**

On-site electric generation covers a broad range of applications, from emergency backup to power for a single piece of equipment to an on-site power plant supplying 100% of the facility’s electrical power needs. A variety of system types and fuel sources are available, but the economic principles described in this chapter apply equally to all of them. Other chapters (e.g., Chapter 71 [Cogeneration Systems and Engine and Turbine Drives], and Chapter 35 [Solar Energy Equipment]) of the 2000 ASHRAE Handbook—Systems and Equipment) may be helpful in describing system details.

An economic study of on-site electrical power generation should include consideration of all owning, operating, and maintenance costs. Typically, on-site generation is capital intensive (i.e., high first cost) and therefore requires a high utilization rate to produce savings adequate to support the investment. High utilization rates mean high run time, which requires planned maintenance and careful operation.

Owning costs include any related systems required to adapt the building to on-site power generation. Additional equipment is required if the building will also utilize purchased power from a utility. The costs associated with shared equipment should also be considered. For example, if the power source for the generator is a steam turbine, and a hot water boiler would otherwise be used to meet the HVAC demand, the boiler would need to be a larger, high-pressure steam boiler with a heat exchanger to meet the hot water needs. In addition to higher first cost, operation and maintenance costs for the boiler are increased due to the increased operating hours.

Consideration must also be given to the costs of an initial investment and ongoing inventory of spare parts. Most equipment manufacturers provide a recommended spare parts list as well as recommended maintenance schedules. Typical maintenance schedules consist of daily, weekly, and monthly routine maintenance and periodic major overhauls. Major overhaul frequency depends on equipment utilization and requires taking the equipment off-line. The cost of either lost building utilization or the provision of electricity from an alternate source during the shutdown should be considered.

**ECONOMIC ANALYSIS TECHNIQUES**

Analysis of overall owning and operating costs and comparisons of alternatives require an understanding of the cost of lost opportunities, inflation, and the time value of money. This process of economic analysis of alternatives falls into two general categories: simple payback analysis and detailed economic analyses (life-cycle cost analyses).

A simple payback analysis reveals options that have short versus long paybacks. Often, however, alternatives are similar and have similar paybacks. For a more accurate comparison, a more comprehensive economic analysis is warranted. Many times it is appropriate to have both a simple payback analysis and a detailed economic analysis. The simple payback analysis shows which options should not be considered further, and the detailed economic analysis determines which of the viable options are the strongest. The strongest options can be accepted or further analyzed if they include competing alternatives.

**Simple Payback**

In the simple payback technique, a projection of the revenue stream, cost savings, and other factors is estimated and compared to the initial capital outlay. This simple technique ignores the cost of borrowing money (interest) and lost opportunity costs. It also ignores inflation and the time value of money.

**Example 2.** Equipment item 1 costs $10 000 and will save $2000 per year in operating costs; equipment item 2 costs $12 000 and saves $3000 per year. Which item has the best simple payback?

\[
\text{Item 1} = \frac{10 000}{2000} = 5 \text{ year simple payback} \\
\text{Item 2} = \frac{12 000}{3000} = 4 \text{ year simple payback}
\]

Because the analysis of equipment for the duration of its realistic life can produce a much different result, the simple payback technique should be used with caution.

**More Sophisticated Economic Analysis Methods**

This section describes a few of the detailed economic techniques available. These techniques are used to examine all costs and incomes to be incurred over the analysis period (1) in terms of their present value (i.e., today’s or initial year’s value, also called constant value); (2) in terms of equal periodic costs or payments
Owning and Operating Costs

(uniform annualized costs); or (3) in terms of periodic cash flows (e.g., monthly or annual cash flows). Each method provides a slightly different insight. The present value method allows easy comparison of alternatives over the analysis period chosen. The uniform annualized costs method allows comparison of average annual costs of different options. The cash flow method allows comparison of actual cash flows rather than average cash flows; it can identify periods of overall positive and negative cash flow, which is helpful for cash management.

Economic analysis should consider details of both positive and negative costs over the analysis period, such as varying inflation rates, capital and interest costs, salvage costs, replacement costs, interest deductions, depreciation allowances, taxes, tax credits, mortgage payments, and all other costs associated with a particular system. See the section on Symbols for definitions of variables.

Example 3. Calculate the value in 10 years at 10% per year interest of a system presently valued at $10 000.

\[ F = P(1 + i)^n = 10 000(1 + 0.1)^{10} = \$25,937.42 \]

Example 4. Using the present worth factor for 10% per year interest and an analysis period of 10 years, calculate the present value of a future sum of money valued at $10 000. (Stated another way, determine what sum of money must be invested today at 10% per year interest to yield $10 000 10 years from now.)

\[ P = F \times PWF(i,n)_{sgl} \]

\[ P = 10 000 \times \frac{1}{(1 + 0.1)^{10}} = \$3855.43 \]

Series of Equal Payments. The present worth factor for a series of future equal payments (e.g., operating costs) is given by

\[ PWF(i,n)_{ser} = \frac{(1 + i)^n - 1}{i(1 + i)^n} \quad (5) \]

The present value \( P \) of those future equal payments (PMT) is then the product of the present worth factor and the payment (i.e., \( P = PWF(i,n)_{ser} \times PMT \)).

The future equal payments to repay a present value of money is determined by the capital recovery factor (CRF), which is the reciprocal of the present worth factor for a series of equal payments:

\[ CRF = \frac{P}{PWF(i,n)_{ser}} \]

\[ CRF(i,n) = \frac{i(1 + i)^n}{(1 + i)^n - 1} = \frac{i}{1 - (1 + i)^{-n}} \quad (7) \]

The CRF is often used to describe periodic uniform mortgage or loan payments. Table 5 gives abbreviated annual CRF values for several values of analysis period \( n \) and annual interest rate \( i \). Some of the values of Table 5 are plotted versus time in Figure 1.

Note that when payment periods other than annual are to be studied, the interest rate must be expressed per appropriate period. For example, if monthly payments or return on investment are being analyzed, then interest must be expressed per month, not per year, and \( n \) must be expressed in months, not years.

Example 5. Determine the present value of an annual operating cost of $1000 per year over 10 years, assuming 10% per year interest rate.

\[ PWF(i,n)_{ser} = \frac{[(1 + 0.1)^{10} - 1]/[0.1(1 + 0.1)^{10}]}{6.14} = 6.14 \]

\[ P = \$1000(6.14) = \$6140 \]

</table>
Example 6. Determine the uniform monthly mortgage payments for a loan of $100,000 to be repaid over 30 years at 10% per year interest. Since we wish monthly payment periods, the payback duration is 30(12) = 360 monthly periods, and the interest rate per period is 0.1/12 = 0.00833% per month.

\[
\text{CRF}(i,n) = \frac{0.00833(1 + 0.00833)^{360}}{[(1 + 0.00833)^{360} - 1]} \\
\text{CRF} = 0.008773 \\
\text{PMT} = P(t)(\text{CRF}) \\
\text{PMT} = $100,000(0.008773) \\
\text{PMT} = $877.30 per month
\]

Improved Payback Analysis. This somewhat more sophisticated payback approach is similar to the simple payback method, except that the cost of money (interest rate, discount rate, etc.) is considered. Solving Equation (7) for \( n \) yields the following:

\[
n = \frac{\ln[\text{CRF}/(\text{CRF} - i)]}{\ln(1 + i)} \\
(8)
\]

Given known investment amounts and earnings, CRFs can be calculated for the alternative investments. Subsequently, the number of periods until payback has been achieved can be calculated using Equation (8). Alternatively, a period-by-period (e.g., month-by-month or year-by-year) tabular cash flow analysis may be performed, or the necessary period to yield the calculated CRF may be obtained from a plot of CRFs, such as that shown in Figure 1.

Example 7. Compare the years to payback of the same items described in Example 2 if the value of money is 10% per year.

Item 1

\[
\text{cost} = $10,000 \\
\text{savings} = $2000/year \\
\text{CRF} = \frac{\text{savings}}{\text{cost}} = \frac{2000}{10,000} = 0.2 \\
\text{n} = \ln[0.2/(0.2 - 0.1)]/\ln(1 + 0.1) = 7.3 \text{ years}
\]

Item 2

\[
\text{cost} = $12,000 \\
\text{savings} = $3000/year \\
\text{CRF} = \frac{\text{savings}}{\text{cost}} = \frac{3000}{12,000} = 0.25 \\
\text{n} = \ln[0.25/(0.25 - 0.1)]/\ln(1 + 0.1) = 5.4 \text{ years}
\]

Accounting for Inflation. Different economic goods may inflate at different rates. Inflation reflects the rise in the real cost of a commodity over time and is separate from the time value of money. Inflation must often be accounted for in an economic evaluation. One way to account for inflation is to substitute effective interest rates that account for inflation into the equations given in this chapter.

The effective interest rate \( i' \), sometimes called the real rate, accounts for inflation rate \( j \) and interest rate \( i \) or discount rate \( j \); it can be expressed as follows (Kreith and Kreider 1978, Kreider and Kreith 1982):

\[
i' = \frac{1 + i}{1 + j} - 1 = \frac{i - j}{1 + j} \\
(9)
\]

Different effective interest rates can be applied to individual components of cost. Projections for future fuel and energy prices are available in the Annual Supplement to NIST Handbook 135 (Lippatt 1994; NIST).

Example 8. Determine the present worth \( P \) of an annual operating cost of $1000 over 10 years, given a discount rate of 10% per year and an inflation rate of 5% per year.

\[
i' = (0.1 - 0.05)/(1 + 0.05) = 0.0476 \\
PWF(i', n)_{\text{cr}} = \frac{(1 + 0.0476)^{10} - 1}{0.0476(1 + 0.0476)^{10}} = 7.813 \\
P = 1000(7.813) = $7813
\]

The following are three commonly used methods of present value analysis that include life-cycle cost factors (life of equipment, analysis period, discount rate, energy escalation rates, maintenance cost, etc., as shown in Table 1). These comparison techniques rely on the same assumptions and economic analysis theories but display the results in different forms. They also use the same definition of each term. All can be displayed as a single calculation or as a cash flow table using a series of calculations for each year of the analysis period.

Savings-to-Investment Ratio. Most large military sponsored work and many other U.S. government entities require a savings-to-investment-ratio (SIR) method. This method produces a ratio that defines the relative economic strength of each option. The higher the ratio, the better the economic strength. If the ratio is less than 1, the measure does not pay for itself within the analysis period. The escalated savings on an annual and a special (nonannual) basis is calculated and discounted. The costs are shown on an annual and special basis for each year over the life of the system or option. The savings and investments are both discounted separately on an annual basis and then the discounted total cumulative savings is divided by the discounted total cumulative investments (costs). The analysis period is usually the life of the system or equipment being considered.

Life-Cycle Costs. This method of analysis compares the cumulative total of implementation, operating, and maintenance costs. The total costs are discounted over the life of the system or over the loan repayment period. The costs and investments are both discounted and displayed as a total combined life-cycle cost at the end of the analysis period. The options are compared to determine which has the lowest total cost over the anticipated project life.

Internal Rate of Return. The internal rate of return (IRR) method calculates a return on investment over the defined analysis period. The annual savings and costs are not discounted, and a cash flow is established for each year of the analysis period, to be used with an initial cost (or value of the loan). Annual recurring and special (nonannual) savings and costs can be used. The cash flow is then discounted until a calculated discount rate is found that yields a net present value of zero. This method gives a basic comparison of return on investments. This method assumes savings are reinvested.
Owning and Operating Costs

at the same calculated rate of return. Therefore, the calculated rates of return can be overstated compared to the actual rates of return.

Another version of this is the modified or adjusted internal rate of return (MIRR or AIRR). In this version, reinvested savings are assumed to have a given rate of return on investment, and the financed monies a given interest rate. The cash flow is then discounted until a calculated discount rate is found that yields a net present value of zero. This method gives a more realistic indication of expected return on investment, but the difference between alternatives can be small.

Uniform Annualized Costs Method. It is sometimes useful to project a uniform periodic (e.g., average annual) cost over the analysis period. The basic procedure for determining uniform annualized costs is to first determine the present worth of all costs and then apply the capital recovery factor to determine equal payments over the analysis period.

Uniform annualized mechanical system owning, operating, and maintenance costs can be expressed, for example, as

\[ C_n = \text{capital and interest} + \text{salvage value} - \text{replacements} - \text{operating energy} - \text{property tax} - \text{maintenance} + \text{insurance} + \text{interest tax deduction} + \text{depreciation} \]

where:

- capital and interest = \( (C_s, init - \text{ITC}) \text{CRF}(i') \)
- salvage value = \( C_s, salv \text{WF}(i', n) \text{CRF}(i') \)
- replacements or disposals = \( \sum_{k=1}^{n} \left[ P_k \text{PWF}(i, k) \text{CRF}(i') \right] \)
- operating energy = \( C_o \left[ \text{CRF}(i')^{n} / \text{CRF}(i'^*)^{n} \right] \)
- property tax = \( C_d \text{SAFE} \text{TPROP}(1 - T_{inc}) \)
- maintenance = \( M(1 - T_{inc}) \)
- interest tax deduction = \( T_{inc} \sum_{k=1}^{n} \left[ i_m P_{k-1} \text{PWF}(i, j) \text{CRF}(i') \right] \)
- depreciation (for commercial systems) = \( T_{inc} \sum_{k=1}^{n} \left[ D_{k} \text{PWF}(i, k) \text{CRF}(i') \right] \)

The outstanding principle \( P_k \) during year \( k \) at market mortgage rate \( i_m \) is given by

\[ P_k = (C_s, init - \text{ITC}) \left[ (1 + i_m)^{k-1} + \frac{(1 + i_m)^{k-1} - 1}{(1 + i_m)^n - 1} \right] \]

Note: \( P_k \) is in current dollars and must, therefore, be discounted by the discount rate \( i' \), not \( i_m \).

Likewise, the summation term for interest deduction can be expressed as

\[ \sum_{k=1}^{n} \left[ i_m P_k / (1 + i_d)^k \right] = (C_s, init - \text{ITC}) \times \left[ \text{CRF}(i_m n) / \text{CRF}(i_d n) + \frac{1}{(1 + i_m) \text{CRF}(i_d - i_m) n} \right] \]

If \( i_d = i_m \),

\[ \sum_{k=1}^{n} \left[ i_m P_k / (1 + i_d)^k \right] = (C_s, init - \text{ITC}) \times \left[ 1 + \frac{n}{1 + i_m} \text{CRF}(i_m n) \right] \]

Depreciation terms commonly used include depreciation calculated by the straight line depreciation method, which is

\[ D_{k, SL} = (C_s, init - C_s, salv) / n \]

and the sum-of-digits depreciation method:

\[ D_{k, SD} = (C_s, init - C_s, salv) [2(n - k + 1)] / n(n + 1) \]

Riggs (1977) and Grant et al. (1982) present further information on advanced depreciation methods. Certified accountants may also be consulted for information regarding accelerated methods allowed for tax purposes. The following example illustrates the use of the uniform annualized cost method. Additional examples are presented by Haberl (1993).

**Example 9.** Calculate the annualized system cost using constant dollars for a $10 000 system considering the following factors: a 5-year life, a salvage value of $1000 at the end of the 5 years, no investment tax credits, a $500 replacement in year 3, a discount rate \( i_d \) of 10%, a general inflation rate \( j \) of 5%, a fuel inflation rate \( j' \) of 8%, a market mortgage rate \( i_m \) of 10%, an annual operating cost for energy of $500, a $100 annual maintenance cost, a $50 annual insurance cost, straight line depreciation, an income tax rate of 50%, a property tax rate of 1% of assessed value, an assessed system value equal to 40% of the initial system value, and a salvage tax rate of 50%.

**Effective interest rate \( i' \) for all but fuel**

\[ i' = (i_d - j)/(1 + j) = (0.10 - 0.05)/(1 + 0.05) = 0.047619 \]

**Effective interest rate \( i' \) for fuel**

\[ i' = (i_d - j)/(1 + j) = (0.10 - 0.08)/(1 + 0.08) = 0.018519 \]

**Capital recovery factor \( \text{CFR}(i', n) \) for items other than fuel**

\[ \text{CFR}(i', n) = i' / \left[ 1 - (1 + i')^{-n} \right] \]

\[ = 0.047619 / [1 - (1.047619)^{-5}] = 0.229457 \]

**Capital recovery factor \( \text{CFR}(i', n) \) for fuel**

\[ \text{CFR}(i', n) = i' / \left[ 1 - (1 + i')^{-n} \right] \]

\[ = 0.018519 / [1 - (1.018519)^{-5}] = 0.211247 \]

**Capital recovery factor \( \text{CFR}(i_m, n) \) for loan or mortgage**

\[ \text{CFR}(i_m, n) = i_m / \left[ 1 - (1 + i_m)^{-n} \right] \]

\[ = 0.10 / [1 - (1.10)^{-5}] = 0.263797 \]

Loan payment = $10 000(0.263797) = $2637.97

**Present worth factor **

\[ \text{PWF}(i', 1) = 1 / (1 + i')(1.10)^{1} = 0.909091 \]

\[ \text{PWF}(i', 2) = 1 / (1 + i')(1.10)^{2} = 0.826446 \]

\[ \text{PWF}(i', 3) = 1 / (1 + i')(1.10)^{3} = 0.751315 \]

\[ \text{PWF}(i', 4) = 1 / (1 + i')(1.10)^{4} = 0.683013 \]

\[ \text{PWF}(i', 5) = 1 / (1 + i')(1.10)^{5} = 0.620921 \]

**Present worth factor **

\[ \text{PWF}(i_m, 1) = 1 / (1 + i_m)(1.10)^{1} = 0.954545 \]

\[ \text{PWF}(i_m, 2) = 1 / (1 + i_m)(1.10)^{2} = 0.911157 \]

\[ \text{PWF}(i_m, 3) = 1 / (1 + i_m)(1.10)^{3} = 0.869741 \]

\[ \text{PWF}(i_m, 4) = 1 / (1 + i_m)(1.10)^{4} = 0.830207 \]

\[ \text{PWF}(i_m, 5) = 1 / (1 + i_m)(1.10)^{5} = 0.792471 \]
1.10

Capital and interest

\[ (C_{\text{init}} - \text{ITC}) \cdot \text{CRF}(i', n) = (10 000 - 0) \cdot 0.229457 = 2294.57 \]

Salvage value

\[ C_{\text{salv}} \cdot \text{PWF}(i', n) \cdot \text{CRF}(i', n)(1 - T_{\text{inc}}) \]

Replacements

\[ \sum_{k=1}^{n} [R_k \cdot \text{PWF}(i', k)] \cdot \text{CRF}(i', n)(1 - T_{\text{inc}}) \]

Operating energy

\[ C_{\text{oper}} \cdot \text{CRF}(i', n)(1 - T_{\text{inc}}) \]

Property tax

\[ C_{\text{prop}} \cdot T_{\text{prop}} \cdot \text{PWF}(i', k) \]

Maintenance

\[ M(1 - T_{\text{inc}}) = 100(1 - 0.5) = 50.00 \]

Insurance

\[ I(1 - T_{\text{inc}}) = 50(1 - 0.5) = 25.00 \]

Interest deduction

\[ T_{\text{inc}} \sum_{k=1}^{n} [i_{\mu} P_k \cdot \text{PWF}(i', k)] \cdot \text{CRF}(i', n) \]

Table 6 summarizes the interest and principle payments for this example. Annual payments are the product of the initial system cost and the capital recovery factor CRF(\(i', 5\)). Also, Equation (10) can be used to calculate total discounted interest deduction directly.

Next, apply the capital recovery factor CRF(\(i', 5\)) and tax rate \(T_{\text{inc}}\) to the total of the discounted interest sum.

\[ $2554.66 \cdot \text{CRF}(i', 5) \cdot T_{\text{inc}} = $2554.66 \times 0.229457 \times 0.5 = $293.09 \]

Depreciation

\[ T_{\text{inc}} \sum_{k=1}^{n} [D_{\text{SL}} \cdot \text{PWF}(i', k)] \cdot \text{CRF}(i', n) \]

Use the straight line depreciation method to calculate depreciation:

\[ D_{\text{SL}} = \frac{(C_{\text{init}} - C_{\text{salv}})}{n} = \frac{(10 000 - 1000)}{5} = $1800.00 \]

Next, discount the depreciation.

Cash Flow Analysis Method. The cash flow analysis method accounts for costs and revenues on a period-by-period (e.g., year-by-year) basis, both actual and discounted to present value. This method is especially useful for identifying periods when net cash flow will be negative due to intermitted large expenses.

Example 10. An eight-year study for a $120 000 investment with depreciation spread equally over the assigned period. The benefits or incomes are variable. The marginal tax rate is 50%. The rate of return on the investment is required. Table 5 has columns showing year, cash outlays, income, depreciation, net taxable income, taxes and net cash flow.

Solution: To evaluate the effect of interest and time, the net cash flow must be multiplied by the single payment present worth factor. An arbitrary interest rate of 10% has been selected and the PWF, obtained by using Equation (4). Its value is listed in Table 7 column 8. Present worth of the net cash flow is obtained by multiplying columns 7 and 8. Column 9 is then added to obtain the total cash flow. If year 0 is ignored, an investment value is obtained for a 10% required rate of return.

The same procedure is used for 15% interest (column 10, but the PWF is not shown) and for 20% interest (column 11).

Discussion. The interest at which the summation of present worth of net cash flow is zero gives the rate of return. In this example, the investment has a rate of return by interpolation of about 15.4%. If this rate offers an acceptable rate of return to the investor, the proposal should be approved; otherwise, it should be rejected.

Another approach would be to obtain an investment value at a given rate of return. This is accomplished by adding the present worth of the net cash flows, but not including the investment cost. In the example, under the 10% given rate of return, $147 700 is obtained as an investment value. This amount, when using money that costs 10%, would be the acceptable value of the investment.

Computer Analysis

Many computer programs are available that incorporate the economic analysis methods described above. These range from simple macros developed for popular spreadsheet applications to more comprehensive, menu-driven computer programs. Commonly used examples of the latter include Building Life-Cycle Cost (BLCC), Life Cycle Cost in Design (LCCID), and PC-ECONPACK.

BLCC was developed by the National Institute of Standards and Technology (NIST) for the U.S. Department of Energy (DOE). The program follows criteria established by the Federal Energy Management Program (FEMP) and the Office of Management and Budget (OMB). It is intended for the evaluation of energy conservation investments in nonmilitary government buildings; however, it is also appropriate for similar evaluations of commercial facilities.

LCCID is an economic analysis program tailored to the needs of the U.S. Department of Defense (DOD). Developed by the U.S. Army Corps of Engineers and the Construction Engineering Research Laboratory (USA-CERL), LCCID uses economic criteria established by FEMP and OMB.

PC-Econpack, developed by the U.S. Army Corps of Engineers for use by the DOD, uses economic criteria established by the OMB. The program performs standardized life-cycle cost calculations such as net present value, equivalent uniform annual cost, SIR, and discounted payback period.

### Table 8 Commonly Used Discount Formulas

<tbody>
<tr>
<td>Single compound-amount (SCA) equation</td>
<td>$F = P \cdot \left(1 + \frac{d}{d_{\text{final}}}</td>
</tr>
</tbody>
</table><p>ight)^n$ |
| Single present value (SPW) equation       | $P = F \cdot \left(1 + \frac{d}{d_{\text{final}}}ight)^n$ |
| Uniform sinking-fund (USF) equation       | $A = F \cdot \frac{d}{\left(1 + \frac{d}{d_{\text{final}}}ight)^n - 1}$ |
| Uniform capital-recovery (UCR) equation   | $A = P \cdot \frac{d}{\left(1 + \frac{d}{d_{\text{final}}}ight)^n - 1}$ |
| Uniform compound-account (UCA) equation   | $F = A \cdot \frac{d}{\left(1 + \frac{d}{d_{\text{final}}}ight)^n - 1}$ |
| Uniform present-value (UPW) equation      | $P = A_0 \cdot \left(1 + \frac{d}{d_{\text{final}}}ight)^n \cdot \frac{\left(1 + \frac{d}{d_{\text{final}}}ight)^n - 1}{\left(1 + \frac{d}{d_{\text{final}}}ight)^n - 1}$ |
| Modified uniform present-value (UPW*) equation | $P = A_0 \cdot \left(1 + \frac{d}{d_{\text{final}}}ight)^n \cdot \frac{\left(1 + \frac{d}{d_{\text{final}}}ight)^n - 1}{\left(1 + \frac{d}{d_{\text{final}}}ight)^n - 1}$ |</p>

where

- $A = $ end-of-period payment (or receipt) in a uniform series of payments (or receipts) over $n$ periods at $d$ interest or discount rate
- $A_0 = $ initial value of a periodic payment (receipt) evaluated at the beginning of the study period
- $A_1 = A_0(1 + c), \text{ for } c = 1, \ldots, n$
- $d = $ interest or discount rate
- $e = $ price escalation rate per period

Source: NIST Handbook 135 (Ruegg).

Note that the USF, UCR, UCA, and UPW equations yield undefined answers when $d = 0$. The correct algebraic forms for this special case would be as follows: USF formula, $A = F \cdot \frac{n}{d}$; UCR formula, $A = F \cdot \frac{n}{d}$; UCA formula, $F = A \cdot n$. The UPW equation also yields an undefined answer when $e = d$. In this case, $P = A_0 n$.

The terms by which the known values are multiplied in these equations are the formulas for the factors found in discount factor tables. Using acronyms to represent the factor formulas, the discounting equations can also be written as $F = P \cdot \text{SCA}$, $P = F \cdot \text{SPW}$, $A = F \cdot \text{USF}$, $A = P \cdot \text{UCR}$, $F = \text{UCA}$, $P = A \cdot \text{UPW}$, and $P = A_0 \cdot \text{UPW}^*$.

Macros developed for common spreadsheet programs generally contain preprogrammed functions for the various life-cycle cost calculations. Although typically not as sophisticated as the menu-driven programs, the macros are easy to install and easy to learn.

Reference Equations

Table 8 lists commonly used discount formulas as addressed by NIST. Refer to NIST Handbook 135 (Ruegg) and Table 2.3 in that handbook for detailed discussions.

### SYMBOLS

- $c = $ cooling system adjustment factor
- $C = $ total annual building HVAC maintenance cost
- $C_e = $ annual operating cost for energy
- $C_{\text{assessed}} = $ assessed system value
- $C_{\text{init}} = $ initial system cost
- $C_{\text{salv}} = $ system salvage value at end of study period
- $C_y = $ uniform annualized mechanical system owning, operating, and maintenance costs
- $\text{CRF} = $ capital recovery factor
- $\text{CRF}(i,n) = $ capital recovery factor for interest rate $i$ and analysis period $n$
- $\text{CRF}(i',n) = $ capital recovery factor for interest rate $i'$ for items other than fuel and analysis period $n$
- $\text{CRF}(i'',n) = $ capital recovery factor for fuel interest rate $i''$ and analysis period $n$
- $\text{CRF}(i_{\text{mort}},n) = $ capital recovery factor for loan or mortgage rate $i_{\text{mort}}$ and analysis period $n$
- $d = $ distribution system adjustment factor
- $D_{de} = $ depreciation during period $d$
1.12

\[ D_{k,SL} \] = depreciation during period \( k \) due to straight line depreciation method

\[ D_{k,SD} \] = depreciation during period \( k \) due to sum-of-digits depreciation method

\( F \) = future value of a sum of money

\( h \) = heating system adjustment factor

\( i \) = compound interest rate per period

\( id \) = discount rate per period

\( i_m \) = market mortgage rate

\( i' \) = effective interest rate for all but fuel

\( i'' \) = effective interest rate for fuel

\( I \) = insurance cost per period

\( ITC \) = investment tax credit

\( j \) = inflation rate per period

\( j_e \) = fuel inflation rate per period

\( k \) = end of period(s) during which replacement(s), repair(s), depreciation, or interest are calculated

\( M \) = maintenance cost per period

\( n \) = number of periods under analysis

\( P \) = present value of a sum of money

\( P_{k} \) = outstanding principle on loan at end of period \( k \)

\( PMT \) = future equal payments

\( PWF \) = present worth factor

\( PWF(i,d,k) \) = present worth factor for discount rate \( i_d \) at end of period \( k \)

\( PWF(i',k) \) = present worth factor for effective interest rate \( i' \) at end of period \( k \)

\( PWF(i,n)_{sgl} \) = single payment present worth factor

\( PWF(i,n)_{ser} \) = present worth factor for a series of future equal payments

\( R_k \) = net replacement, repair, or disposal costs at end of period \( k \)

\( T_{net} \) = net income tax rate

\( T_{prop} \) = property tax rate

\( T_{salv} \) = tax rate applicable to salvage value of system

OWNING and operating cost information for the HVAC system
should be part of the investment plan of a facility. This information
can be used for preparing annual budgets, managing assets,
and selecting design options. Table 1 shows a representative form
that summarizes these costs.

A properly engineered system must also be economical. Eco-
nomics are difficult to assess because of the complexities surround-
ing the effective management of money and the inherent difficulty
of predicting future operating and maintenance expenses. Complex
tax structures and the time value of money can affect the final engi-
eering decision. This does not imply the use of either the cheapest
or the most expensive system; instead, it demands an intelligent
analysis of the financial objectives and requirements of the owner.

Certain tangible and intangible costs or benefits must also be
considered when assessing owning and operating costs. Local codes
may require highly skilled or certified operators for specific types of
equipment. This could be a significant cost over the life of the sys-
tem. Similarly, such intangible items as aesthetics, acoustics, com-
fort, safety, security, flexibility, and environmental impact may be
important to a particular building or facility.

OWNING COSTS

The following elements must be established to calculate annual
owning costs: (1) initial cost, (2) analysis or study period, (3) inter-
est or discount rate, and (4) other periodic costs such as insurance,
property taxes, refurbishment, or disposal fees. Once established,
these elements are coupled with operating costs to develop an eco-
nomic analysis, which may be a simple payback evaluation or an in-
depth analysis such as outlined in the section on Economic Analysis
Techniques.

Initial Cost

Major decisions affecting annual owning and operating costs for
the life of the building must generally be made prior to the comple-
tion of contract drawings and specifications. To achieve the best
performance and economics, comparisons between alternate meth-
ods of solving the engineering problems peculiar to each project
must be made in the early stages of design. Oversimplified esti-
mates can lead to substantial errors in evaluating the system.

A thorough understanding of the installation costs and accessory
requirements must be established. Detailed lists of materials, con-
trols, space and structural requirements, services, installation labor,
and so forth can be prepared to increase the accuracy in preliminary
cost estimates. A reasonable estimate of the capital cost of compo-
nents may be derived from cost records of recent installations of
comparable design or from quotations submitted by manufacturers
and contractors. Table 2 shows a representative checklist for initial
costs.

The preparation of this chapter is assigned to TC 1.8, Owning and Operating
Costs.

</table>
The time frame over which an economic analysis is performed greatly affects the results of the analysis. The analysis period is usually determined by specific analysis objectives, such as length of planned ownership or loan repayment period. The chosen analysis period is often unrelated to the equipment depreciation period or service life, although these factors may be important in the analysis. Table 3 lists representative estimates of the service life of various system components. Service life as used here is the time during which a particular system or component remains in its original service application. Replacement may be for any reason, including, but not limited to, failure, general obsolescence, reduced reliability, excessive maintenance cost, and changed system requirements due to such influences as building characteristics, energy prices, or environmental considerations.

Depreciation periods are usually set by federal, state, or local tax laws, which change periodically. Applicable tax laws should be consulted for more information on depreciation.

### Interest or Discount Rate

Most major economic analyses consider the opportunity cost of borrowing money, inflation, and the time value of money. **Opportunity cost** of money reflects the earnings that investing (or loaning) the money can produce. **Inflation (price escalation)** decreases the purchasing or investing power (value) of future money because it can buy less in the future. **Time value of money** reflects the fact that money received today is more useful than the same amount received a year from now, even with zero inflation, because the money is available earlier for reinvestment.

The cost or value of money must also be considered. When borrowing money, a percentage fee or interest rate must normally be paid. However, the interest rate may not necessarily be the correct cost of money to use in an economic analysis. Another factor, called the **discount rate**, is more commonly used to reflect the true cost of money. Discount rates used for analyses vary depending on individual investment, profit, and other opportunities. Interest rates, in contrast, tend to be more centrally fixed by lending institutions.

To minimize the confusion caused by the vague definition and variable nature of discount rates, the U.S. government has specified particular discount rates that can be used in economic analyses relating to federal expenditures. These discount rates are updated annually (Lippiatt 1994, OMB 1972, NIST) but may not be appropriate for private sector economic analyses.

### Periodic Costs

Regularly or periodically recurring costs include insurance, property taxes, income taxes, rent, refurbishment expenses, disposal fees (e.g., refrigerant recycling costs), occasional major repair costs, and decommissioning expenses.

**Insurance.** Insurance reimburses a property owner for a financial loss so that equipment can be repaired or replaced. Insurance often indemnifies the owner from liability as well. Financial recovery may include replacing income, rents, or profits lost due to property damage.

Some of the principal factors that influence the total annual insurance premium are building size, construction materials, amount and size of mechanical equipment, geographic location, and policy deductibles. Some regulations set minimum required insurance coverages and premiums that may be charged for various forms of insurable property.

**Property Taxes.** Property taxes differ widely and may be collected by one or more agencies, such as state, county, or local governments or special assessment districts. Furthermore, property taxes may apply to both real (land, buildings) and personal (everything else) property. Property taxes are most often calculated as a percentage of assessed value but are also determined in other ways, such as fixed fees, license fees, registration fees, etc. Moreover, definitions of assessed value vary widely in different geographic areas. Tax experts should be consulted for applicable practices in a given area.

**Income Taxes.** Taxes are generally imposed in proportion to net income, after allowance for expenses, depreciation, and numerous other factors. Special tax treatment is often granted to encourage certain investments. Income tax experts can provide up-to-date information on income tax treatments.

### Additional Periodic Costs

Examples of additional costs include changes in regulations that require unscheduled equipment refurbishment to eliminate use of hazardous substances, and disposal costs for such substances. Moreover, at the end of the equipment’s useful life there may be negative salvage value (i.e., removal, disposal, or decommissioning costs).

### OPERATING COSTS

Operating costs are those incurred by the actual operation of the system. They include costs of fuel and electricity, wages, supplies, water, material, and maintenance parts and services. Chapter 30 of the 1997 ASHRAE Handbook—Fundamentals outlines how fuel and electrical requirements are estimated. Note that total energy consumption cannot generally be multiplied by a per unit energy cost to arrive at annual utility cost.

Electrical Energy

Fundamental changes in the purchase of electrical energy are occurring in the United States, which is opening access to and eventually deregulating the electric energy industry. Individual electric utility rates and regulations may vary widely during this period of deregulation. Consequently, electrical energy providers and brokers or marketers need to be contacted to determine the most competitive supplier. Contract conditions need to be reviewed carefully to be sure that the service will suit the purchaser’s requirements.

The total cost of electrical energy is usually a combination of several components: energy consumption charges, fuel adjustment charges, special allowances or other adjustments, and demand charges.

Energy Consumption Charges. Most utility rates have step rate schedules for consumption, and the cost of the last unit of energy consumed may be substantially different from that of the first. The last unit may be cheaper than the first because the fixed costs to the utility may already have been recovered from earlier consumption costs. Alternatively, the last unit of energy may be sold at a higher rate to encourage conservation.

To reflect time-varying operating costs, some utilities charge different rates for consumption according to the time of use and season; typically, costs rise toward the peak period of use. This may justify the cost of shifting the load to off-peak periods.

Fuel Adjustment Charge. Due to substantial variations in fuel prices, electric utilities may apply a fuel adjustment charge to recover costs. This adjustment may not be reflected in the rate schedule. The fuel adjustment is usually a charge per unit of energy and may be positive or negative depending on how much of the actual fuel cost is recovered in the energy consumption rate.

Power plants with multiple generating units that use different fuels typically have the greatest effect on this charge (especially during peak periods, when more expensive units must be brought on-line). Although this fuel adjustment charge can vary monthly, the utility should be able to estimate an average annual or seasonal fuel adjustment for calculations.

Allowances or Adjustments. Special allowances may be available for customers who can receive power at higher voltages or for those who own transformers or similar equipment. Special rates may be available for specific interruptible loads such as domestic water heaters.

Certain facility electrical systems may produce a low power factor, which means that the utility must supply more current on an intermittent basis, thus increasing their costs. These costs may be passed on as an adjustment to the utility bill if the power factor is below a level established by the utility. The power factor is the ratio of active (real) kilowatt power to apparent (reactive) kVA power.

When calculating power bills, utilities should be asked to provide detailed cost estimates for various consumption levels. The final calculation should include any applicable special rates, allowances, taxes, and fuel adjustment charges.

Demand Charges. Electric rates may also have demand charges based on the customer’s peak kilowatt demand. While consumption charges typically cover the utility’s operating costs, demand charges typically cover the owning costs.

Demand charges may be formulated in a variety of ways:

1. Straight charge—cost per kilowatt per month, charged for the peak demand of the month.
2. Excess charge—cost per kilowatt above a base demand (e.g., 50 kW), which may be established each month.
3. Maximum demand (ratchet)—cost per kilowatt for the maximum annual demand, which may be reset only once a year. This established demand may either benefit or penalize the owner.

4. Combination demand—cost per hour of operation of the demand. In addition to a basic demand charge, utilities may include further demand charges as demand-related consumption charges.

The actual demand represents the peak energy use averaged over a specific period, usually 15, 30, or 60 min. Accordingly, high electrical loads of only a few minutes’ duration may never be recorded at the full instantaneous value. Alternatively, peak demand is recorded as the average of several consecutive short periods (i.e., 5 min out of each hour).

The particular method of demand metering and billing is important when load shedding or shifting devices are considered. The portion of the total bill attributed to demand may vary greatly, from 0% to as high as 70%.

Natural Gas

Rates. Conventional natural gas rates are usually a combination of two main components: (1) utility rate for gas consumption and (2) purchased gas adjustment (PGA) charges.

Although gas is usually metered by volume, it is often sold by energy content. The utility rate is the amount the local distribution company charges per unit of energy to deliver the gas to a particular location. This rate may be graduated in steps; the first 10 GJ of gas consumed may not be the same price as the last 10 GJ. The PGA is an adjustment for the cost of the gas per unit of energy to the local utility. It is similar to the electric fuel adjustment charge. The total cost per unit of energy is then the sum of the appropriate utility rate and the PGA, plus taxes and other adjustments.

Interruptible Gas Rates and Contract/Transport Gas. Large industrial plants usually have the ability to burn alternate fuels at the plant and can qualify for special interruptible gas rates. During peak periods of severe cold weather, these customers may be curtailed by the gas utility and may have to switch to propane, fuel oil, or some other backup fuel. The utility rate and PGA are usually considerably cheaper for these interruptible customers than they are for firm rate (noninterruptible) customers.

Deregulation of the natural gas industry allows end users to negotiate for gas supplies on the open market. The customer actually contracts with a gas producer or broker and pays for the gas at the source. Transport fees must be negotiated with the pipeline companies carrying the gas to the customer’s local gas utility. This can be a very complicated administrative process and is usually economically feasible for large gas users only. Some local utilities have special rates for delivering contract gas volumes through their system; others simply charge a standard utility fee (PGA is not applied because the customer has already negotiated with the supplier for the cost of the fuel itself).

When calculating natural gas bills, be sure to determine which utility rate and PGA and/or contract gas price is appropriate for the particular interruptible or firm rate customer. As with electric bills, the final calculation should include any taxes, prompt payment discounts, or other applicable adjustments.

Other Fossil Fuels

Propane, fuel oil, and diesel are examples of other fossil fuels in widespread use. Calculating the cost of these fuels is usually much simpler than calculating typical utility rates. When these fuels are used, other items that can affect owning or operating costs must be considered.

The cost of the fuel itself is usually a simple charge per unit volume or per unit mass. The customer is free to negotiate for the best price. However, trucking or delivery fees must also be included in final calculations. Some customers may have their own transport trucks, while most shop around for the best delivered price. If storage tanks are not customer-owned, rental fees must be considered. Periodic replacement of diesel-type fuels may be necessary due to storage or shelf-life limitations and must also be considered. The final fuel cost calculation should include any of these costs that are applicable, as well as the appropriate taxes.

MAINTENANCE COSTS

The quality of maintenance and maintenance supervision can be a major factor in the energy cost of a building. Chapter 37 covers the maintenance, maintainability, and reliability of systems. Dohrmann and Alereza (1986) obtained maintenance costs and HVAC system information from 342 buildings located in 35 states in the United States. In 1983 U.S. dollars, data collected showed a mean HVAC system maintenance cost of $3.40/m² per year, with a median cost of $2.60/m² per year. The age of the building has a statistically significant but minor effect on HVAC maintenance costs. When analyzed by geographic location, the data revealed that location does not significantly affect maintenance costs. Analysis also indicated that building size is not statistically significant in explaining cost variation.

The type of maintenance program or service agency that the building management contracts for can also have a significant effect on total HVAC maintenance costs. While extensive or thorough routine and preventive maintenance programs cost more to administer, they usually produce benefits such as extended equipment life, improved reliability, and less system downtime.

Estimating Maintenance Costs

Total HVAC maintenance cost for existing buildings with various types of equipment can be estimated using data from Table 4 and the method described below. For equipment types not included in Table 4, or as an alternate estimating method, contact equipment manufacturers or firms that provide maintenance contracts on buildings with similar equipment.

Several important limitations of the data presented here should be noted:

- Only selected data from Table 12 of the report by Dohrmann and Alereza (1986) are presented here.
- Data were collected for office buildings only.

*These results pertain to buildings with older, single-stage absorption chillers. The data from the survey are not sufficient to draw inferences about the costs of HVAC maintenance in buildings equipped with new absorption chillers.
Owning and Operating Costs

- Data measure total HVAC building maintenance costs, not the costs associated with maintaining particular items or individual pieces of equipment.
- The cost data are not intended for use in selecting new HVAC equipment or systems. This information is for equipment and systems already in place and may not be representative of the maintenance costs expected with newer equipment.

This method assumes that the base HVAC system in the building consists of fire-tube boilers for heating equipment, centrifugal chillers for cooling equipment, and VAV distribution systems. The total annual building HVAC maintenance cost for this system is $3.59/m². Adjustment factors from Table 4 are then applied to this base cost to account for building age and variations in type of HVAC equipment as follows:

\[ C = \text{Total annual building HVAC maintenance cost ($/m}^2) \]
\[ = \text{Base system maintenance costs} + (\text{Age adjustment factor} \times \text{age in years} n) + \text{Heating system adjustment factor} h + \text{Cooling system adjustment factor} c + \text{Distribution system adjustment factor} d \]

\[ C = 3.59 + 0.019n + h + c + d \]

Example 1. Estimate the total annual building HVAC maintenance cost per square metre for a building that is 10 years old and has an electric boiler, a reciprocating chiller, and a constant volume distribution system.

\[ C = 3.59 + 0.019(10) - 0.287 - 0.431 + 0.948 \]

\[ C = $4.01/m^2 \text{ in 1983 dollars} \]

This estimate can be adjusted to current dollars by multiplying the maintenance cost estimate by the current Consumer Price Index (CPI) divided by the CPI in July 1983. In July 1983, the CPI was 100.1. Monthly CPI statistics are recorded in Survey of Current Business (U.S. Department of Commerce). This estimating method is limited to one equipment variable per situation. That is, the method can estimate maintenance costs for a building having either a centrifugal chiller or a reciprocating chiller, but not both. Assessing the effects of combining two or more types of equipment within a single category requires a more complex statistical analysis.

IMPACT OF REFRIGERANT PHASEOUTS

The production phaseout of many commonly used refrigerants has presented building owners with decisions regarding the replacement of existing equipment versus retrofit to alternative refrigerant compatibility. Several factors must be considered, including

- **Initial Cost.** New equipment may have a significantly higher installed cost than the retrofit of existing equipment. For example, the retrofit of an existing centrifugal chiller to operate on R-123 may cost 50% of the cost for a new chiller. The cost of rigging a new unit may significantly raise the installed cost, improving the first cost advantage of conversion.
- **Operating Costs.** The overall efficiency of new equipment is often substantially better than that of existing equipment, depending on age, usage, and level of maintenance performed over the life of the existing unit. In addition, conversion to alternative refrigerants may reduce capacity and/or efficiency.
- **Maintenance Costs.** The maintenance cost for new equipment is generally lower than that for existing equipment. The level of retrofit required to attain compatibility often includes replacement or remanufacture of major unit components, which can bring the maintenance and repair costs in line with those expected of new equipment.
- **Equipment Useful Life.** The impact of a retrofit on equipment useful life is determined by the extent of modification required.

The complete remanufacture of a unit should extend the remaining useful life to a level comparable to that of new equipment.

Decisions regarding the replacement of existing equipment or the conversion to alternative refrigerants offer opportunities to improve overall system efficiency. Reduced capacity requirements and the introduction of new technologies such as variable-speed drives and microprocessor-based controllers can substantially reduce annual operating costs and significantly improve a project’s economic benefit.

Information should be gathered to complete Table 4 for each alternative. The techniques described in the section on Economic Analysis Techniques may then be applied to compare the relative values of each option.

OTHER ISSUES

Financing Alternatives

Alternative financing is commonly used in the third-party funding of projects, particularly retrofit projects, and is variously called privatization, third-party financing, energy services, outsourcing, performance contracting, energy savings performance contracting (ESPC), or innovative financing. In these programs, an outside party performs an energy study to identify or quantify attractive energy-saving retrofit projects and then (to varying degrees) designs, builds, and finances the retrofit program on behalf of the owner or host facility. These contracts range in complexity from simple projects such as lighting upgrades to more detailed projects involving all aspects of energy consumption and facility operation.

Alternative financing can be used to accomplish any or all of the following objectives:

- Upgrade capital equipment
- Provide for maintenance of existing facilities
- Speed project implementation
- Conserve or defer capital outlay
- Save energy
- Save money

The benefits of alternative financing are not free. In general terms, these financing agreements transfer the risk of attaining future savings from the owner to the contractor. The contractor will want to be paid for assuming this risk. In addition, these innovative owning and operating cost reduction approaches have important tax consequences that should be investigated on a case-by-case basis.

There are many variations of the basic arrangements and nearly as many terms to define them. Common nomenclature includes guaranteed savings (performance-based), shared savings, paid from savings, guaranteed savings loans, capital leases, municipal leases, and operating leases. For more information, refer to the U.S. Department of Energy’s Web page and to the DOE-sponsored document entitled “International Performance Measurement and Verification Protocol.”

A few examples of alternative financing techniques follow.

Leasing. Among the most common methods of alternative financing is the lease arrangement. In a true lease or lease-purchase arrangement, outside financing provides capital for the construction of a facility. The institution then leases the facility at a fixed monthly charge and assumes responsibility for fuel and personnel costs associated with its operation.

Leasing is also commonly available for individual pieces of equipment or retrofit systems and often includes all design and installation costs. Equipment suppliers or independent third parties retain ownership of new equipment and lease it to the user.

Outsourcing. For a cogeneration, steam, or chilled water plant, either a lease or an energy output contract can be used. An energy output contract enables a private company to provide all the capital
and operating costs, such as personnel and fuel, while the host facility purchases energy from the operating company at a variable monthly charge.

**Energy Savings.** Retrofit projects that lower energy usage create an income stream that can be used to amortize the investment. In paid-from-savings programs, utility payments remain constant over a period of years while the contractor is paid out of savings until the project is amortized. In shared savings programs, the institution receives a percentage of savings over a longer period of years until the project becomes its property. In a guaranteed savings program, the owner retains all the savings and is guaranteed that a certain level of savings will be attained. A portion of the savings is used to amortize the project. In any type of energy savings project, building operation and utilization can have a major impact on the amount of savings actually realized.

**Low-Interest Financing.** In this arrangement, the supplier offers the equipment with special financing arrangements at below-market interest rates.

**Cost Sharing.** Several variations of cost-sharing programs exist. In some instances, two or more groups jointly purchase and share new equipment or facilities, thereby increasing utilization of the equipment and improving the economic benefits for both parties. In other cases, equipment suppliers or independent third parties (such as utilities) who receive an indirect benefit may share part of the equipment or project cost to establish a market foothold for the product.

**District Energy Service**

District energy service is increasingly available to building owners; district heating and cooling eliminates most on-site heating and cooling equipment. A third party produces treated water or steam and pipes it from a central plant directly to the building. The building owner then pays a metered rate for the energy that is used.

A cost comparison of district energy service versus on-site generation requires careful examination of numerous, often site-specific, factors extending beyond demand and energy charges for fuel. District heating and cooling eliminates or minimizes most costs associated with the installation, maintenance, administration, repair and operation of on-site heating and cooling equipment. Specifically, the costs associated with providing water, water treatment, specialized maintenance services, insurance, staff time, space to house on-site equipment, and structural additions needed to support equipment should be considered. Costs associated with auxiliary equipment, which represent 20 to 30% of the total plant annual operating costs, should also be included.

Any analysis that fails to include all the associated costs does not give a clear picture of the building owner’s heating and cooling alternatives. In addition to the tangible costs, there are a number of other factors that should be considered, such as convenience, risk, environmental issues, flexibility, and backup.

**On-Site Electric Generation**

On-site electric generation covers a broad range of applications, from emergency backup to power for a single piece of equipment to an on-site power plant supplying 100% of the facility’s electrical power needs. A variety of system types and fuel sources are available, but the economic principles described in this chapter apply equally to all of them. Other chapters (e.g., Chapter 71 Cogeneration Systems and Engine and Turbine Drives, and Chapter 33 Solar Energy Equipment, of the 2000 ASHRAE Handbook—Systems and Equipment) may be helpful in describing system details.

An economic study of on-site electrical power generation should include consideration of all owning, operating, and maintenance costs. Typically, on-site generation is capital intensive (i.e., high first cost) and therefore requires a high utilization rate to produce savings adequate to support the investment. High utilization rates mean high run time, which requires planned maintenance and careful operation.

Owning costs include any related systems required to adapt the building to on-site power generation. Additional equipment is required if the building will also utilize purchased power from a utility. The costs associated with shared equipment should also be considered. For example, if the power source for the generator is a steam turbine, and a hot water boiler would otherwise be used to meet the HVAC demand, the boiler would need to be a larger, high-pressure steam boiler with a heat exchanger to meet the hot water needs. In addition to higher first cost, operation and maintenance costs for the boiler are increased due to the increased operating hours.

Consideration must also be given to the costs of an initial investment and ongoing inventory of spare parts. Most equipment manufacturers provide a recommended spare parts list as well as recommended maintenance schedules. Typical maintenance schedules consist of daily, weekly, and monthly routine maintenance and periodic major overhauls. Major overhaul frequency depends on equipment utilization and requires taking the equipment off-line. The cost of either lost building utilization or the provision of electricity from an alternate source during the shutdown should be considered.

**ECONOMIC ANALYSIS TECHNIQUES**

Analysis of overall owning and operating costs and comparisons of alternatives require an understanding of the cost of lost opportunities, inflation, and the time value of money. This process of economic analysis of alternatives falls into two general categories: simple payback analysis and detailed economic analyses (life-cycle cost analyses).

A simple payback analysis reveals options that have short versus long paybacks. Often, however, alternatives are similar and have similar paybacks. For a more accurate comparison, a more comprehensive economic analysis is warranted. Many times it is appropriate to have both a simple payback analysis and a detailed economic analysis. The simple payback analysis shows which options should not be considered further, and the detailed economic analysis determines which of the viable options are the strongest. The strongest options can be accepted or further analyzed if they include competing alternatives.

**Simple Payback**

In the simple payback technique, a projection of the revenue stream, cost savings, and other factors is estimated and compared to the initial capital outlay. This simple technique ignores the cost of borrowing money (interest) and lost opportunity costs. It also ignores inflation and the time value of money.

**Example 2.** Equipment item 1 costs $10 000 and will save $2000 per year in operating costs; equipment item 2 costs $12 000 and saves $3000 per year. Which item has the best simple payback?

- Item 1 — $10 000/($2000/yr) = 5 year simple payback
- Item 2 — $12 000/($3000/yr) = 4 year simple payback

Because the analysis of equipment for the duration of its realistic life can produce a much different result, the simple payback technique should be used with caution.

**More Sophisticated Economic Analysis Methods**

This section describes a few of the detailed economic techniques available. These techniques are used to examine all costs and incomes to be incurred over the analysis period (1) in terms of their present value (i.e., today’s or initial year’s value, also called constant value); (2) in terms of equal periodic costs or payments...
Owning and Operating Costs

(uniform annualized costs); or (3) in terms of periodic cash flows (e.g., monthly or annual cash flows). Each method provides a slightly different insight. The present value method allows easy comparison of alternatives over the analysis period chosen. The uniform annualized costs method allows comparison of average annual costs of different options. The cash flow method allows comparison of actual cash flows rather than average cash flows; it can identify periods of overall positive and negative cash flow, which is helpful for cash management.

Economic analysis should consider details of both positive and negative costs over the analysis period, such as varying inflation rates, capital and interest costs, salvage costs, replacement costs, interest deductions, depreciation allowances, taxes, tax credits, mortgage payments, and all other costs associated with a particular system. See the section on Symbols for definitions of variables.

**Present Value (Present Worth) Analysis.** All sophisticated economic analysis methods use the basic principles of present value analysis to account for the time value of money. Therefore, a good understanding of these principles is important.

The total present value (present worth) for any analysis is determined by summing the present worths of all individual items under consideration, both future single payment items and series of equal future payments. The scenario with the highest present value is the preferred alternative.

**Single Payment Present Value Analysis.** The cost or value of money is a function of the available interest rate and inflation rate. The future value of a present sum of money \( F \) over \( n \) periods with compound interest rate \( i \) per period is

\[
F = P(1+i)^n
\]

Conversely, the present value or present worth \( P \) of a future sum of money \( F \) is given by

\[
P = F/(1+i)^n
\]

or

\[
P = F \times PWF(i,n)_{sgl}
\]

where the single payment present worth factor \( PWF(i,n)_{sgl} \) is defined as

\[
PWF(i,n)_{sgl} = 1/(1+i)^n
\]

**Example 3.** Calculate the value in 10 years at 10% per year interest of a system presently valued at $10,000.

\[
F = P(1+i)^n = 10,000(1+0.1)^{10} = 25,937.42
\]

**Example 4.** Using the present worth factor for 10% per year interest and an analysis period of 10 years, calculate the present value of a future sum of money valued at $10,000. (Stated another way, determine what sum of money must be invested today at 10% per year interest to yield $10,000 10 years from now.)

\[
P = F \times PWF(i,n)_{sgl}
\]

\[
P = 10,000 \times 1/(1+0.1)^{10} = 3855.43
\]

**Series of Equal Payments.** The present worth factor for a series of future equal payments (e.g., operating costs) is given by

\[
PWF(i,n)_{ser} = \left( \frac{1+i}{i} \right)^n - 1
\]

The present value \( P \) of those future equal payments (PMT) is then the product of the present worth factor and the payment (i.e., \( P = PWF(i,n)_{sgl} \times PMT \)).

The future equal payments to repay a present value of money is determined by the capital recovery factor (CRF), which is the reciprocal of the present worth factor for a series of equal payments:

\[
CRF = PMT/P
\]

\[
CRF(i,n) = \frac{i(1+i)^n}{(1+i)^n - 1} = \frac{i}{1 - (1+i)^{-n}}
\]

The CRF is often used to describe periodic uniform mortgage or loan payments. Table 5 gives abbreviated annual CRF values for several values of analysis period \( n \) and annual interest rate \( i \). Some of the values in Table 5 are plotted versus time in Figure 1.

Note that when payment periods other than annual are to be studied, the interest rate must be expressed per appropriate period. For example, if monthly payments or return on investment are being analyzed, then interest must be expressed per month, not per year, and \( n \) must be expressed in months, not years.

**Example 5.** Determine the present value of an annual operating cost of $1000 per year over 10 years, assuming 10% per year interest rate.

\[
PWF(i,n)_{ser} = [(1+0.1)^{10} - 1]/[0.1(1+0.1)^{10}] = 6.14
\]

\[
P = 1000(6.14) = 6140
\]
a commodity over time and is separate from the time value of money. Inflation must often be accounted for in an economic evaluation. One way to account for inflation is to substitute effective interest rates that account for inflation into the equations given in this chapter.

The effective interest rate \( i' \), sometimes called the real rate, accounts for inflation rate \( j \) and interest rate \( i \) or discount rate \( i_d \); it can be expressed as follows (Kreith and Kreider 1978, Kreider and Kreith 1982):

\[
i' = \frac{1 + i}{1 + j} - 1 = \frac{i}{1 + j}
\]

Different effective interest rates can be applied to individual components of cost. Projections for future fuel and energy prices are available in the *Annual Supplement to NIST Handbook 135* (Lippitt 1994; NIST).

**Example 8.** Determine the present worth \( P \) of an annual operating cost of $1000 over 10 years, given a discount rate of 10% per year and an inflation rate of 5% per year.

\[
i' = \frac{(0.1 - 0.05)}{(1 + 0.05)} = 0.0476
\]

\[
PWF(i',n)_{ef} = \frac{(1 + 0.0476)^{10} - 1}{0.0476(1 + 0.0476)^{10}} = 7.813
\]

\[
P = 1000(7.813) = 7813
\]

The following are three commonly used methods of present value analysis that include life-cycle cost factors (life of equipment, analysis period, discount rate, energy escalation rates, maintenance cost, etc., as shown in Table 1). These comparison techniques rely on the same assumptions and economic analysis theories but display the results in different forms. They also use the same definition of each term. All can be displayed as a single calculation or as a cash flow table using a series of calculations for each year of the analysis period.

**Savings-to-Investment Ratio.** Most large military sponsored work and many other U.S. government entities require a savings-to-investment-ratio (SIR) method. This method produces a ratio that defines the relative economic strength of each option. The higher the ratio, the better the economic strength. If the ratio is less than 1, the measure does not pay for itself within the analysis period. The escalated savings on an annual and a special (nonannual) basis is calculated and discounted. The costs are shown on an annual and special basis for each year over the life of the system or option. The savings and investments are both discounted separately on an annual basis. The results in different forms. They also use the same definition of each term. All can be displayed as a single calculation or as a cash flow table using a series of calculations for each year of the analysis period.

**Life-Cycle Costs.** This method of analysis compares the cumulative total of implementation, operating, and maintenance costs. The total costs are discounted over the life of the system or over the loan repayment period. The costs and investments are both discounted and displayed as a total combined life-cycle cost at the end of the analysis period. The options are compared to determine which has the lowest total cost over the anticipated project life.

**Internal Rate of Return.** The internal rate of return (IRR) method calculates a return on investment over the defined analysis period. The annual savings and costs are not discounted, and a cash flow is established for each year of the analysis period, to be used with an initial cost (or value of the loan). Annual recurring and special (nonannual) savings and costs can be used. The cash flow is then discounted until a calculated discount rate is found that yields a net present value of zero. This method gives a basic comparison of return on investments. This method assumes savings are reinvested.
Owning and Operating Costs

at the same calculated rate of return. Therefore, the calculated rates of return can be overstated compared to the actual rates of return.

Another version of this is the modified or adjusted internal rate of return (MIRR or AIRR). In this version, reinvested savings are assumed to have a given rate of return on investment, and the financed moneys a given interest rate. The cash flow is then discounted until a calculated discount rate is found that yields a net present value of zero. This method gives a more realistic indication of expected return on investment, but the difference between alternatives can be small.

Uniform Annualized Costs Method. It is sometimes useful to project a uniform periodic (e.g., average annual) cost over the analysis period. The basic procedure for determining uniform annualized costs is to first determine the present worth of all costs and then apply the capital recovery factor to determine equal payments over the analysis period.

Uniform annualized mechanical system owning, operating, and maintenance costs can be expressed, for example, as

\[ C_y = \text{capital and interest} + \text{salvage value} - \text{replacements} - \text{operating energy} - \text{property tax} - \text{maintenance} - \text{insurance} + \text{interest tax deduction} + \text{depreciation} \]

where

- capital and interest = \( (C_{y,\text{init}} - \text{ITC}) \cdot \text{CRF}(i',n) \)
- salvage value = \( C_{y,\text{salv}} \cdot \text{PWF}(i',n) \cdot (1 - T_{\text{salv}}) \)
- replacements or disposals = \( \sum_{k=1}^{n} \left[ R_k \cdot \text{PWF}(i',k) \cdot \text{CRF}(i',n) \cdot (1 - T_{\text{inc}}) \right] \)
- operating energy = \( C_y \cdot \text{CRF}(i',n) \cdot (1 - T_{\text{inc}}) \)
- property tax = \( C_{y,\text{assess}} \cdot T_{\text{prop}} \cdot (1 - T_{\text{inc}}) \)
- maintenance = \( M(1 - T_{\text{inc}}) \)
- insurance = \( I(1 - T_{\text{inc}}) \)
- interest tax deduction = \( T_{\text{inc}} \sum_{k=1}^{n} \left[ i_m P_{k-1} \cdot \text{PWF}(i',k) \cdot \text{CRF}(i',n) \right] \)
- depreciation = \( T_{\text{inc}} \sum_{k=1}^{n} \left[ D_k \cdot \text{PWF}(i',k) \cdot \text{CRF}(i',n) \right] \)

The outstanding principle \( P_k \) during year \( k \) at market mortgage rate \( i_m \) is given by

\[
P_k = (C_{y,\text{init}} - \text{ITC}) \left[ (1 + i_m)^{k-1} + \frac{(1 + i_m)^{k-1} - 1}{(1 + i_m)^n - 1} \right] \quad (10)
\]

Note: \( P_k \) is in current dollars and must, therefore, be discounted by the discount rate \( i' \), not \( i' \).

Likewise, the summation term for interest deduction can be expressed as

\[
\sum_{k=1}^{n} \left[ i_m P_k / (1 + i_m)^k \right] = (C_{y,\text{init}} - \text{ITC}) \times \left[ \frac{\text{CRF}(i_m,n)}{\text{CRF}(i',n)} + \frac{1}{(1 + i_m) \cdot \text{CRF}(i'd - i_m)/(1 + i_m) \cdot n} \right] \quad (11)
\]

If \( i_d = i_m \),

\[
\sum_{k=1}^{n} \left[ i_m P_k / (1 + i_m)^k \right] = (C_{y,\text{init}} - \text{ITC}) \times \left[ 1 + \frac{n}{1 + i_m} \cdot \text{CRF}(i_m,n) \right] \quad (12)
\]

Depreciation terms commonly used include depreciation calculated by the straight line depreciation method, which is

\[
D_{k,SL} = \frac{(C_{y,\text{init}} - C_{y,\text{salv}})}{n} \quad (13)
\]

and the sum-of-digits depreciation method:

\[
D_{k,SD} = \frac{(C_{y,\text{init}} - C_{y,\text{salv}}) \cdot [2(n - k + 1)] / (n + 1)}{n + 1} \quad (14)
\]

Riggs (1977) and Grant et al. (1982) present further information on advanced depreciation methods. Certified accountants may also be consulted for information regarding accelerated methods allowed for tax purposes. The following example illustrates the use of the uniform annualized cost method. Additional examples are presented by Haberl (1993).

Example 9. Calculate the annualized system cost using constant dollars for a $10,000 system considering the following factors: a 5-year life, a salvage value of $1000 at the end of the 5 years, no investment tax credits, a $500 replacement in year 3, a discount rate \( i_d \) of 10%, a general inflation rate \( j \) of 5%, a fuel inflation rate \( i_f \) of 8%, a market mortgage rate \( i_m \) of 10%, an annual operating cost for energy of $500, a $100 annual maintenance cost, a $50 annual insurance cost, straight line depreciation, an income tax rate of 50%, a property tax rate of 1% of assessed value, an assessed system value equal to 40% of the initial system value, and a salvage tax rate of 50%.

Effective interest rate \( i' \) for all but fuel

\[
i' = (i_d - j) / (1 + j) = (0.10 - 0.05) / (1 + 0.05) = 0.047619
\]

Effective interest rate \( i' \) for fuel

\[
i' = (i_d - j) / (1 + j) = (0.10 - 0.08) / (1 + 0.08) = 0.018519
\]

Capital recovery factor \( \text{CRF}(i',n) \) for items other than fuel

\[
\text{CRF}(i',n) = i'/[(1 - (1 + i')^{-n})] = 0.047619 / [1 - (1.047619)^{-5}] = 0.229457
\]

Capital recovery factor \( \text{CRF}(i',n) \) for fuel

\[
\text{CRF}(i'',n) = i''/[(1 - (1 + i'')^{-n})] = 0.018519 / [1 - (1.018519)^{-5}] = 0.211247
\]

Capital recovery factor \( \text{CRF}(i_m,n) \) for loan or mortgage

\[
\text{CRF}(i_m,n) = i_m/[(1 - (1 + i_m)^{-n}] = 0.10 / [1 - (1.10)^{-5}] = 0.263797
\]

Loan payment = $10 000(0.263797) = $2637.97

Present worth factor \( \text{PWF}(i', \text{years 1 to 5}) \)

\[
\text{PWF}(i',1) = 1 / (1 + i') = 0.909091
\]

\[
\text{PWF}(i',2) = 1 / (1 + i')^2 = 0.826446
\]

\[
\text{PWF}(i',3) = 1 / (1 + i')^3 = 0.751315
\]

\[
\text{PWF}(i',4) = 1 / (1 + i')^4 = 0.683013
\]

\[
\text{PWF}(i',5) = 1 / (1 + i')^5 = 0.620921
\]

Present worth factor \( \text{PWF}(i', \text{years 1 to 5}) \)

\[
\text{PWF}(i',1) = 1 / (1 + i') = 0.954545
\]

\[
\text{PWF}(i',2) = 1 / (1 + i')^2 = 0.911157
\]

\[
\text{PWF}(i',3) = 1 / (1 + i')^3 = 0.869741
\]

\[
\text{PWF}(i',4) = 1 / (1 + i')^4 = 0.830207
\]

\[
\text{PWF}(i',5) = 1 / (1 + i')^5 = 0.792471
\]
1.10

Capital and interest
\[
(C_{s,\text{init}} - ITC) \cdot \text{CRF}(i'rn) = (\$10,000 - \$0) \times 0.229457 = \$2294.57
\]

Salvage value
\[
C_{s,\text{salv}} \cdot \text{PWF}(i'rn) \cdot \text{CRF}(i'rn)(1 - T_{\text{salv}})
\]
\[
= \$1000 \times 0.792471 \times 0.229457 \times 0.5 = \$90.92
\]

Replacements
\[
\sum_{k=1}^{n} [R_k \cdot \text{PWF}(i'kn) \cdot \text{CRF}(i'rn)(1 - T_{\text{inc}})]
\]
\[
= \$500 \times 0.869741 \times 0.229457 \times 0.5 = \$49.89
\]

Operating energy
\[
\text{CRF}(i'rn)/\text{CRF}(i'rn)(1 - T_{\text{inc}})
\]
\[
= \$500[0.229457/0.211247] \times 0.5 = \$271.55
\]

Property tax
\[
C_{s,\text{assess}} \cdot T_{\text{prey}}(1 - T_{\text{inc}}) = \$10,000 \times 0.40 \times 0.01 \times 0.5 = \$20.00
\]

Maintenance
\[
M(1 - T_{\text{inc}}) = \$100(1 - 0.5) = \$50.00
\]

Insurance
\[
I(1 - T_{\text{inc}}) = \$50(1 - 0.5) = \$25.00
\]

Interest deduction
\[
T_{\text{inc}} \sum_{k=1}^{n} [i_{k} \cdot P_{k-1} \cdot \text{PWF}(i_{m}k) \cdot \text{CRF}(i'rn)] = \ldots \text{see Table 6}
\]

Table 6 summarizes the interest and principle payments for this example. Annual payments are the product of the initial system cost

\[C_{\text{init}}\] and the capital recovery factor CRF(i'rn). Also, \textbf{Equation (10)} can be used to calculate total discounted interest deduction directly.

Next, apply the capital recovery factor CRF(i'rn) and tax rate T_{\text{inc}} to the total of the discounted interest sum.

\[
\$2554.66 \times \text{CRF}(i'rn)/T_{\text{inc}} = \$2554.66 \times 0.229457 \times 0.5 = \$293.09
\]

Depreciation
\[
T_{\text{inc}} \sum_{k=1}^{n} [D_{k,\text{SL}} \cdot \text{PWF}(i_{m}k)] \cdot \text{CRF}(i'rn) \ldots
\]

Use the straight line depreciation method to calculate depreciation:

\[D_{k,\text{SL}} = (C_{s,\text{init}} - C_{s,\text{salv}})/n = (\$10,000 - \$1000)/5 = \$1800.00
\]

Next, discount the depreciation.

<table>

</tbody>
</table>

Total \$6823.42

Finally, the capital recovery factor and tax are applied.

\$6823.42 \times \text{CRF}(i'rn)/T_{\text{inc}} = \$6823.42 \times 0.229457 \times 0.5 = \$782.84

U.S. tax code recommends estimating the salvage value prior to depreciating. Then depreciation is claimed as the difference between the initial and salvage value, which is the way depreciation is treated in this example. The more common practice is to initially claim zero sal-

where

- $ A_0 = \text{initial value of a periodic payment (receipt) evaluated at the beginning of the study period} $  
- $ A_0 = \frac{d}{1 + e} $, for $ t = 1, \ldots, n $  
- $ d = \text{interest or discount rate} $  
- $ e = \text{price escalation rate per period} $  

Source: NIST Handbook 135 (Ruegg).

$ ^{a} $Note that the USF, UCR, UCA, and UPW equations yield undefined answers when $ d = 0 $. The correct algebraic forms for this special case would be as follows: USF formula, $ A = F; $ UCR formula, $ A = P; $ UCA formula, $ F = A \cdot n $. The UPW equation also yields an undefined answer when $ e = d $. In this case, $ P = A_0 \cdot n $.  

$ ^{b} $The terms by which the known values are multiplied in these equations are the formulas for the factors found in discount factor tables. Using acronyms to represent the factor formulas, the discounting equations can also be written as $ F = P \cdot \text{USF}, P = F \cdot \text{SPW}, A = F \cdot \text{USF}, A = P \cdot \text{UCR}, F = \text{UCA}, P = A \cdot \text{UPW}, $ and $ P = A_0 \cdot \text{UPW} $.  

Macros developed for common spreadsheet programs generally contain preprogrammed functions for the various life-cycle cost calculations. Although typically not as sophisticated as the menu-driven programs, the macros are easy to install and easy to learn.

The system that controls the environment in a building is a dynamic entity that changes with time and use, and it must be rebalanced accordingly. The designer must consider initial and supplementary testing and balancing requirements for commissioning. Complete and accurate operating and maintenance instructions that include intent of design and how to test, adjust, and balance the building systems are essential. Building operating personnel must be well trained, or qualified operating service organizations must be employed to ensure optimum comfort, proper process operations, and economy of operation.

This chapter does not suggest which groups or individuals should perform the functions of a complete testing, adjusting, and balancing procedure. However, the procedure must produce repeatable results that meet the intent of the designer and the requirements of the owner. Overall, one source must be responsible for testing, adjusting, and balancing all systems. As part of this responsibility, the testing organization should check all equipment under field conditions to ensure compliance.

Testing and balancing should be repeated as the systems are renovated and changed. The testing of boilers and other pressure vessels for compliance with safety codes is not the primary function of the testing and balancing firm; rather it is to verify and adjust operating personnel must be trained, or qualified operating service organizations must be employed to ensure optimum comfort, proper process operations, and economy of operation.

Termology

Testing, adjusting, and balancing is the process of checking and adjusting all the environmental systems in a building to produce the design objectives. This process includes (1) balancing air and water distribution systems, (2) adjusting the total system to provide design quantities, (3) electrical measurement, (4) establishing quantitative performance of all equipment, (5) verifying automatic controls, and (6) sound and vibration measurement. These procedures are accomplished by checking installations for conformity to design, measuring and establishing the fluid quantities of the system as required to meet design specifications, and recording and reporting the results.

The following definitions are used in this chapter. Refer to ASHRAE Terminology of Heating, Ventilation, Air Conditioning, and Refrigeration (1991) for additional definitions.

Test. Determine quantitative performance of equipment.

Balance. Proportion flows within the distribution system (submains, branches, and terminals) according to specified design quantities.

Adjust. Regulate the specified fluid flow rate and air patterns at the terminal equipment (e.g., reduce fan speed, adjust a damper).

Procedure. An approach and execution of a sequence of work operations to yield repeatable results.

The preparation of this chapter is assigned to TC 9.7, Testing and Balancing.

Report forms. Test data sheets arranged in logical order for submission and review. The data sheets should also form the permanent record to be used as the basis for any future testing, adjusting, and balancing.

Terminal. A point where the controlled medium (fluid or energy) enters or leaves the distribution system. In air systems, these may be variable air or constant volume boxes, registers, grilles, diffusers, louvers, and hoods. In water systems, these may be heat transfer coils, fan coil units, convectors, or finned-tube radiation or radiant panels.

General Criteria

Effective and efficient testing, adjusting, and balancing require a systematic, thoroughly planned procedure implemented by experienced and qualified staff. All activities, including organization, calibration of instruments, and execution of the actual work, should be scheduled. Air-side must be coordinated with water-side work. Preparatory work includes planning and scheduling all procedures, collecting necessary data (including all change orders), reviewing data, studying the system to be worked on, preparing forms, and making preliminary field inspections.

Leakage can significantly reduce performance; therefore ducts must be designed, constructed, and installed to minimize and control air leakage. During construction, all duct systems should be sealed and tested for air leakage; and water, steam, and pneumatic piping should be tested for leakage.

Design Considerations

Testing, adjusting, and balancing begin as design functions, with most of the devices required for adjustments being integral parts of the design and installation. To ensure that proper balance can be achieved, the engineer should show and specify a sufficient number of dampers, valves, flow measuring locations, and flow balancing devices; these must be properly located in required straight lengths of pipe or duct for accurate measurement. The testing procedure depends on system characteristics and layout. The interaction between individual terminals varies with pressures, flow requirements, and control devices.

The design engineer should specify balancing tolerances. Suggested tolerances are ±10% for individual terminals and branches in noncritical applications and ±5% for main ducts. For critical applications where differential pressures must be maintained, the following tolerances are suggested:

AIR VOLUMETRIC MEASUREMENT METHODS

General
The pitot-tube traverse is the generally accepted method of measuring airflow in ducts. Other methods of measuring airflow at individual terminals are described by the terminal manufacturers. The primary objective is to establish repeatable measurement procedures that correlate with the pitot-tube traverse.

Laboratory tests, data, and techniques prescribed by equipment and air terminal manufacturers must be reviewed and checked for accuracy, applicability, and repeatability of results. Conversion factors that correlate field data with laboratory results must be developed to predict the equipment’s actual field performance.

Air Devices
Generally, loss coefficients given by air diffuser manufacturers should be checked for accuracy by field measurement and by comparing actual flow measured by pitot-tube traverse to actual measured velocity. Air diffuser manufacturers usually base their volumetric test measurements on a deflecting vane anemometer. The velocity is multiplied by an empirical effective area to obtain the air diffuser’s delivery. Accurate results are obtained by measuring at the vena contracta with the probe of the deflecting vane anemometer.

The methods advocated for measuring the airflow of troffer-type terminals are similar to the methods described for air diffusers. The capture hood is frequently used to measure device airflows, primarily of diffusers and slots. Loss coefficients should be established for hood measurements with varying flow and deflection settings. If the air does not fill the measurement grid, the readings will require a correction factor (similar to the loss coefficient).

Rotating vane anemometers are commonly used to measure airflow from sidewall grilles. Effective areas (loss coefficients) should be established with the face dampers fully open and deflection set uniformly on all grilles. Correction factors are required when measuring airflow in open ducts, i.e., damper openings and fume hoods (Sauer and Howell 1990). All airflow measuring instruments should be field verified by running pitot-tube traverses to establish correction and/or density factors.

Duct Flow
Most procedures for testing, adjusting, and balancing air-handling systems rely on measuring volumes in the ducts rather than at the terminals. These measurements are more reliable than those obtained at the terminals, which are based on manufacturer’s data. In such procedures, terminal measurements are relied on only for proportionally balancing the distribution within a space or zone.

The preferred method of duct volumetric flow measurement is the pitot-tube traverse average. Care should be taken to obtain the maximum straight run before and after the traverse station. To obtain the best duct velocity profile, measuring points should be located as shown in Chapter 14 of the 1997 ASHRAE Handbook—Fundamentals and ASHRAE Standard 111. Where factory-fabricated volume measuring stations are used, the measurements should be checked against a pitot-tube traverse.

The power input to a fan’s driver should be used only as a guide to indicate its delivery. It may be used to verify performance determined by a reliable method (e.g., pitot-tube traverse of system’s main) considering system effects that may be present. The flow rate from some fans is not proportional to the power needed to drive them. In some cases, as with forward-curved blade fans, the same power is required for two or more flow rates. The backward-curved blade centrifugal fan is the only type with suitable characteristics, i.e., flow rate that varies directly with the power input. If an installation has an inadequate straight length of ductwork or no ductwork to allow a pitot-tube traverse, a procedure prescribed by Sauer and Howell (1990) can be followed. In this procedure a vane anemometer is used to read air velocities at multiple points across the face of a coil to determine a loss coefficient.

Mixture Plenums
Approach conditions are often so unfavorable that the air quantities comprising a mixture (e.g., outdoor air and return air) cannot be determined accurately by volumetric measurements. In such cases, the temperature of the mixture indicates the balance (proportions) between the component airstreams. Temperatures must be measured carefully to account for stratification of the air, and the difference between the outside and return air temperatures must be greater than 10 K. The temperature of the mixture can be calculated from Equation (1) as follows:

\[
Q_t \cdot t_m = Q_o \cdot t_o + Q_r \cdot t_r
\]

where

- \(Q_t\) = total measured air quantity, %
- \(Q_o\) = outside air quantity, %
- \(Q_r\) = return air quantity, %
- \(t_m\) = temperature of outside and return mixture, °C
- \(t_o\) = outdoor temperature, °C
- \(t_r\) = return temperature, °C

Pressure Measurement
The air pressures measured include barometric pressure, static pressure, velocity pressure, total pressure, and differential pressure. Measurement for field evaluation of air-handling performance, pressure should be measured as recommended in ASHRAE Standard 111 and analyzed together with the manufacturers’ fan curves and system effect as predicted by applying methods in AMCA Standard 210. When measured in the field, pressure readings, air quantity, and power input often do not correlate with the manufacturers’ certified performance curves unless proper correction is made.

Pressure drops through equipment such as coils, dampers, or filters should not be used to measure airflow. Pressure is an acceptable means of establishing flow volumes only where it is required by, and performed in accordance with, the manufacturer certifying the equipment.

Stratification
Normal design minimizes conditions causing air turbulence in order to produce the least friction, resistance, and consequent pressure loss. Under certain conditions, however, air turbulence is desirable and necessary. For example, two airstreams of different temperatures can stratify in smooth, uninterrupted flow conditions. In this situation, mixing should be promoted in the design. The return and outside airstreams at the inlet side of the air-handling unit tend to stratify where enlargement of the inlet plenum or casing size decreases the air velocity. Without a deliberate effort to mix the two airstreams (i.e., in cold climates, placing the outdoor air entry at the top of the plenum and the return air at the bottom of the plenum to allow natural mixing), stratification can exist and be carried throughout the system (e.g., filter, coils, eliminators, fans, and ducts). Stratification can cause damage by freezing coils and rupturing tubes. It can also affect temperature control in plenums, spaces, or both.

Stratification can further be reduced by adding vanes to break up and mix the two airstreams. No solution to stratification problems is guaranteed; each condition must be evaluated by field measurements and experimentation.
Testing, Adjusting, and Balancing

**BALANCING PROCEDURES FOR AIR DISTRIBUTION**

General procedures for testing and balancing are described here, although no one established procedure is applicable to all systems. The bibliography lists sources of additional information.

**Instruments for Testing and Balancing**

The minimum instruments necessary for air balance are:

- Manometer calibrated in 1 Pa divisions
- Combination inclined and vertical manometer (0 to 2.5 kPa)
- Pitot tubes in various lengths, as required
- Tachometer (direct contact, self-timing type) or strobe light
- Clamp-on ammeter with voltage scales (rms type)
- Rotating vane anemometer
- Flow hood
- Dial thermometers (50 mm diameter minimum and 0.5 K graduations minimum) and glass stem thermometers (0.5 K graduations minimum)
- Sound level meter with octave band filter set, calibrator, and microphone
- Vibration analyzer capable of measuring displacement velocity and acceleration
- Water flowmeters (0 to 12 kPa and 0 to 100 kPa ranges)
- Compound gage
- Test gages (700 kPa and 2000 kPa)
- Sling psychrometer
- Etched stem thermometer (0 to 50°C in 0.05 K increments)
- Compound gage
- Test gages (700 kPa and 2000 kPa)
- Sling psychrometer
- Etched stem thermometer (0 to 50°C in 0.05 K increments)
- Hygrometers
- Digital thermometers, relative humidity and dew-point instruments

Instruments must be calibrated periodically to verify their accuracy and repeatability prior to use in the field.

**Preliminary Procedure for Air Balancing**

Before balancing the system, the following steps should be performed:

1. Obtain as-built design drawings and specifications, and become thoroughly acquainted with the design intent.
2. Obtain copies of approved shop drawings of all air-handling equipment, outlets (supply, return, and exhaust), and temperature control diagrams including performance curves. Compare design requirements with shop drawing capacities.
3. Compare design to installed equipment and field installation.
4. Walk the system from the air-handling equipment to terminal units to determine variations of installation from design.
5. Check dampers (both volume and fire) for correct and locked position and temperature control for completeness of installation before starting fans.
6. Prepare report test sheets for both fans and outlets. Obtain manufacturer’s outlet factors and recommended test procedure. A summation of required outlet volumes permits a cross-checking with required fan volumes.
7. Determine the best locations in the main and branch ductwork for the most accurate duct traverses.
8. Place all outlet dampers in the full open position.
9. Prepare schematic diagrams of system as-built ductwork and piping layouts to facilitate reporting.
10. Check filters for cleanliness and proper installation (no air bypass). If specifications require, establish procedure to simulate dirty filters.
11. For variable volume air systems, develop a plan to simulate diversity.

**Equipment and System Check**

1. All fans (supply, return, and exhaust) must be operating before checking the following items:
   - (a) Motor amperage and voltage to guard against overload.
   - (b) Fan rotation.
   - (c) Operability of static pressure limit switch.
   - (d) Automatic dampers for proper position.
   - (e) Air and water controls operating to deliver required temperatures.
   - (f) Air leaks in the casing and in the scarfing around the coils and filter frames must be sealed. Note points where piping enters the casing to ensure that escutcheons are right. Do not rely on pipe insulation to seal these openings because the insulation may shrink. In prefabricated units, check that all panel-fastening holes are filled to prevent whistling.

2. Traverse the main supply ductwork whenever possible. All main branches should also be traversed where duct arrangement permits. Selection of traverse points and method of traverse should be as follows:
   - (a) Traverse each main or branch after the longest possible straight run for the duct involved.
   - (b) For test hole spacing, refer to Chapter 14 of the 1997 ASHRAE Handbook—Fundamentals.
   - (c) Traverse using a pitot tube and manometer where velocities are over 3 m/s. Below this velocity, use either a micromanometer and pitot tube or a recently calibrated thermal anemometer.
   - (d) Note temperature and barometric pressure to determine if they need to be corrected for standard air quantity. Corrections are normally insignificant below 600-m elevation; however, where accurate results are desirable, corrections are justified.
   - (e) After establishing the total air being delivered, adjust the fan speed to obtain the design airflow, if necessary. Check power and speed to see that motor power and/or critical fan speed have not been exceeded.
   - (f) Proportionally adjust branch dampers until each has the proper air volume.
   - (g) With all the dampers and registers in the system open and with the supply, return, and exhaust blowers operating at or near design airflow, set the minimum outdoor and return air ratio. If duct traverse locations are not available, this can be done by measuring the mixture temperature with thermometers in the return air, outdoor air louver, and the filter section. As an approximation, the temperature of the mixture may be calculated from \[ T_{mixture} = \frac{T_{outdoor} + T_{return}}{2} \]
   - After the minimum outdoor air damper has been set for the proper percentage of outdoor air, run another traverse of mixture temperatures and install baffling if the variation from the average is more than 5%. Remember that stratified mixed air temperatures vary greatly with the outdoor temperature in cold weather, while return air temperature has only a minor effect.

3. Balance the terminal outlets in each control zone in proportion to each other. The following steps may be followed to balance the terminals:
   - (a) Once the preliminary fan quantity is set, proportion the terminal outlet balance from the outlets into the branches to the fan. Concentrate on proportioning the flow rather than the
absolute quantity. As changes are made to the fan settings and branch dampers, the outlet terminal quantities remain proportional. Branch dampers should be used to control minor adjusting and terminal dampers for trim or minor adjustment only. It may be necessary to install additional subbranch dampers to decrease the use of terminal dampers that create objectionable noise.

(b) Normally, several passes through the entire system are necessary to obtain proper outlet values.

(c) The total tested outlet air quantity compared to duct traverse air quantities may be an indicator of duct leakage.

(d) With total design air established in the branches and at the outlets, perform the following: (1) take new fan motor amperage readings, (2) find static pressure across the fan, (3) read and record static pressure across each component (intake, filters, coils, and mixing dampers), and (4) take a final duct traverse.

Dual-Duct Systems

Most constant volume dual-duct systems are designed to handle a portion of the total system’s supply through the cold duct and smaller air quantities through the hot duct. Balancing should be accomplished as follows:

1. When adjusting multizone or double-duct constant volume systems, establish the ratio of the design volume through the cooling coil to total fan volume to achieve the desired diversity factor. Keep the proportion of cold to total air constant during the balance. However, check each zone or branch with this component on full cooling. If the design calls for full flow through the cooling coil, the entire system should be set to full flow through the cooling side while making tests. Perform the same procedure for the hot air side.

2. Check the leaving air temperature at the nearest terminal to verify that the hot and cold damper inlet leakage is not greater than the established maximum allowable leakage.

3. Check apparatus and main trunks, as outlined in the section on Equipment and System Check.

4. Determine whether the static pressure at the end of the system (the longest duct run) is at or above the minimum required for mixing box operation. Proceed to the extreme end of the system and check the inlet static pressure with an inclined manometer. The inlet static pressure should exceed the minimum static pressure recommended by the mixing box manufacturer. Additional static pressure is required for the low-pressure distribution system downstream of the box.

5. Proportionately balance the diffusers or grilles on the low-pressure side of the box, as described for low-pressure systems in the previous section.

6. Change the control settings to full heating, and make certain that the controls and dual-duct boxes function properly. Spot-check the airflow at several diffusers. Check for stratification.

7. If the engineer has included a diversity factor in selecting the apparatus and whether the static pressure at the end of the system (the longest duct run) is at or above the minimum required for mixing box operation. Proceed to the extreme end of the system and check the inlet static pressure with an inclined manometer. The inlet static pressure should exceed the minimum static pressure recommended by the mixing box manufacturer. Additional static pressure is required for the low-pressure distribution system downstream of the box.

5. Proportionately balance the diffusers or grilles on the low-pressure side of the box, as described for low-pressure systems in the previous section.

6. Change the control settings to full heating, and make certain that the controls and dual-duct boxes function properly. Spot-check the airflow at several diffusers. Check for stratification.

7. If the engineer has included a diversity factor in selecting the apparatus and whether the static pressure at the end of the system (the longest duct run) is at or above the minimum required for mixing box operation. Proceed to the extreme end of the system and check the inlet static pressure with an inclined manometer. The inlet static pressure should exceed the minimum static pressure recommended by the mixing box manufacturer. Additional static pressure is required for the low-pressure distribution system downstream of the box.

VARIABLE VOLUME SYSTEMS

Many types of variable volume systems have been developed to conserve energy. These systems can be categorized as pressure dependent or pressure independent.

Pressure-dependent systems incorporate air terminal boxes that have a thermostat signal controlling a damper actuator. The air volume to the space varies to maintain the space temperature, while the air temperature supplied to the terminal boxes remains constant. The balance of this system constantly varies with loading changes; therefore, any balancing procedure will not produce repeatable data unless changes in system load are simulated by using the same configuration of thermostat settings each time the system is tested—that is, the same terminal boxes are fixed in the minimum and maximum positions for the test.

Pressure-independent systems incorporate air terminal boxes that have a thermostat signal used as a master control to open or close the damper actuator and a velocity controller used as a submaster control to maintain the maximum and minimum amounts of air to be supplied to the space. The air volume to the space varies to maintain the space temperature, while the air temperature supplied to the terminal remains constant. Care should be taken to verify the operating range of the damper actuator as it responds to the velocity controller to prevent dead bands or overlap of control in response to other system components (e.g., double-duct VAV, fan-powered boxes, and retrofit systems). Care should also be taken to verify the action of the thermostat with regard to the damper position, as the velocity controller can change the control signal ratio or reverse the control signal.

In a pressure-dependent system, the setting of minimum airflows to the space, other than at no flow, is not suggested, unless the terminal box has a normally closed damper and the manufacturer of the damper actuator provides adjustable mechanical stops. The pressure-independent system requires verification that the velocity controller is operating properly. Inlet duct configuration can adversely affect the operation of the velocity controller (Griggs et al. 1990). The primary difference between the two systems is that the pressure-dependent system supplies a different amount of air to the space as the pressure upstream of the terminal box changes. If the thermostats are not calibrated properly to meet the space load, several zones may overcool or overheat. When the zone cooling and receive greater amounts of supply air than required, they decrease the amount of air that can be supplied to overheated zones. The pressure-independent system is not affected by improper thermostat calibration in the same way that a pressure-dependent system is, because the minimum and maximum airflow limits may be set for each zone.

Static Control

Static control saves energy and prevents overpressurizing the duct system. The following procedures and equipment are some of the means used to control static pressure.

No Fan Volumetric Control. This is sometimes referred to as “riding the fan curve.” This type of control should be limited to systems with minimum airflows of 50% of peak design and forward curved fans with flat pressure curves. Pressure and noise are potential problems, and this control is not energy efficient.

System Bypass Control. As the system pressure increases due to the closing of terminal boxes, a relief damper bypasses air back to the fan inlet. With this type of control, the economy of varied fan output and noise is nonexistent, and the relief damper is usually a major source of duct leakage and noise. The relief damper should be modulated to maintain a minimum duct static pressure.

Discharge Damper. Losses and noise should be considered with this type of damper.

Vortex Damper. Losses due to inlet air conditions are a problem, and the vortex damper does not completely close. The minimum expected airflow should be evaluated.

Variable Inlet Cones. System loss can be a problem because the cone does not typically close completely. The minimum expected airflow should be evaluated.

Varying Fan Speed Mechanically. Slippage, loss of belts, cost of belt replacement, and the initial cost of components are of concern.

Variable Pitch-in-Motion Fans. Maintenance and preventing the fan from running in the stall condition must be evaluated.
Testing, Adjusting, and Balancing

Varying Fan Speed Electrically. This method of control, which varies the voltage or frequency to the fan motor, is usually the most efficient. Some versions of motor drives may cause electrical noise and affect other devices.

In controlling VAV fan systems, the location of the static pressure sensors is critical and should be field verified to give the most representative point of operation. After the terminal boxes have been proportioned, the static pressure control can be verified by observing static pressure changes at the fan discharge and the static pressure sensor as the load is simulated from maximum airflow to minimum airflow (i.e., set all terminal boxes to balanced airflow conditions and determine whether any changes in static pressure occur by placing one terminal box at a time to minimum airflow, until all terminals are placed at the minimal airflow setting). Care should be taken to verify that the maximum to minimum airflow changes are within the fan curve performance (speed or total pressure).

Diversity

Diversity may be used on a VAV system, assuming that the total airflow is lower by design and that all terminal boxes will never fully open at the same time. Care should be taken to avoid duct leakage. All ductwork upstream of the terminal box should be considered as medium-pressure ductwork, whether in a low- or medium-pressure system.

A procedure to test the total air on the system should be established by setting terminal boxes to the zero or minimum position nearest the fan. During peak load conditions, care should be taken to verify that an adequate pressure is available upstream of all terminal boxes to achieve design airflow to the spaces.

Outside Air Requirements

Maintaining the space under a slight positive or neutral pressure to atmosphere is difficult with all variable volume systems. In most systems, the exhaust requirement for the space is constant; hence, the outside air used to equal the exhaust air and meet the minimum outside air requirements for the building codes must also remain constant. Due to the location of the outside air intake and the changes in pressure, this does not usually happen. The outside air should enter the fan at a point of constant pressure (i.e., supply fan volume can be controlled by proportional static pressure control, which can control the volume of the return air fan). Makeup air fans can also be used for outside air control.

Return Air Fans

If return air fans are required in series with a supply fan, the type of control and sizing of the fans is most important. Serious over- and underpressurization can occur, especially during the economizer cycle.

Types of VAV Systems

Single-Duct VAV. This system incorporates a pressure-dependent or -independent terminal and usually has reheat at some predetermined minimal setting on the terminal unit or separate heating system.

Bypass. This system incorporates a pressure-dependent damper, which, on demand for heating, closes the damper to the space and opens to the return air plenum. Bypass sometimes incorporates a constant bypass airflow or a reduced amount of airflow bypassed to the return plenum in relation to the amount supplied to the space. No economical value can be obtained by varying the fan speed with this system. A control problem can exist if any return air sensing is done to control a warm-up or cool-down cycle.

VAV Using Single-Duct VAV and Fan-Powered, Pressure-Dependent Terminals. This system has a primary source of air from the fan to the terminal and a secondary powered fan source that pulls air from the return air plenum before the additional heat source. This system places additional maintenance of terminal filters, motors, and capacitors on the building owner. In certain fan-powered boxes, backdraft dampers are a source of duct leakage when the system calls for the damper to be fully closed. Typical applications include geographic areas where the ratio of heating hours to cooling hours is low.

Double-Duct VAV. This type of terminal incorporates two single-duct variable terminals. It is controlled by velocity controllers that operate in sequence so that both hot and cold ducts can be opened or closed. Some controls have a downstream flow sensor in the terminal unit to maintain either the heating or the cooling. The other flow sensor is in the inlet controlled by the thermostat. As this inlet damper closes, the downstream controller opens the other damper to maintain the set airflow. Often, low pressure in the decks controlled by the thermostat causes unwanted mixing of air, which results in excess energy use or discomfort in the space. On most direct digital controls (DDC) inlet control on both ducts is favored in lieu of the downstream controller.

Balancing the VAV System

The general procedure for balancing a VAV system is:

1. Determine the required maximum air volume to be delivered by the supply and return air fans. Diversity of load usually means that the volume will be somewhat less than the outlet total.
2. Obtain fan curves on these units, and request information on surge characteristics from the fan manufacturer.
3. If an inlet vortex damper control is to be used, obtain the fan manufacturer’s data pertaining to the deaeration of the fan when used with the damper. If speed control is used, find the maximum and minimum speed that can be used on the project.
4. Obtain from the manufacturer the minimum and maximum operating pressures for terminal or variable volume boxes to be used on the project.
5. Construct a theoretical system curve, including an approximate surge area. The system curve starts at the minimum inlet static pressure of the boxes, plus system loss at minimum flow, and terminates at the design maximum flow. The operating range using an inlet vane damper is between the surge line intersection with the system curve and the maximum design flow. When variable speed control is used, the operating range is between (a) the minimum speed that can produce the necessary minimum box static pressure at minimum flow still in the fan’s stable range and (b) the maximum speed necessary to obtain maximum design flow.
6. Position the terminal boxes to the proportion of maximum fan air volume to total installed terminal maximum volume.
7. Set the fan to operate at approximate design speed (increase about 5% for a full open inlet vane damper).
8. Check a representative number of terminal boxes. If a wide variation in static pressure is encountered, or if the airflow at a number of boxes is below minimum at maximum flow, check every box.
9. Run a total air traverse with a pitot tube.
10. Increase the speed if static pressure and/or volume are low. If the volume is correct, but the static is high, reduce the speed. If the static is high or correct, but the volume is low, check for system effect at the fan. If there is no system effect, go over all terminals and adjust them to the proper volume.
11. Run steps (7) through (10) with the return or exhaust fan set at design flow as measured by a pitot-tube traverse and with the system set on minimum outdoor air.
12. Proportion the outlets, and verify the design volume with the VAV box on the maximum flow setting. Verify the minimum flow setting.
13. Set the terminals to minimum, and adjust the inlet vane or speed controller until minimum static pressure and airflow are obtained.

14. The temperature control personnel, the balancing personnel, and the design engineer should agree on the final placement of the sensor for the static pressure controller. This sensor must be placed in a representative location in the supply duct to sense average maximum and minimum static pressures in the system.

15. Check the return air fan speed or its inlet vane damper, which tracks or adjusts to the supply fan airflow, to ensure proper outside air volume.

16. Operate the system on 100% outside air (weather permitting), and check supply and return fans for proper power and static pressure.

### Induction Systems

Most induction systems use high-velocity air distribution. Balancing should be accomplished as follows:

1. Perform steps outlined under the basic procedures common to all systems for apparatus and main trunk capacities.

2. Determine the primary airflow at each terminal unit by reading the unit plenum pressure with a manometer and locating the point on the charts (or curves) of air quantity versus static pressure supplied by the unit manufacturer.

3. Normally, about three complete passes around the entire system are required for proper adjustment. Make a final pass without adjustments to record the end result.

4. To provide the quietest possible operation, adjust the fan to run at the slowest speed that provides sufficient nozzle pressure to all units with minimum throttling of all unit and riser dampers.

5. After balancing each induction system with minimum outdoor air, reposition to allow maximum outdoor air and check power and static pressure readings.

### Report Information

To be of value to the consulting engineer and owner’s maintenance department, the air-handling report should consist of at least the following items:

1. **Design**
   - (a) Air quantity to be delivered
   - (b) Fan static pressure
   - (c) Motor power installed or required
   - (d) Percent of outside air under minimum conditions
   - (e) Speed of the fan
   - (f) Input power required to obtain this air quantity at design static pressure

2. **Installation**
   - (a) Equipment manufacturer (indicate model number and serial number)
   - (b) Size of unit installed
   - (c) Arrangement of the air-handling unit
   - (d) Nameplate power, nameplate voltage, phase, cycles, and full-load amperes of the motor installed

3. **Field tests**
   - (a) Fan speed
   - (b) Power readings (voltage, amperes of all phases at motor terminals)
   - (c) Total pressure differential across unit components
   - (d) Fan suction and fan discharge static pressure (equals fan total pressure)
   - (e) Plot of actual readings on manufacturer’s fan performance curve to show the installed fan operating point
   - (f) Measured airflow rate

4. **Terminal Outlets**
   - (a) Outlet by room designation and position
   - (b) Outlet manufacturer and type
   - (c) Outlet size (using manufacturer’s designation to ensure proper factor)
   - (d) Manufacturer’s outlet factor (Where no factors are available, or field tests indicate the listed factors are incorrect, a factor must be determined in the field by traverse of a duct leading to a single outlet.)
   - (e) Design air quantity and the required velocity to obtain it
   - (f) Test velocities and resulting air quantity
   - (g) Adjustment pattern for every air terminal

5. **Additional Information (if applicable)**
   - (a) Air-handling units
     - (1) Belt number and size
     - (2) Drive and driven sheave size
     - (3) Belt position on adjusted drive sheaves (bottom, middle, and top)
     - (4) Motor speed under full load
     - (5) Motor heater size
     - (6) Filter type and static pressure at initial use and full load; time to replace
     - (7) Variations of velocity at various points across the face of the coil
     - (8) Existence of vortex or discharge dampers, or both
   - (b) Distribution system
     - (1) Unusual duct arrangements
     - (2) Branch duct static readings in double-duct and induction system
     - (3) Ceiling pressure readings where plenum ceiling distribution is being used; tightness of ceiling
     - (4) Relationship of building to outdoor pressure under both minimum and maximum outdoor air
     - (5) Induction unit manufacturer and size (including required air quantity and plenum pressures for each unit) and a test plenum pressure and resulting primary air delivery from the manufacturer’s listed curves
     - (c) All equipment nameplates visible and easily readable

Many independent firms have developed detailed procedures suitable to their own operations and the area in which they function. These procedures are often available for information and evaluation upon request.

### PRINCIPLES AND PROCEDURES FOR BALANCING HYDRONIC SYSTEMS

It is important to establish the initial static pressures accurately for the air treatment equipment and the duct system so that the variation in air quantity due to filter loading can be calculated. It enables the designer to ensure that the total air quantity will never be less than the minimum requirements. Because the design air quantity for peak loading of the filters has already been calculated, it also serves as a check of dirt loading in coils.

4. **Terminal Outlets**
   - (a) Outlet by room designation and position
   - (b) Outlet manufacturer and type
   - (c) Outlet size (using manufacturer’s designation to ensure proper factor)
   - (d) Manufacturer’s outlet factor (Where no factors are available, or field tests indicate the listed factors are incorrect, a factor must be determined in the field by traverse of a duct leading to a single outlet.)
   - (e) Design air quantity and the required velocity to obtain it
   - (f) Test velocities and resulting air quantity
   - (g) Adjustment pattern for every air terminal

5. **Additional Information (if applicable)**
   - (a) Air-handling units
     - (1) Belt number and size
     - (2) Drive and driven sheave size
     - (3) Belt position on adjusted drive sheaves (bottom, middle, and top)
     - (4) Motor speed under full load
     - (5) Motor heater size
     - (6) Filter type and static pressure at initial use and full load; time to replace
     - (7) Variations of velocity at various points across the face of the coil
   - (b) Distribution system
     - (1) Unusual duct arrangements
     - (2) Branch duct static readings in double-duct and induction system
     - (3) Ceiling pressure readings where plenum ceiling distribution is being used; tightness of ceiling
     - (4) Relationship of building to outdoor pressure under both minimum and maximum outdoor air
     - (5) Induction unit manufacturer and size (including required air quantity and plenum pressures for each unit) and a test plenum pressure and resulting primary air delivery from the manufacturer’s listed curves
     - (c) All equipment nameplates visible and easily readable

Many independent firms have developed detailed procedures suitable to their own operations and the area in which they function. These procedures are often available for information and evaluation upon request.

### PRINCIPLES AND PROCEDURES FOR BALANCING HYDRONIC SYSTEMS

Both air- and water-side balance techniques must be performed with sufficient accuracy to ensure that the system operates economically, with minimum energy, and with proper distribution. Air-side balance requires a precise flow measuring technique because air, which is usually the prime heating or cooling transport medium, is more difficult to measure in the field. Reducing the airflow to less than the design requirement directly reduces the heat transfer. In contrast, the heat transfer rate for the water side of the terminal does not vary linearly with the water flow rate. Therefore, the proper balancing valve with the correct control characteristics must be provided at each terminal to proportionally balance the water flow rate according to the design conditions.
Heat Transfer at Reduced Flow Rate

The typical heating-only hydronic terminal gradually reduces its heat output as flow is reduced (Figure 1). Decreasing water flow to 50% of design reduces the heat transfer to 90% of that at full design flow. The control valve must reduce the water flow to 10% to reduce the heat output to 50%. The reason for the relative insensitivity to changing flow rates is that the governing coefficient for heat transfer is the air-side coefficient. A change in internal or water-side coefficient with flow rate does not materially affect the overall heat transfer coefficient. This means that (1) heat transfer for water-to-air terminals is established by the mean air-to-water temperature difference, (2) the heat transfer is measurably changed, and (3) a change in the mean water temperature requires a greater change in the water flow rate.

A secondary concern also applies to heating terminals. Unlike chilled water, hot water can be supplied at a wide range of temperatures. So, in some cases, an inadequate terminal heating capacity caused by insufficient flow can be overcome by raising the supply water temperature. Design below the temperature limit of 120°C (ASME low-pressure boiler code) must be considered.

The previous comments apply to heating terminals selected for a 10 K temperature drop (Δt) and with a supply water temperature of about 93°C. Figure 3 shows the flow variation when 90% terminal capacity is acceptable. Note that heating tolerance decreases with temperature and flow rates and that chilled water terminals are much less tolerant of flow variation than hot water terminals.

Dual-temperature heating/cooling hydronic systems are sometimes completed and started during the heating season. Adequate heating ability in the terminals may suggest that the system is balanced. Figure 3 shows that 40% of design flow through the terminal provides 90% of design heating with 60°C supply water and a 5 K temperature drop. Increased supply water temperature establishes the same heat transfer at terminal flow rates of less than 40% design.

In some cases, dual-temperature water systems may experience a decreased flow during the cooling season because of the chiller pressure drop; this could cause a flow reduction of 25%. For example, during the cooling season, a terminal that originally heated satisfactorily would only receive 30% of the design flow rate.

While the example of reduced flow rate at Δt = 10 K only affects the heat transfer by 10%, this reduced heat transfer rate may have the following negative effects:

1. The object of the system is to deliver (or remove) heat where required. When the flow is reduced from the design rate, the system must supply heating or cooling for a longer period to maintain room temperature.
2. As the load reaches design conditions, the reduced flow rate is unable to maintain room design conditions.

Terminals with lower water temperature drops have a greater tolerance for unbalanced conditions. However, larger water flows are necessary, requiring larger pipes, pumps, and pumping cost. Also, automatic valve control is more difficult.

System balance becomes more important in terminals with a large temperature difference. Less water flow is required, which reduces the size of pipes, valves, and pumps, as well as pumping costs. A more linear emission curve gives better system control.

Heat Transfer at Excessive Flow

The flow rate should not be increased above design in an effort to increase heat transfer. Figure 3 shows that increasing the flow to 200% of design only increases heat transfer by 6% while increasing the resistance or pressure drop 4 times and the power by the cube of the original power (pump laws).

Generalized Chilled Water Terminal—
Heat Transfer Versus Flow

The heat transfer for a typical chilled water coil in an air duct versus water flow rate is shown in Figure 4. The curves shown are based on ARI rating points: 7.2°C inlet water at a 5.6 K rise with entering air at 26.7°C dry bulb and 19.4°C wet bulb.

The basic curve applies to catalog ratings for lower dry-bulb temperatures providing a consistent entering air moisture content (e.g., 23.9°C dry bulb, 18.3°C wet bulb). Changes in inlet water temperature, temperature rise, air velocity, and dry- and wet-bulb temperatures will cause terminal performance to deviate from the curves. Figure 4 is only a general representation of the total heat transfer change versus flow for a hydronic cooling coil and does not apply to all chilled water terminals. Comparing Figure 4 with Figure 3 indicates the similarity of the nonlinear heat transfer and flow for both the heating and the cooling terminal.

Table 1 shows that if the coil is selected for the load, and the flow is reduced to 90% of the load, three flow variations can satisfy the reduced load at various sensible and latent combinations.
Flow Tolerance and Balance Procedure

The design procedure rests on a design flow rate and an allowable flow tolerance. The designer must define both the terminal’s flow rates and feasible flow tolerance, bearing in mind that the cost of balancing rises with tightened flow tolerance. Also, the designer must remember that any overflow increases pumping cost, and any decrease of flow reduces the maximum heating or cooling at design conditions.

WATER-SIDE BALANCING

The water side should be balanced by direct flow measurement. This method is accurate because it avoids the compounding errors introduced by temperature difference procedures. Measuring the flow at each terminal enables proportional balancing and ultimate matching of the pump to the actual system requirements (by trimming the pump impeller or reducing the pump motor power, for example). In many cases, reduction in pump operating cost will pay for the cost of water-side balancing.

Equipment

Proper equipment selection and preplanning are needed to successfully balance hydronic systems. Circumstances sometimes dictate that flow, temperature, and pressure be measured. The designer should specify the water flow balancing devices for installation during construction and testing during the balancing of the hydronic system. The devices may consist of all or some of the following:

- Flowmeters (ultrasonic stations, turbines, venturi, orifice plate, multiported pitot tubes, and flow indicators)
- Manometers, ultrasonic digital meters, and differential pressure gages (either analog or digital)
- Portable digital meter to measure flow and pressure drop
- Portable pyrometers to measure temperature differentials when test wells are not provided
- Test pressure taps, pressure gages, thermometers, and wells.
- Balancing valve with a factory-rated flow coefficient \( C \), a flow versus handle position and pressure drop table, or a slide rule flow calculator
- Dynamic balancing valves or flow limiting valves (for prebalanced systems only); field adjustment of these devices is not normally required or possible
- Pumps with factory-certified pump curves
- Components used as flowmeters (terminal coils, chillers, heat exchangers, or control valves if using the manufacturer’s factory-certified flow versus pressure drop curves); not recommended as a replacement for metering stations

Record Keeping

Balancing requires keeping accurate records while making field measurements. The actual dated and signed field test report helps the designer or customer in approval of the work, and the owner will have a valuable reference when documenting future changes.

Sizing Balancing Valves

A balancing valve is placed in the system to adjust water flow to a terminal, branch, zone, riser, or main. A common valve-sizing method is to select for the line size; however, this is unwise because balancing valves should be selected to pass design flows when near or at their full open position with a minimum of 3 kPa pressure drop. Many balancing valves and measuring meters can give an accuracy of ±5% of range down to a pressure drop of 3 kPa with the balancing valve in the wide open position. Too large a balancing valve pressure drop will affect the performance and flow characteristic of

Note: Dual-temperature systems are designed to chilled flow requirements and often operate on a 5 K temperature drop at full-load heating.
the control valve. \( A_v \) may be used to determine the flow coefficient for a balancing valve. The equation is also used to size a control valve.

The pressure drop across a control valve is a function of a flow coefficient \( A_v \), which represents the flow rate in cubic metres per second through a fully open valve at a pressure drop of 1 Pa. The flow coefficient is defined as follows:

\[
A_v = Q(\rho/\Delta p)^{0.5}
\]

where

- \( Q \) = design flow for terminal or valve, m\(^3\)/s
- \( \rho \) = density of fluid, kg/m\(^3\)
- \( \Delta p \) = pressure drop across valve, Pa

The traditional inch-pound flow coefficient \( C_v \) may be converted to the SI coefficient \( A_v \) by the following factor:

\[
A_v = 24.0 \times 10^{-6} C_v
\]

**HYDRONIC BALANCING METHODS**

A variety of techniques is used to balance hydronic systems. Balance by temperature difference and water balance by proportional method are the most common.

**Balance by Temperature Difference**

This often-used balancing procedure is based on measurement of the water temperature difference between supply and return at the terminal. The designer selects the cooling and/or heating terminal for a calculated design load at full-load conditions. At less than full load, which is true for most operating hours, the temperature drop is proportionately less. Figure 5 demonstrates this relationship for a terminal at a design temperature of 20°C and room design of 20°C.

For every outside temperature other than design, the balancing technician should construct a similar chart and read off the \( \Delta t \) for balancing. For example, at 50% load, or –1°C outdoor air, the \( \Delta t \) required is 5 K, or 50% of the design drop.

The temperature balance method is a rough approximation and should not be used where great accuracy is required. It is not accurate enough for a cooling system or heating systems with a large temperature drop.

**Water Balance by Proportional Method**

The proportional method of water-side balance uses as-built conditions and adapts well to design diversity factors. Circuits in a system are proportionately balanced to each other by a flow quotient, which is the actual flow rate divided by the design flow rate through a circuit.

\[
\text{Flow quotient} = \frac{\text{Actual flow rate}}{\text{Design flow rate}}
\]

To balance a branch system proportionally, first open the balancing valves and the control valves in that branch to their wide-open position, and then calculate each balancing valve’s quotient based on actual measurements at each terminal. Record these values on the test form, and note the circuit with the lowest flow quotient.

The reference circuit has the lowest quotient and is the circuit with the greatest pressure loss. Adjust all other balancing valves in that branch until they have the same quotient as the reference circuit (at least one valve in the branch should be fully open).

Note that when a second valve is adjusted, the flow quotient in the reference valve will also change, and continued adjustment is required to make their flow quotients equal. Once they are equal, they will remain equal or in proportional balance to each other while other valves in the branch are adjusted or there is a change in pressure or flow.

When all the balancing valves are adjusted to their branch’s respective flow quotient, the total system water flow is adjusted to a flow quotient of one.

The pressure drop across the balancing valve at the pump discharge is pressure produced by the pump that is not required in providing the design flow. This excess pressure can be removed by trimming the pump impeller or reducing the pump speed. Once the trimming is done, the pump discharge balancing valve must be reopened to its wide-open position to provide the design flow.

As in variable-speed pumping, diversity and flow changes are well accommodated by a system that has been proportionately balanced. Since the balancing valves have been balanced to each other at a particular flow (design), any changes in that flow are proportionately distributed.

Balancing of the water side in a system that uses diversity must be done at full flow. Because the components are selected based on heat transfer at full flow, they must be balanced to this point. To accomplish full-flow proportional balance, shut off part of the system while balancing the remaining sections. When a section has been balanced, shut it off and open the section that was open originally to complete full balance of the system. When balancing, proper care should be taken if the building is occupied or if near full load conditions exist.

**Variable-Speed Pumping.** To achieve hydronic balance, full flow through the system is required during the balancing procedure. Once balance is achieved, the system can be placed on automatic control and the pump speed allowed to change.

After the full-flow condition is balanced and the system differential pressure set point is established, to control the variable-speed pumps, observe the flow on the circuit with the greatest resistance as the other circuits are closed one at a time. The flow in the observed circuit should remain equal to, or more than, the previously set flow. Note that water flow may become laminar at less than 0.6 m/s, which alters the heat transfer characteristics of the system.

**Other Balancing Techniques**

**Flow Balancing by Rated Differential Procedure.** This procedure depends on deriving a performance curve for the test coil that compares water temperature difference \( \Delta t \) entering water temperature \( t_{en} \) minus entering air temperature \( t_{en} \). One point of
the desired curve can be determined from the manufacturer’s ratings since these are published as \((t_{ew} - t_{ea})\). A second point is established by observing that the heat transfer from air to water is zero when \((t_{ew} - t_{ea})\) is zero (consequently, \(\Delta t_w = 0\)). With these two points, an approximate performance curve can be drawn (see Figure 6). Then, for any other \((t_{ew} - t_{ea})\), this curve is used to determine the appropriate \(\Delta t_w\).

**Example 1.** From the following manufacturer certified data, determine the required \(\Delta t_w\):

- Capacity = 3 kW
- \(t_{ew} = 95^\circ\text{C}\)
- \(t_{ea} = 15^\circ\text{C}\)
- Water flow = 0.1 L/s
- \(c_p = 4.18 \text{ kJ/(kg·K)}\)
- \(\rho = 1.0 \text{ kg/L}\)

**Solution:**

1. Calculate rated \(\Delta t_w\):

\[
\Delta t_w = \frac{3}{4.18 \times 0.1 \times 1} = 7.18 \text{ K}
\]

2. Construct a performance curve as illustrated in Figure 6.

3. From test data:

\[
\begin{align*}
t_{ew} &= 80^\circ\text{C} \\
t_{ea} &= 20^\circ\text{C} \\
t_{ew} - t_{ea} &= 60^\circ\text{C}
\end{align*}
\]

4. From Figure 6 read \(\Delta t_w = 5.4 \text{ K}\), which is required to balance water flow at 0.1 L/s. The water temperature difference may also be calculated as proportion of the rate value as follows:

\[
\frac{(t_{ew} - t_{ea})_{\text{test}}}{(t_{ew} - t_{ea})_{\text{rated}}} \times (\Delta t_w)_{\text{rated}} = (\Delta t_w)_{\text{required}}
\]

\[
\frac{80 - 20}{95 - 15} \times 7.18 = 5.4 \text{ K}
\]

This procedure is useful for balancing terminal devices such as finned tube convectors, where flow measuring devices do not exist and where airflow measurements cannot be made. It may also be used for cooling coils for sensible transfer (dry coil).

**Flow Balancing by Total Heat Transfer.** This procedure determines water flow by running an energy balance around the coil. From field measurements of airflow, wet- and dry-bulb temperatures both upstream and downstream of the coil, and the difference \(\Delta t_w\) between the entering and leaving water temperatures, water flow can be determined by the following equations:

\[
Q_w = \frac{Q}{4180 \Delta t_w}
\]

\[
q_{cooling} = 1.20 Q_a (h_1 - h_2)
\]

\[
q_{heating} = 1.23 Q_a (t_1 - t_2)
\]

**Example 2.** Find the water flow for a cooling system having the following characteristics:

- \(t_{ewb} = 20.3^\circ\text{C}\) entering wet-bulb temperature
- \(t_{lb} = 11.9^\circ\text{C}\) leaving wet-bulb temperature
- \(Q_a = 10000 \text{ L/s}\) airflow rate
- \(t_{ew} = 15.0^\circ\text{C}\) entering water temperature
- \(t_{lw} = 8.6^\circ\text{C}\) leaving water temperature

From psychrometric chart

\[
\begin{align*}
h_1 &= 76.52 \text{ kJ/kg} \\
h_2 &= 52.01 \text{ kJ/kg}
\end{align*}
\]

**Solution:** From Equations (5) and (6)

\[
Q_w = \frac{1.20 \times 10000 (76.52 - 52.01)}{4180 (8.6 - 15.0)} = 11.0 \text{ L/s}
\]

The desired water flow is achieved by successive manual adjustments and recalculations. Note that these temperatures can be greatly influenced by the heat of compression, stratification, bypassing, and duct leakage.

**General Balance Procedures**

All the variations of balancing hydronic systems cannot be listed; however, the general method should balance the system while minimizing operating cost. Excess pump pressure (excess operating power) can be eliminated by trimming the pump impeller. Allowing excess pressure to be absorbed by throttle valves adds a lifelong operating cost penalty to the operation.

The following is a general procedure based on setting the balance valves on the site:

1. Develop a flow diagram if one is not included in the design drawings. Illustrate all balance instrumentation, and include any additional instrument requirements.
2. Compare pumps, primary heat exchangers, and specified terminal units; and determine whether a design diversity factor can be achieved.
3. Examine the control diagram and determine the control adjustments needed to obtain design flow conditions.

![Fig. 6 Coil Performance Curve](image-url)
Balance Procedure—Primary and Secondary Circuits

1. Inspect the system completely to ensure that (a) it has been flushed out, it is clean, and all air is removed; (b) all manual valves are open or in operating position; (c) all automatic valves are in their proper positions and operative; and (d) the expansion tank is properly charged.

2. Place the controls in position for design flow.

3. Examine the flow diagram and piping for obvious short circuits; check flow and adjust the balance valve.

4. Take pump suction, discharge, and differential pressure readings at both full flow and no flow. For larger pumps, a no flow condition may not be safe. In any event, valves should be closed slowly.

5. Read pump motor amperage and voltage, and determine approximate power.

6. Establish a pump curve, and determine the approximate flow rate.

7. If a total flow station exists determine the flow, and compare this flow with the pump curve flow.

8. If possible, set the total flow about 10% high using the total flow station first and the pump differential pressure second; then maintain pumped flow at a constant value as balance proceeds by adjusting the pump throttle valve.

9. If branch main flow stations exist, these should be set, starting by setting the shortest runs low as balancing proceeds to the longer branch runs.

10. With primary and secondary pumping circuits, a reasonable balance must be obtained in the primary loop before the secondary loop can be considered. The secondary pumps must be running and terminal units must be open to flow when the primary loop is being balanced, unless the secondary loop is decoupled.

**FLUID FLOW MEASUREMENT**

**Flow Measurement Based on Manufacturer’s Data**

Any component (terminal, control valve, or chiller) that has an accurate, factory-certified flow/pressure drop relationship can be used as a flow-indicating device. The flow and pressure drop may be used to establish an equivalent flow coefficient as shown in Equation (3). According to the Bernoulli equation, pressure drop varies as the square of the velocity or flow rate, assuming density is constant:

$$\frac{Q_1^2}{Q_2^2} = \frac{\Delta h_1}{\Delta h_2}$$  \hspace{1cm} (8)

For example, a chiller has a certified pressure drop of 80 kPa at 10 L/s. The calculated flow with a field-measured pressure drop of 90 kPa is

$$Q_2 = \sqrt{\frac{90}{80}} \times 10 = 10.6 \text{ L/s}$$

Flow calculated in this manner is only an estimate. The accuracy of components used as flow indicators depends on (1) the accuracy of cataloged information concerning flow/pressure drop relationships and (2) the accuracy of the pressure differential readings. As a rule, the component should be factory-certified flow tested if it is to be used as a flow indicator.

**Pressure Differential Readout by Gage**

Gages are used to read differential pressures. Gages are usually used for high differential pressures and manometers for lower differentials. Accurate gage readout is diminished when two gages are used, especially when the gages are permanently mounted and, as such, subject to malfunction.

A single high-quality gage should be used for differential readout (Figure 7). This gage should be alternately valved to the high- and low-pressure side to establish the differential. A single gage needs no static height correction, and errors caused by gage calibration are eliminated.

Differential pressure can also be read from differential gages, thus eliminating the need to subtract outlet from inlet pressures to establish differential pressure. Differential pressure gages are usually dual gages mechanically linked to read differential pressure.

**Conversion of Differential Pressure to Head**

Gages may be calibrated to metres of fluid head, which, historically, refers to the height of water above a point in the fluid circuit. Head is a function of density and is related to pressure by the hydrostatic law as:

$$h = \frac{p}{\rho g}$$  \hspace{1cm} (9)

where

- $h$ = fluid head, m
- $p$ = pressure, Pa
- $\rho$ = density, kg/m$^3$
- $g$ = standard force of gravity = 9.806 65 N/kg

But because the calibration only applies at one density (typically at a standard temperature of 15°C), the reading of head may require correction when the gage is applied to high-temperature water with a significantly lower density. The relationship between head and pressure as a function of density is shown in Table 2.

</table>

¹Differential kPa readout is multiplied by this number to obtain metres fluid head when gage is calibrated in kPa.

For example, a manufacturer may test a boiler control valve with 40°C water. Differential pressures from another test made in the field at 120°C may be correlated with the manufacturer’s data by using Equation (8) to account for the density differences of the two tests.

When differential heads are used to estimate flow, a density correction must be made because of the shape of the pump curve. For example, in the uncorrected differential reading for pumped water with a density of 900 kg/m³ is 25 m; the gage conversion was assumed to be for water with a density of 999 kg/m³. The uncorrected or false reading gives a 40% error in flow estimation.

Differential Head Readout with Manometers

Manometers are used for differential pressure readout, especially when very low differentials, great precision, or both, are required. But manometers must be handled with care; they should not be used for field testing because fluid could blow out into the water and rapidly deteriorate the components. A proposed manometer arrangement is shown in Figure 9 and the following instructions provide accurate manometer readings with minimum risk of blowout.

1. Make sure that both legs of the manometer are filled with water.
2. Open the purge bypass valve.
3. Open valve connections to high and low pressure.
4. Open the bypass vent valve slowly and purge air here.
5. Open manometer block vents and purge air at each point.
6. Close the needle valves. The columns should zero in if the manometer is free of air. If not, vent again.
7. Open the needle valves and begin throttling the purge bypass valve slowly, watching the fluid columns. If the manometer has an adequate available fluid column, the valve can be closed and the differential reading taken. However, if the fluid column reaches the top of the manometer before the valve is completely closed, insufficient manometer height is indicated and further throttling will blow fluid into the blowout collector. A longer manometer or the single gage readout method should then be used.

An error is often introduced when converting millimetres of gage fluid to the pressure difference (in kilopascals) of the test fluid. The conversion factor changes with test fluid temperature, density, or both. Conversion factors shown in Table 2 are to a water base, and the counterbalancing water height \( H \) (Figure 9) is at room temperature.

![Fig. 9 Fluid Manometer Arrangement for Accurate Reading and Blowout Protection](image)

Orifice Plates, Venturi, and Flow Indicators

Manufacturers provide flow information for several devices used in hydronic system balance. In general, the devices can be classified as (1) orifice flowmeters, (2) venturi flowmeters, (3) velocity impact meters, (4) pitot-tube flowmeters, (5) bypass spring impact flowmeters, (6) calibrated balance valves, (7) turbine flowmeters, and (8) ultrasonic flowmeters.

The orifice flowmeter is widely used and is extremely accurate. The meter is calibrated and shows differential pressure versus flow. Accuracy generally increases as the pressure differential across the meter increases. The differential pressure readout instrument may be a manometer, differential gage, or single gage (Figure 7).

The venturi flowmeter has lower pressure loss than the orifice plate meter because a carefully formed flow path increases velocity head recovery. The venturi flowmeter is placed in a main flow line where it can be read continuously.

Velocity impact meters have precise construction and calibration. The meters are generally made of specially contoured glass or plastic, which permits observation of a flow float. As flow increases, the flow float rises in the calibrated tube to indicate flow rate. Velocity impact meters generally have high accuracy.

A special version of the velocity impact meter is applied to hydronic systems. This version operates on the velocity pressure difference between the pipe side wall and the pipe center, which causes fluid to flow through a small flowmeter. Accuracy depends on the location of the impact tube and on a velocity profile that corresponds to theory and the laboratory test calibration base. Generally, the accuracy of this bypass flow impact or differential velocity pressure flowmeter is less than a flow-through meter, which can operate without creating a pressure loss in the hydronic system.

The pitot-tube flowmeter is also used for pipe flow measurement. Manometers are generally used to measure velocity pressure differences because these differences are low.

The bypass spring impact flowmeter uses a defined piping pressure drop to cause a correlated bypass side branch flow. The side branch flow pushes against a spring that increases in length with increased side branch flow. Each individual flowmeter is calibrated to relate extended spring length position to main flow. The bypass spring impact flowmeter has, as its principal merit, a direct readout. However, dirt on the spring reduces accuracy. The bypass
Testing, Adjusting, and Balancing

is opened only when a reading is made. Flow readings can be taken at any time.

The calibrated balance valve is an adjustable orifice flowmeter. Balance valves can be calibrated so that a flow/pressure drop relationship can be obtained for each incremental setting of the valve. A ball, rotating plug, or butterfly valve may have its setting expressed in percent open or degree open; a globe valve, in percent open or number of turns. The calibrated balance valve must be manufactured with precision and care to ensure that each valve of a particular size has the same calibration characteristics.

The turbine flowmeter is a mechanical device. The velocity of the liquid spins a wheel in the meter, which generates a 4 to 20 mA output that may be calibrated in units of flow. The meter must be well maintained, as wear or water impurities on the bearing may slow the wheel, and debris may clog or break the wheel.

The ultrasonic flowmeter senses sound signals, which are calibrated in units of flow. The ultrasonic metering station may be installed as part of the piping, or it may be a strap-on meter. In either case, the meter has no moving parts to maintain, nor does it intrude into the pipe and cause a pressure drop. Two distinct types of ultrasonic meter are available: (1) the transit time meter for HVAC or clear water systems and (2) the Doppler meter for systems handling sewage or large amounts of particulate matter.

If any of the above meters are to be useful, the minimum distance of straight pipe upstream and downstream, as recommended by the meter manufacturer and flow measurement handbooks, must be adhered to. Figure 10 presents minimum installation suggestions.

Using a Pump as an Indicator

Although the pump is not a meter, it can be used as an indicator of flow together with the other system components. Differential pressure readings across a pump can be correlated with the pump curve to establish the pump flow rate. Accuracy depends on (1) accuracy of readout, (2) pump curve shape, (3) actual conformance of the pump to its published curve, (4) pump operation without cavitation, (5) air-free operation, and (6) velocity pressure correction.

When a differential pressure reading must be taken, a single gage with manifold provides the greatest accuracy. The pump suction to discharge differential can be used to establish pump differential pressure and, consequently, pump flow rate. The single gage and manifold may also be used to check for strainer clogging by measuring the pressure differential across the strainer.

If the pump curve is based on fluid head, pressure differential, as obtained from the gage reading, needs to be converted to head, which is pressure divided by the fluid density and gravity. The pump differential head is then used to determine pump flow rate. As long as the differential head used to enter the pump curve is expressed as head of the fluid being pumped, the pump curve shown by the manufacturer should be used as described. The pump curve may state that it was defined by test with 30°C water. This is unimportant, since the same curve applies from 15 to 120°C water, or to any fluid within a broad viscosity range.

Generally, pump-derived flow information, as established by the performance curve, is questionable unless the following precautions are observed:

Fig. 10 Minimum Installation Dimensions for Flowmeter

Fig. 11 Single Gage for Differential Readout Across Pump and Strainer

Fig. 12 Differential Pressure Used to Determine Pump Flow

1. The installed pump should be factory calibrated by a test to establish the actual flow-pressure relationship for that particular pump. Production pumps can vary from the cataloged curve because of minor changes in impeller diameter, interior casting tolerances, and machine fits.

2. When a calibration curve is not available for a centrifugal pump being tested, the discharge valve can be closed briefly to establish the no-flow shutoff pressure, which can be compared to the published curve. If the shutoff pressure differs from that published, draw a new curve parallel to the published curve. While not exact, the new curve will usually fit the actual pumping circumstance more accurately. Clearance between the impeller and casing minimize the danger of damage to the pump during a no-flow test, but manufacturer verification is necessary.

3. Differential pressure should be determined as accurately as possible, especially for pumps with flat flow curves.

4. The pump should be operating air-free and without cavitation. A cavitating pump will not operate to its curve, and differential readings will provide false results.

5. Ensure that the pump is operating above the minimum net positive suction pressure.

6. Power readings can be used (1) as a check for the operating point when the pump curve is flat or (2) as a reference check when there is suspicion that the pump is cavitating or providing false readings because of air.

7. The flow determined by the pump curve should be compared to the flow measured at the flowmeters, flow measured by pressure drops through circuits, and flow measured by pressure drops through exchangers.

8. The pump flow derived from the pressure differential at the suction and discharge connections is only an indicator of the actual flow—it cannot be used to verify the test and balance measurements. If the pump flow is to be used for balancing verification it needs to be determined using the Hydraulic Institute procedure or by measuring the flow through a properly installed metering station 15 to 20 straight pipe diameters downstream from the pump discharge.

The power draw should be measured in watts. Ampere readings cannot be trusted because of voltage and power factor problems. If motor efficiency is known, the wattage drawn can be related to pump brake power (as described on the pump curve) and the operating point determined.

Central Plant Chilled Water Systems

For existing installations, establishing accurate thermal load profiles is of prime importance because it establishes proper primary chilled water supply temperature and flow. In new installations, actual load profiles can be compared with design load profiles to obtain valid operating data.

To perform proper testing and balancing, all interconnecting points between the primary and secondary systems must be designed with sufficient temperature, pressure, and flow connections so that adequate data may be indicated and/or recorded.

Water Flow Instruments

As indicated previously, proper location and use of instruments is vital to accurate balancing. Instruments for testing temperature and pressure at various locations are listed in Table 3. Flow-indicating devices should be placed in water systems as follows:

- At each major heating coil bank (0.6 L/s or more)
- At each major cooling coil bank (0.6 L/s or more)
- At each bridge in primary-secondary systems
- At each main pumping station
- At each water chiller evaporator
- At each water chiller condenser
- At each water boiler outlet
- At each floor takeoff to booster reheat coils, fan coil units, induction units, ceiling panels, and radiation (Do not exceed 25 terminals off of any one zone meter probe.)
- At each vertical riser to fan coil units, induction units, and radiation
- At the point of tie-in to existing systems

STEAM DISTRIBUTION

Procedures for Steam Balancing Variable Flow Systems

Steam distribution cannot be balanced by adjustable flow-regulating devices. Instead, fixed restrictions built into the piping in accordance with carefully designed pipe and orifice sizes are used to regulate flow.

It is important to have a balanced distribution of steam to all portions of the steam piping at all loads. This is best accomplished by properly designing the steam distribution piping, which includes carefully considering steam pressure, steam quantities required by each branch circuit, pressure drops, steam velocities, and pipe sizes. Just as other flow systems are balanced, steam distribution systems are balanced by ensuring that the pressure drops are equalized at design flow rates for all portions of the piping. Only marginal balancing can be done by pipe sizing. Therefore, additional steps must be taken to achieve a balanced performance.

Steam flow balance can be improved by using spring-type packless supply valves equipped with precalibrated orifices. The valves should have a tight shutoff between 80 to 400 kPa (gage). These valves have a nonrising stem, are available with a lockshield, and have a replaceable disk. Orifice flanges can also be used to regulate and measure steam flow at appropriate locations throughout the system. The orifice sizes are determined by the pressure drop required for a given flow rate at a given location. A schedule should be prepared showing (1) orifice sizes, (2) valve or pipe sizes, (3) required flow rates, and (4) corresponding pressure differentials for each flow rate. It may be useful to calculate pressure differentials for several flow rates for each orifice size. Such a schedule should be maintained for future reference.

After the appropriate regulating orifices are installed in the proper locations, the system should be tested for tightness by sealing all openings in the system and applying a vacuum of 35 kPa (absolute), held for 2 hours. Next, the system should be readied for warm-up and pressurizing with steam following the procedures outlined in Section VI of the ASME Boiler and Pressure Vessel Code. After the initial warm-up and system pressurization, evaluate system steam flow, and compare it to system requirements. The orifice schedule calculated earlier will now be of value should any of the orifices need to be changed.

Steam Flow Measuring Devices

Many devices are available for measuring flow in steam piping: (1) steam meters, (2) condensate meters, (3) orifice plates, (4) venturi fittings, (5) steam recorders, and (6) manometers for reading differential pressures across orifice plates and venturi fittings. Some of these devices are permanently affixed to the piping system to facilitate taking instantaneous readings that may be necessary for proper operation and control. A surface pyrometer used in conjunction with a pressure gage is a convenient way to determine steam saturation temperature and the degree of superheat at various
Testing, Adjusting, and Balancing

locations in the system. Such information can be used to evaluate
performance characteristics.

COOLING TOWERS

Field testing cooling towers is a demanding and difficult task.
ASME Standard PTC 23 (1986) and CTI Standard Specification
ATC-105 (1997) establish procedures for these tests. Certain
gen-eral guidelines for testing cooling towers are as follows:

Conditions at Time of Test

- Water flow within 15% of design flow
- Heat load within 30% of design heat load and stabilized
- Entering wet bulb within 6.7 K of entering design wet bulb

Using the above limitations and field readings that are as accu-
rate as possible, a projection to design conditions produces an accu-
- racy of ±5% of tower performance.

Conditions for Performing Test

- Water-circulating system serving the tower should be thoroughly
  cleaned of all dirt and foreign matter. Samples of water should be
  clear and indicate clear passage of water through pumps, piping,
screens, and strainers.
- Fans serving the cooling tower should operate in proper rotation.
Foreign obstructions should be removed. Permanent obstruction
should be noted.
- Interior filling of cooling tower should be clean and free of foreign
  materials such as scale, algae, or tar.
- Water level in the tower basin should be maintained at the proper
  level. Visually check the basin sump during full flow to determine
  that the centrifugal action of the water is not causing entrainment
  of air, which could cause pump cavitation.
- Water-circulating pumps should be tested with full flow through
  the tower. If flow exceeds design, it should be valved down until
  design is reached. The flow that is finally set should be main-
tained throughout the test period. All valves, except necessary
  balancing valves, should be in the full-open position.
- If makeup and blowdown have facilities to determine flow, set
  them to design flow at full flow through the tower. If flow cannot
  be determined, shut off both.

Instruments

Testing and balancing agencies provide instruments to perform
the required tests. Mechanical contractors provide and install all
components such as orifice plates, venturis, balancing valves, ther-
- mometer wells, gage cocks, and corporation cocks. Designers spec-
ify measuring point locations.

Instruments used should be recently calibrated as follows:

Temperature

- Thermometer with divisions of 0.1 K in a proper well for water
  should be used.
- Thermometer with solar shield and 0.1 K divisions or thermocou-
  ple with 0.1 K readings having mechanical aspiration for wet-bulb
  readings should be used.
- Sling psychrometer may be used for rough checks.
- Thermometer with 0.1 K divisions should be used for dry-bulb
  readings.

Water Flow

- Orifice, venturi, and balancing valve pressure drops can be read us-
ing a manometer or a recently calibrated differential pressure gage.
- Where corporation cocks are installed, a pitot tube and manome-
ter traverse can be made by trained technicians.

Test Method

The actual test consists of the following steps:

1. Conduct water flow tests to determine volume of water on the
tower, and volume of makeup and blowdown water.
2. Conduct water temperature tests, if possible, in suitable wells
as close to the tower as possible. Temperature readings at
pumps or the condensing element are not acceptable in tower
evaluation. If there are no wells, surface pyrometer readings
are acceptable.
3. Take makeup water volume and temperature readings at the
point of entry into the tower.
4. Take blowdown volume and temperature readings at the point
of discharge from the tower.
5. Take inlet and outlet dry- and wet-bulb temperature readings
using the prescribed instruments.
   (a) Use wet-bulb entering and leaving temperatures to deter-
   mine tower actual performance against design.
   (b) Use wet- and dry-bulb entering and leaving temperatures to
determine evaporation involved.
6. If the tower has a ducted inlet or outlet where a reasonable duct
  traverse can be made, use this air volume as a cross-check of
tower performance.
7. Take wet- and dry-bulb temperature readings between 1 and
  1.5 m from the tower on all inlet sides. These readings shall be
taken halfway between the base and the top of the inlet louvers
at no more than 1.5-m spacing horizontally; then they should
be averaged. Note any unusual inlet conditions.
8. Note wind velocity and direction at the time of test.
9. Take test readings continually with a minimum time lapse
between readings.
10. If the first test indicates a tower deficiency, perform two addi-
tional tests to verify the original readings.

TEMPERATURE CONTROL VERIFICATION

The test and balance technician should work closely with the
temperature control installer to ensure that the project is completed
correctly. The balancing technician needs to verify proper operation
of the control and communicate findings back to the agency respon-
sible for ensuring that the controls have been installed correctly.
This is usually the HVAC system designer, although others may be
involved. Generally, the balancing technician does not adjust, relo-
cate, or calibrate the controls. However, this is not always the case,
and differences do occur with VAV terminal unit controllers. The
balancing technician should be familiar with the specifications and
design intent of the project so that all responsibilities are understood.

During the design and specification phase of the project, the
designer should specify verification procedures for the controls and
responsibilities for the contractor who installs the temperature
controls. It is important that the designer specify (1) the degree of
coordination between the installer of the control and the balancing
technician and (2) the testing responsibilities of each.

Verification of control operation starts with the balancing tech-
nician reviewing the submitted documents and shop drawings of the
control system. In some cases the controls technician should
instruct the balancing technician in the operation of certain control
elements, such as digital terminal unit controllers. This is followed
by schedule coordination between the control and balancing techni-
cians. In addition, the balancing technician and the controls techni-
cian need to work together when reviewing the operation of some
sections of the HVAC system (not all). This is particularly important
with regard to VAV systems and the setting of the flow measurement
parameters in digital terminal unit controllers.

Major mechanical systems should be verified after the testing,
adjusting, and balancing is completed. The control system should
be operated in stages to prove its capability of matching system
capacity to varying load conditions. Mechanical subsystem con-
trollers should be verified when balancing data is collected, con-
sidering that the entire system may not be completely functional at
the time of verification. Testing and verification should account for seasonal variations; tests should be performed under varying outdoor loads to assure operational performance. A retest of a random sampling of terminal units may be desirable to verify the work of the control technician.

Suggested Procedures

Although both electrical and pneumatic controls are used, the following verification procedures may be used with either.

1. Obtain design drawings and documentation, and become well acquainted with the design intent and specified responsibilities.
2. Obtain copies of approved control shop drawings.
3. Compare design to installed field equipment.
4. Obtain recommended operating and test procedures from the manufacturers.
5. Verify with the control contractor that all controllers are calibrated and commissioned.
6. Check the location of transmitters and controllers. Note adverse conditions that would affect control, and suggest relocation as necessary.
7. Note settings on controllers. Note discrepancies between set point for controller and actual measured variable.
8. Verify operation of all limiting controllers, positioners and relays (e.g., high- and low-temperature thermostats, high- and low-differential pressure switches, etc.).
9. Activate controlled devices, checking for free travel and proper operation of stroke for both dampers and valves. Verify normally open (NO) or normally closed (NC) operation.
10. Verify sequence of operation of controlled devices. Note line pressures and controlled device positions. Correlate to air or water flow measurements. Note speed of response to step change.
11. Confirm interaction of electrically operated switch transducers.
12. Confirm interaction of interlock and lockout systems.
13. Coordinate balancing and control technicians’ schedules to avoid duplication of work and testing errors.

Pneumatic System Modifications

1. Verify main control supply air pressure and observe compressor and dryer operation.
2. For hybrid systems using electronic transducers for pneumatic actuation, modify procedures accordingly.

Electronic Systems

1. Monitor voltages of power supply and controller output. Determine whether the system operates on a grounded or non-grounded power supply, and check condition. Although electronic controls now have more robust electronic circuits, improper grounding can cause functional variation in the controller and actuator performance from system to system.
2. Note operation of electric actuators using spring return. Generally, actuators should be under control and use springs only upon power failure to return to a fail-safe position.

Direct Digital Controllers

Direct digital control (DDC) offers nontraditional challenges to the balancing technician. Many of the control devices, such as sensors and actuators, are the same as those in electronic and pneumatic systems. Currently DDC is dominated by two types of controllers—one is fully programmable and one is application-specific. Fully programmable controllers offer a group of functions that are linked together in an applications program to control a system such as an air-handling unit. Application-specific controllers are functionally defined with the programming necessary to carry out the functions required for a system, but not all of the adjustments and settings are defined. Both types of controllers and their functions have some variations. One of the functions is adaptive control, which includes control algorithms that automatically adjust settings of various controller functions.

The balancing technician must understand the controller functions so that they do not interfere with the test and balance functions. The balancing technician does not need to be literate in computer programming, although it does help. When testing the DDC, the following steps should be included:

1. Obtain controller application program. Discuss application of the designer’s sequence with the control programmer.
2. Coordinate testing and adjustment of controlled systems with mechanical systems testing. Avoid duplication of efforts between technicians.
3. Coordinate storage (e.g., saving to central DDC database and controller memory) of all required system adjustments with control technician.

In cases where the balancing agency is required to test discrete points in the control system, the following steps are necessary:

1. Establish criteria for test with the designer.
2. Use reference standards that test the end device through the entire controller chain (e.g., device, wiring, controller, communications, and operator monitoring device). An example of this would be using a dry block temperature calibrator (a testing device that allows a temperature to be set, monitored, and maintained in a small chamber) to test a space temperature sensor. The sensor is installed with extra wire so that it may be removed from the wall and placed in the calibrator chamber. After the system is thermally stabilized, the temperature is read at the controller and the central monitor, if installed.
3. Report findings of reference and all points of reading.

FIELD SURVEY FOR ENERGY AUDIT

An energy audit is an organized survey of a specific building to identify and measure all energy uses, determine probable sources of energy losses, and list energy conservation opportunities. This is usually performed as a team effort under the direction of a qualified energy engineer. The field data can be gathered by firms employing technicians trained in testing, adjusting, and balancing.

Instruments

To determine a building’s energy use characteristics, an accurate measurement of existing conditions must be made with proper instruments. Accurate measurements point out opportunities to reduce waste and provide a record of the actual conditions in the building before energy conservation measures were taken. They provide a compilation of installed equipment data and a record of equipment performance prior to changes. Judgments will be made based on the information gathered during the field survey; that which is not accurately measured cannot be properly evaluated.

Generally, the instruments required for testing, adjusting, and balancing are sufficient for energy conservation surveying. Possible additional instruments include a power factor meter, a light meter, combustion testing equipment, refrigeration gages, and equipment for recording temperatures, fluid flow rates, and energy use over time. Only high-quality instruments should be used.

Observation of system operation and any information the technician can obtain from the operating personnel pertaining to the operation should be included in the report.

Data Recording

Organized record keeping is extremely important. A camera is also helpful. Photographs of building components and mechanical and electrical equipment can be reviewed later when the data is analyzed.
Data sheets needed for energy conservation field surveys contain different and, in some cases, more comprehensive information than those used for testing, adjusting, and balancing. Generally, the energy engineer determines the degree of fieldwork to be performed; data sheets should be compatible with the instructions received.

Building Systems

The most effective way to reduce building energy waste is to identify, define, and tabulate the energy load by building system. For this purpose, load is defined as the quantity of energy used in a building, or by one of its subsystems, for a given period. By following this procedure, the most effective energy conservation opportunities can be achieved more quickly because high priorities can be assigned to systems that consume the most energy.

A building can be divided into nonenergized systems and energized systems. Nonenergized systems do not require outside energy sources such as electricity and fuel. Energized systems (e.g., mechanical and electrical systems) require outside energy. Energized and nonenergized systems can be divided into subsystems defined by function. Nonenergized subsystems are (1) building site, envelope, and interior; (2) building use; and (3) building operation.

Building Site, Envelope, and Interior. The site, envelope, and interior should be surveyed to determine how they can be modified to reduce the building load that the mechanical and electrical systems must meet without adversely affecting the building’s appearance. It is important to compare actual conditions with conditions assumed by the designer, so that the mechanical and electrical systems can be adjusted to balance their capacities to satisfy actual needs.

Building Use. These loads can be classified as people occupancy loads or people operation loads. People occupancy loads are related to schedule, density, and mixing of occupancy types (e.g., process and office). People operation loads are varied, and include (1) operation of manual window shading devices; (2) setting of room thermostats; and (3) conservation-related habits such as turning off lights, closing doors and windows, turning off energized equipment when not in use, and not wasting domestic hot or chilled water.

Building Operation. This subsystem consists of the operation and maintenance of all the building subsystems. The load on the building operation subsystem is affected by factors such as (1) the time at which janitorial services are performed, (2) janitorial crew size and time required to clean, (3) amount of lighting used to perform janitorial functions, (4) quality of the equipment maintenance program, (5) system operational practices, and (6) equipment efficiencies.

Building Energized Systems

The energized subsystems of the building are generally plumbing, heating, ventilating, cooling, space conditioning, control, electrical, and food service. Although these systems are interrelated and often use common components, logical organization of data requires evaluating the energy use of each subsystem as independently as possible. In this way, proper energy conservation measures for each subsystem can be developed.

Process Loads

In addition to building subsystem loads, the process load in most buildings must be evaluated by the energy field auditor. Most tasks not only require energy for performance, but also affect the energy consumption of other building subsystems. For example, if a process releases large amounts of heat to the space, the process consumes energy and also imposes a large load on the cooling system.

Guidelines for Developing a Field Study Form

A brief checklist follows that outlines requirements for a field study form needed to conduct an energy audit.

**Inspection and Observation of All Systems.** Record physical and mechanical condition of the following:

- Fan blades, fan scroll, drives, belt tightness, and alignment
- Filters, coils, and housing tightness
- Ductwork (equipment room and space, where possible)
- Strainers
- Insulation ducts and piping
- Makeup water treatment and cooling tower

**Interview of Physical Plant Supervisor.** Record answers to the following survey questions:

- Is the system operating as designed? If not, what changes have been made to ensure its performance?
- Have there been modifications or additions to the system?
- If the system has been a problem, list problems by frequency of occurrence.
- Are any systems cycled? If so, which systems and when, and would building load permit cycling systems?

**Recording System Information.** Record the following system/equipment identification:

- Type of system—single-zone, multizone, double-duct, low- or high-velocity, reheat, variable volume, or other
- System arrangement—fixed minimum outside air, no relief, gravity or power relief, economizer gravity relief, exhaust return, or other
- Air-handling equipment—fans (supply, return, and exhaust): manufacturer, model, size, type, and class; dampers (vortex, scroll, or discharge); motors: manufacturer, power requirement, full load amperes, voltage, phase, and service factor
- Chilled and hot water coils—area, tubes on face, fin spacing, and number of rows (coil data necessary when shop drawings are not available)
- Terminals—high-pressure mixing box: manufacturer, model, and type (reheat, constant volume, variable volume, induction); grilles, registers, and diffusers: manufacturer, model, style, and loss coefficient to convert field-measured velocity to flow rate
- Main heating and cooling pumps, over 3.5 kW—manufacturer, pump service and identification, model, size, impeller diameter, speed, flow rate, head at full flow, and head at no flow; motor data: power, speed, voltage, amperes, and service factor
- Refrigeration equipment—chiller manufacturer, type, model, serial number, nominal tons, input power, total heat rejection, motor (kilowatts, amperes, volts), chiller pressure drop, entering and leaving chilled water temperatures, condenser pressure drop, condenser entering and leaving water temperatures, running amperes and volts, no-load running amperes and volts
- Cooling tower—manufacturer, size, type, nominal cooling capacity, range, flow rate, and entering wet-bulb temperature
- Heating equipment—boiler (small through medium) manufacturer, fuel, energy input (rated), and heat output (rated)

**Recording Test Data.** Record the following test data:

- Systems in normal mode of operation (if possible)—fan motor: running amperes and volts and power factor (over 3.5 kW); fan: speed, total air (pitot-tube traverse where possible), and static pressure (discharge static minus inlet total); static profile drawing (static pressure across filters, heating coil, cooling coil, and dampers); static pressure at ends of runs of the system (identifying locations)
- Cooling coils—entering and leaving dry- and wet-bulb temperatures, entering and leaving water temperatures, coil pressure drop (where pressure taps permit and manufacturer’s ratings can be...
Testing for sound and vibration ensures that equipment is operating satisfactorily and that no objectionable noise and vibration are transmitted to the building structure and occupied space. Although sound and vibration are specialized fields that require expertise not normally developed by the HVAC engineer, the procedures to test HVAC are relatively simple and can be performed with a minimum of equipment by following the steps outlined in this section. Although this section provides useful information for resolving common noise and vibration problems, Chapter 46 should be consulted for information on problem solving or the design of HVAC.

Testing for Sound

Present technology does not permit tests of whether equipment is operating with desired sound levels. Field tests can only determine sound pressure levels, and equipment ratings are almost always in terms of sound power levels. Until new techniques are developed, the testing engineer can only determine (1) whether sound pressure levels are in desired limits and (2) which equipment, systems, or components are the source of excessive or disturbing transmission.

Sound-Measuring Instruments

Although an experienced listener can often determine whether systems are operating in an acceptably quiet manner, sound-measuring instruments are necessary to determine whether system noise levels are in compliance with specified criteria, and if not, to obtain and report detailed information to evaluate the cause of noncompliance. Instruments normally used in field testing are as follows:

- **Precision sound level meter** is used to measure sound pressure level. The most basic sound level meters measure overall sound pressure level and have up to three weighted scales that provide limited filtering capability. The instrument is useful in assessing outdoor noise levels in certain situations and can provide limited information on the low-frequency content of overall noise levels, but it provides insufficient information for problem diagnosis and solution. Its usefulness in evaluating indoor HVAC sound sources is thus limited.

- **Sound analyzers** provide detailed information about the sound pressure levels at various frequencies through filtering networks. The most popular sound analyzers are the octave band and center frequency, which break the sound into the eight octave bands of audible sound. Instruments are also available for 0.33, 0.1, and narrower spectrum analysis; however, these are primarily for laboratory and research applications. Sound analyzers (octave band or center frequency) are required where specifications are based on noise criteria (NC) curves or similar frequency criteria and for problem jobs where a knowledge of frequency is necessary to determine proper corrective action.

- **Personal computers** are a versatile sound-measuring tool. Software used in conjunction with portable computers has all the functional capabilities described previously, plus many that previously required a fully equipped acoustical laboratory. This type of sound-measuring system is many times faster and much more versatile than conventional sound level meters. With suitable accessories, it can also be used to evaluate vibration levels.

- A **stethoscope** is an invaluable instrument in measuring sound levels and tracking down problems, as it enables the listener to determine the direction of the sound source.

- Regardless of which sound-measuring system is used, it should be calibrated prior to each use. Some systems have built-in calibrators, while others use external calibrators. Much information is available on the proper application and use of sound-measuring instruments.

- **Air noise**, caused by air flowing at a velocity of over 5 m/s or by winds over 19 km/h, can cause substantial error in sound measurements due to wind effect on the microphone. For outdoor measurements or in places where air movement is prevalent, either a wind screen for the microphone or a special microphone is required.

Sound Level Criteria

In the absence of specified values, the testing engineer must determine whether sound levels are within acceptable limits. Note that complete absence of noise is seldom a design criterion, except for certain critical locations such as sound and recording studios. In most locations, a certain amount of noise is desirable to mask other noises and provide speech privacy; it also provides an acoustically pleasing environment, since few people can function effectively in extreme quiet. Table 3 in Chapter 3 of the 1997 ASHRAE Handbook—Fundamentals lists typical sound pressure levels. In determining allowable HVAC equipment noise, it is as inappropriate to demand 30 dB for a factory where the normal noise level is 75 dB as it is to specify 60 dB for a private office where normal noise level might be 35 dB.

Most field sound-measuring instruments and techniques yield an accuracy of ±3 dB, the smallest difference in sound pressure level that the average person can discern. A reasonable tolerance for sound criteria is 5 dB; if 35 dBA is considered the maximum allowable noise, the design engineer should specify 30 dBA.

The measured sound level of any location is a combination of all sound sources present, including sound generated by HVAC equipment as well as sound from other sources such as plumbing systems and fixtures, elevators, light ballasts, and outside noises. In testing for sound, all sources from other than HVAC equipment are considered background or ambient noise.
Testing, Adjusting, and Balancing

Background sound measurements generally have to be made (1) when the specification requires that the sound levels from HVAC equipment only, as opposed to the sound level in a space, not exceed a certain specified level; (2) when the sound level in the space exceeds a desirable level, in which case the noise contributed by the HVAC system must be determined; and (3) in residential locations where little significant background noise is generated during the evening hours and where generally low allowable noise levels are specified or desired. Because background noise from outside sources such as vehicular traffic can fluctuate widely, sound measurements for residential locations are best made in the normally quiet evening hours.

Sound Testing

Ideally, a building should be completed and ready for occupancy before sound level tests are taken. All spaces in which readings will be taken should be furnished with drapes, carpeting, and furniture, as these affect the room absorption and the subjective quality of the sound. In actual practice, since most tests have to be conducted before the space is completely finished and furnished for final occupancy, the testing engineer must make some allowances. Because furnishings increase the absorption coefficient and reduce to 4 dB the sound pressure level that can be expected between most live and dead spaces, the following guidelines should suffice for measurements made in unfurnished spaces. If the sound pressure level is 5 dB or more over specified or desired criterion, it can be assumed that the criterion will not be met, even with the increased absorption provided by furnishings. If the sound pressure level is 0 to 4 dB greater than specified or desired criterion, recheck when the room is furnished to determine compliance.

Follow this general procedure:

1. Obtain a complete set of accurate, as-built drawings and specifications, including duct and piping details. Review specifications to determine sound and vibration criteria and any special instructions for testing.
2. Visually check for noncompliance with plans and specifications, obvious errors, and poor workmanship. Turn system on for aural check. Listen for noise and vibration, especially duct leaks and loose fittings.
3. Adjust and balance equipment, as described in other sections, so that final acoustical tests are made with the HVAC as it will be operating. It is desirable to perform acoustical tests for both summer and winter operation, but where this is not practical, make tests for the summer operating mode, as it usually has the potential for higher sound levels. Tests must be made for all mechanical equipment and systems, including standby.
4. Check calibration of instruments.
5. Measure sound levels in all areas as required, combining measurements as indicated in item 3 if equipment or systems must be operated separately. Before final measurements are made in any particular area, survey the area using an A-weighted scale reading (dBA) to determine the location of the highest sound pressure level. Indicate this location on a testing form, and use it for test measurements. Restrict the preliminary survey to determine location of test measurements to areas that can be occupied by standing or sitting personnel. For example, measurements would not be made directly in front of a diffuser located in the ceiling, but they would be made as close to the diffuser as standing or sitting personnel might be situated. In the absence of specified sound criteria, the testing engineer should measure sound pressure levels in all occupied spaces to determine compliance with criteria indicated in Chapter 46 and to locate any sources of excessive or disturbing noise.
6. Determine whether background noise measurements must be made.

(a) If specification requires determination of sound level from HVAC equipment only, it will be necessary to take background noise readings by turning HVAC equipment off.
(b) If specification requires compliance with a specific noise level or criterion (e.g., sound levels in office areas shall not exceed 35 dBA), ambient noise measurements must be made only if the noise level in any area exceeds the specified value.
(c) For residential locations and areas requiring very low noise, such as sound recording studios and locations that are used during the normally quieter evening hours, it is usually desirable to take sound measurements in the evening and/or take ambient noise measurements.

7. For outdoor noise measurements to determine noise radiated by outdoor or roof-mounted equipment such as cooling towers and condensing units, the section on Sound Control for Outdoor Equipment in Chapter 46 and the section on Testing for Vibration in this chapter is desirable before attempting to resolve any noise and vibration transmission problems. The following is intended as an overall guide rather than a detailed problem-solving procedure.

All noise transmission problems can be evaluated in terms of the source-path-receiver concept. Objectionable transmission can be resolved by (1) reducing the noise at the source by replacing defective equipment, repairing improper operation, proper balancing and adjusting, and replacing with quieter equipment; (2) attenuating the paths of transmission with silencers, vibration isolators, and wall treatment to increase transmission loss; and (3) reducing or masking objectionable noise at the receiver by improving room absorption or introducing a non objectionable masking sound. The following discussion includes (1) ways to identify actual noise sources using simple instruments or no instruments and (2) possible corrections.

When troubleshooting in the field, the engineer should listen to the offending sound. The best instruments are no substitute for careful listening, as the human ear has the remarkable ability to identify certain familiar sounds such as bearing squeak or duct leaks and is able to discern small changes in frequency or sound character that might not be apparent from meter readings only. The ear is also a good direction and range finder; because noise generally gets louder as one approaches the source, direction can often be determined by turning the head. Hands can also identify noise sources. Air jets from duct leaks can often be felt, and the sound of rattling or vibrating panels or parts often changes or stops when these parts are touched.

In trying to locate noise sources and transmission paths, the engineer should consider the location of the affected area. In areas that are remote from equipment rooms containing significant noise producers but adjacent to shafts, noise is usually the result of structure-borne transmission through pipe and duct supports and anchors. In areas adjoining, above, or below equipment rooms, noise is usually caused by openings (acoustical leaks) in the separating floor or wall or by improper, ineffective, or maladjusted vibration isolation systems.

Unless the noise source or path of transmission is quite obvious, the best way to identify it is by eliminating all sources systematically as follows:

1. Turn off all equipment to make sure that the objectionable noise is caused by the HVAC. If the noise stops, the HVAC components (compressors, fans, and pumps) must be operated
separately to determine which are contributing to the objectionable noise. Where one source of disturbing noise predominates, the test can be performed starting with all equipment in operation and turning off components or systems until the disturbing noise is eliminated. Tests can also be performed starting with all equipment turned off and operating various component equipment singularly, which permits evaluation of noise from each individual component.

Any equipment can be termed a predominant noise source if, when the equipment is shut off, the sound level drops 3 dBA or if, when measurements are taken with equipment operating individually, the sound level is within 3 dBA of the overall objectionable measurement.

When a sound level meter is not used, it is best to start with all equipment operating and shut off components one at a time because the ear can reliably detect differences and changes in noise but not absolute levels.

2. When some part of the HVAC system is established as the source of the objectionable noise, try to further isolate the source. By walking around the room, determine whether the noise is coming through the air outlets or returns, the hung ceiling, or the floors or walls.

3. If the noise is coming through the hung ceiling, check that ducts and pipes are isolated properly and not touching the hung ceiling supports or electrical fixtures, which would provide large noise radiating surfaces. If ducts and pipes are the source of noise and are isolated properly, the possible remedies to reduce the noise are changing flow conditions, installing silencers, and/or wrapping the duct or pipe with an acoustical barrier such as a lead blanket.

4. If noise is coming through the walls, ceiling, or floor, check for any obstructions to adjoining shafts or equipment rooms, and check vibration isolation systems to ensure that there is no structure-borne transmission from nearby equipment rooms or shafts.

5. Noise traced to air outlets or returns usually requires careful evaluation by an engineer or acoustical consultant to determine the source and proper corrective action. In general, air outlets can be selected to meet any acoustical design goal by keeping the velocity sufficiently low. For any given outlet, the sound level increases about 2 dB for each 10% increase in airflow velocity over the vanes, and doubling the velocity increases the sound level by about 16 dB. Also, the sound approach conditions caused by improperly located control dampers or improperly sized diffuser necks can easily increase sound levels by 10 to 20 dB.

A simple yet effective instrument that aids in locating noise is a microphone mounted on a pole. It can be used to localize noises in hard-to-reach places, such as hung ceilings and behind heavy furniture.

6. If the noise is traced to an air outlet, measure the A-sound level close to it but with no air blowing against the microphone. Then, remove the inner assembly or core of the air outlet and repeat the measurement with equipment operating. If the second reading is more than 3 dB below the first, a significant amount of noise is caused by airflow over the vanes of the diffuser or grille. In this case, check whether the system is balanced properly. As little as 10% too much air will increase the sound generated by an air outlet by 2.5 dB. As a last resort, a larger air outlet could be substituted to obtain lower airflow velocities and hence less turbulence for the same air quality.

Before this is considered, however, the air approach to the outlet should be checked.

Noise far exceeding the normal rating of a diffuser or grille is generated when a throttled damper is installed close to it. Air jets impinge on the vanes or cones of the outlet and produce edge tones similar to the hiss heard when blowing against the edge of a ruler. The material of the vanes has no effect on this noise, although loose vanes may cause additional noise from vibration.

When balancing air outlets with integral volume dampers, consider the static pressure drop across the damper, as well as the air quantity. Separate volume dampers should be installed sufficiently upstream from the outlet that there is no jet impingement. Plenum inlets should be brought in from the side, so that the jets do not impinge on the outlet vanes.

7. If the air outlets are eliminated as sources of excessive noise, inspect the fan room. If possible, change the fan speed by about 10%. If resonance is involved, this small change can make a significant difference.

8. Sometimes fans are poorly matched to the system. If a belt-driven fan delivers air at a higher static pressure than is needed to move the design air quantity through the system, reduce the fan speed by changing sheaves. If the fan does not deliver enough air, consider increasing the fan speed only after checking the duct system for unavoidable losses. Turbulence in the air approach to the fan inlet not only increases the fan sound generation, but decreases its air capacity. Other parts that may cause excessive turbulence are dampers, duct bends, and sudden enlargements or contractions of the duct.

When investigating fan noise, seek assistance from the supplier or manufacturer of the fan.

9. If additional acoustical treatment is to be installed in the ductwork, obtain a frequency analysis. This involves the use of an octave-band analyzer and should generally be left to a trained acoustician.

TESTING FOR VIBRATION

Vibration testing is necessary to ensure that (1) equipment is operating within satisfactory vibration levels and (2) objectionable vibration and noise are not transmitted to the building structure. Although these two factors are interrelated, they are not necessarily interdependent. A different solution is required for each, and it is essential to test both the isolation and vibration levels of equipment.

General Procedure

The general order of steps in vibration testing are as follows:

1. Make a visual check of all equipment for obvious errors that must be corrected immediately.
2. Make sure all isolation is free floating and not short-circuited by any obstruction between equipment or equipment base and building structure.
3. Turn on the system for an aural check of any obviously rough operation. Check bearings with a stethoscope. Bearing check is especially important because bearings can become defective in transit and/or if equipment was not properly stored, installed, or maintained. Defective bearings should be replaced immediately to avoid damage to the shaft and other components.
4. Adjust and balance equipment and systems so that final vibration tests are made on equipment as it will actually be operating.
5. Test equipment vibration.

Instruments

Although instruments are not required to test vibration isolation systems, they are essential to test equipment vibration properly. Sound level meters and computer-driven sound-measuring systems are the most useful instruments for measuring and evaluating vibration. Usually, they are fitted with accelerometers or vibration pickups for a full range of vibration measurement and analysis. Other instruments used for testing vibration in the field are described as follows.
Reed vibrometers are relatively inexpensive instruments often used for testing vibration, but relative inaccuracy limits their usefulness. Vibrometers are moderately priced instruments that measure vibration amplitude by means of a light beam projected on a graduated scale. Vibration meters are moderately priced electronic instruments that measure vibration amplitude on a meter scale and are simple to use. Vibrographs are moderately priced mechanical instruments that measure both amplitude and frequency. They are useful for analysis and testing because they provide a chart recording showing amplitude, frequency, and actual wave form of vibration. They can be used for simple yet accurate determination of the natural frequency of shafts, components, and systems by a bump test. Vibration analyzers are relatively expensive electronic instruments that measure amplitude and frequency, usually incorporating a variable filter. Strobe lights are often used with many of the aforementioned instruments for analyzing and balancing rotating equipment. Stethoscopes that amplify sound are available as inexpensive mechanic's type (basically, a standard stethoscope with a probe attachment); relatively inexpensive types incorporating a tuneable filter; and moderately priced powered types that electronically amplify sound and provide some type of meter and/or chart recording. Stethoscopes are often used to determine whether bearings are bad.

The choice of instruments depends on the test. A stethoscope should be part of every tester's kit as it is one of the most practical, yet least expensive, instruments and one of the best means of checking bearings. Vibrometers and vibration meters can be used to measure vibration amplitude as an acceptance check. Since they cannot measure frequency, they cannot be used for analysis and primarily function as a go-no-go instrument. The best acceptance criteria consider both amplitude and frequency. However, because vibrometers and vibration meters are moderately priced and easy to use, they are widely used. Anyone seriously concerned with vibration testing should use an instrument that can determine frequency as well as amplitude, such as a vibrograph or vibration analyzer.

Testing Vibration Isolation

The following steps should be taken to ensure that vibration isolators are functioning properly:

1. Ensure that the equipment is free floating by applying an unbalanced load, which should cause the equipment to move freely and easily. On floor-mounted equipment, check that there are no obstructions between the base or foundation and the building structure that would cause transmission while still permitting equipment to rock relatively freely because of the application of an unbalanced force. On suspended equipment, check that hanger rods are not touching the hanger. Rigid connections such as pipes and ducts can prohibit mounts from functioning properly and from providing a transmission path. Note that the fact that the equipment is free floating does not mean that the isolators are functioning properly. For example, a 500 rpm fan installed on isolators having a natural frequency of 500 cycles per minute (8.33 Hz) could be free floating but would actually be in resonance, resulting in transmission to the building and excessive movement.

2. Determine whether isolators are adjusted properly and providing desired isolation efficiency. All isolators supporting a piece of equipment should have approximately the same deflection (i.e., they should be compressed the same under the equipment). If not, they have been improperly adjusted, installed, or selected; this should be corrected immediately. Note that isolation efficiency cannot be checked by comparing vibration amplitude on equipment to amplitude on the structure.

The only accurate check of isolation efficiencies is to compare vibration measurements of equipment operating with isolators to measurements of equipment operating without isolators. Because this type of test is usually impractical, it is better to check whether the isolator’s deflection is as specified and whether the specified or desired isolation efficiency is being provided. Figure 15 shows natural frequency of isolators as a function of deflection and indicates the theoretical isolation efficiencies for various frequencies at which the equipment operates.

While it is easy to determine the deflection of spring mounts by measuring the difference between the free heights with a ruler (information as shown on submittal drawings or available from a manufacturer), such measurements are difficult with most pad or rubber mounts. Further, most pad and rubber mounts do not lend themselves to accurate determination of natural frequency as a function of deflection. For such mounts, the most practical approach is to check that there is no excessive vibration of the base and no noticeable or objectionable vibration transmission to the building structure.

If isolators are in the 90% efficiency range, and there is transmission of vibration to the building, then there is no flanking path of transmission, such as connecting piping or obstruction, under the base.

Testing Equipment Vibration

Testing equipment vibration is necessary as an acceptance check to determine whether equipment is functioning properly and to ensure that objectionable vibration and noise are not transmitted. Although a person familiar with equipment can determine when it is...
Evaluating Vibration Measurements

Procedure for Testing Equipment Vibration

The following steps should be taken to ensure that equipment vibration is properly tested:

1. Determine operating speeds of equipment from nameplates, drawings, or a speed-measuring device such as a tachometer or strobe, and indicate them on the test form. For any equipment where the driving speed (motor) is different from the driven speed (fan wheel, rotor, impeller) because of belt drive or gear reducers, indicate both driving and driven speeds.

2. Determine acceptance criteria from specifications, and indicate them on the test form. If specifications do not provide criteria, use those shown in Chapter 46.

3. Ensure that the vibration isolation system is functioning properly (see the section on Vibration Analysis).

4. Operate equipment and make visual and aural checks for any apparent rough operation. Check all bearings with a stethoscope. Any defective bearings, misalignment, or obvious rough operation should be corrected before proceeding further. If not corrected, equipment should be considered unacceptable.

5. Measure and record vibration at bearings of driving and driven components in horizontal, vertical, and, if possible, axial directions. At least one axial measurement should be made for each rotating component (fan motor, pump motor).

6. Evaluate measurements as described below.

Evaluating Vibration Measurements

Vibration measurements are made as follows:

Amplitude Measurement. When specification for acceptable equipment vibration is based on amplitude measurements only, and measurements are made with an instrument that measures only amplitude (e.g., a vibration meter or vibrometer):

1. No measurement should exceed specified values or values shown in Tables 43 or 44 of Chapter 46. Taking into consideration reduced values for equipment installed on inertia blocks.

2. No measurement should exceed values shown in Tables 43 or 44 of Chapter 46 for driving and driven speeds, taking into consideration reduced values for equipment installed on inertia blocks. For example, with a belt-driven fan operating at 800 rpm and having an 1800 rpm driving motor, amplitude measurements at fan bearings must be in accordance with values shown for 800 cpm (13.3 Hz), and measurements at motor bearings must be in accordance with values shown for 1800 cpm (30 Hz). If measurements at motor bearings exceed specified values, take measurements of the motor only with belts removed to determine whether there is feedback vibration from the fan.

3. No axial vibration measurement should exceed maximum radial (vertical or horizontal) vibration at the same location.

Amplitude and Frequency Measurement. When specification for acceptable equipment vibration is based on both amplitude and frequency measurements, and measurements are made with instruments that measure both amplitude and frequency (e.g., a vibrorgraph or vibration analyzer):

1. Amplitude measurements at driving and driven speeds should not exceed specified values or values shown in Tables 43 or 44 of Chapter 46 taking into consideration reduced values for equipment installed on inertia blocks. Measurements that exceed acceptable amounts may be evaluated as explained in the section on Vibration Analysis.

2. Axial vibration measurements should not exceed maximum radial (vertical or horizontal) vibration at the same location.

3. The presence of any vibration at frequencies other than driving or driven speeds is generally reason to rate operation unacceptable, and such vibration should be analyzed as explained in the section on Vibration Analysis.

Vibration Analysis

The following guide covers most vibration problems that may be encountered.

Axial Vibration Exceeds Radial Vibration. When the amplitude of axial vibration (parallel with shaft) at any bearing exceeds radial vibration (perpendicular to shaft—vertical or horizontal), it usually indicates misalignment. This is most common on direct-driven equipment because flexible couplings accommodate parallel and angular misalignment of shafts. Such misalignment can generate forces that cause axial vibration. Axial vibration can cause premature bearing failure, so misalignment should be checked carefully and corrected promptly. Other possible causes of large-amplitude axial vibration are resonance, defective bearings, insufficient rigidity of bearing supports or equipment, and loose hold-down bolts.

Vibration Amplitude Exceeds Allowable Tolerance at Rotational Speed. The allowable vibration limits established by Table 41 of Chapter 46 are based on vibration caused by rotor imbalance, which results in vibration at rotational frequency. While vibration caused by imbalance must be at the frequency at which the part is rotating, a vibration at rotational frequency does not have to be caused by imbalance. An unbalanced rotating part develops centrifugal force, which causes it to vibrate at rotational frequency. Vibration at rotational frequency can also result from other conditions such as a bent shaft, an eccentric sheave, misalignment, and resonance. If vibration amplitude exceeds allowable tolerance at rotational frequency, the following steps should be taken before performing field balancing of rotating parts.

1. Check vibration amplitude as equipment goes up to operating speed and as it coasts to a stop. Any significant peaks at or near operating speed, as shown in Figure 16, indicate a probable...
condition of resonance, i.e., some part having a natural frequency close to the operating speed, resulting in greatly amplified levels of vibration.

A bent shaft or eccentricity usually causes imbalance that results in significantly higher vibration amplitude at lower speeds, as shown in Figure 17, whereas vibration caused by imbalance generally increases as speed increases.

If a bent shaft or eccentricity is suspected, check the dial indicator. A bent shaft or eccentricity between bearings as shown in Figure 18A can usually be compensated for by field balancing, although some axial vibration might remain. Field balancing cannot correct vibration caused by a bent shaft on direct-connected equipment, on belt-driven equipment where the shaft is bent at the location of sheave, or if the sheave is eccentric (Figure 18B). This is because the center-to-center distance of the sheaves will fluctuate, each revolution resulting in vibration.

2. For belt- or gear-driven equipment where vibration is at rotational frequency close to the operating speed, it is best to disconnect the drive to perform tests. If the vibration amplitude of the motor operating by itself does not exceed specified or allowable values, excessive vibration (when the drive is connected) is probably a function of bent shaft, misalignment, eccentricity, resonance, or loose hold-down bolts.

3. Vibration caused by imbalance can be corrected in the field by firms specializing in this service or by testing personnel if they have appropriate equipment and experience.

Vibration at Other than Rotational Frequency. Vibration at frequencies other than driving and driven speeds is generally considered unacceptable. Table 4 shows some common conditions that can cause vibration at other than rotational frequency.

**Resonance.** If resonance is suspected, determine which part of the system is in resonance.

Isolation Mounts. The natural frequency of the most commonly used spring mounts is a function of spring deflection, as shown in Figure 11 in Chapter 7 of the 1997 ASHRAE Handbook—Fundamentals, and it is relatively easy to calculate by determining the difference between the free and operating height of the mount, as explained in the section on Testing Vibration Isolation. This technique cannot be applied to rubber, pad, or fiberglass mounts, which have a natural frequency in the 5 to 50 Hz range. Natural frequency for such mounts is determined by a bump test. Any resonance with isolators should be immediately corrected as it results in excessive movement of equipment and more transmission to the building structure than if equipment were attached solidly to the building (installed without isolators).

Components. Resonance can occur with any shaft, structural base, casing, and connected piping. The easiest way to determine natural frequency is to perform a bump test with a vibrograph. This test consists of bumping the part and measuring with an instrument; the part will vibrate at its natural frequency, which is recorded on instrument chart paper. Similar tests, though not as convenient or accurate, can be made with a reed vibrometer or a vibration analyzer. However, most of these instruments are restricted to frequencies above 8.3 Hz. They therefore cannot be used to determine natural frequencies of most isolation systems, which usually have natural frequencies lower than 8.3 Hz.

Checking for Vibration Transmission. The source of vibration transmission can be checked by determining frequency with a vibration analyzer and tracing back to equipment operating at this speed. However, the easiest and usually the best method (even if test equipment is being used) is to shut off components one at a time until the source of transmission is located. Most transmission problems cause disturbing noise; listening is the most practical approach to determine a noise source because the ear is usually better than sound-measuring instruments at distinguishing small differences and changes in character and amount of noise. Where disturbing transmission consists solely of vibration, a measuring instrument will probably be helpful, unless vibration is significantly above the

sensory level of perception. Vibration below the sensory level of perception is generally not objectionable. If equipment is located near the affected area, check isolation mounts and equipment vibration. If vibration is not being transmitted through the base, or if the affected area is remote from equipment, the probable cause is transmission through connected piping and/or ducts. Ducts can usually be isolated by isolation hangers. However, transmission through connected piping is very common and presents numerous problems that should be understood before attempting to correct them as discussed in the following section.

Vibration and Noise Transmission in Piping

Vibration and noise in connected piping can be generated by either equipment (e.g., pump or compressor) or flow (velocity). Mechanical vibration due to equipment can be transmitted through the walls of pipes or by a water column. Flexible pipe connectors, which provide system flexibility to permit isolators to function properly and protect equipment from stress caused by misalignment and thermal expansion, can be useful in attenuating mechanical vibration transmitted through a pipe wall. However, they rarely suppress flow vibration and noise and only slightly attenuate mechanical vibration as transmitted through a water column.

Tie rods are often used with flexible rubber hose and rubber expansion joints [Figure 19]. While they accommodate thermal movements, they hinder the isolation of vibration and noise. This is because pressure in the system causes the hose or joint to expand until resilient washers under tie rods are virtually rigid. To isolate noise adequately with a flexible rubber connector, tie rods and anchor piping should not be used. However, this technique generally cannot be used with pumps that are on spring mounts because they would still permit the hose to elongate. Flexible metal hose can be used with spring-isolated pumps since wire braid serves as tie rods; metal hose controls vibration but not noise.

Problems of transmission through connected piping are best resolved by changes in the system to reduce noise (improve flow characteristics, turn down impeller) or by completely isolating piping from the building structure. Note, however, that it is almost impossible to isolate piping completely from the structure, as required resiliency is inconsistent with rigidity requirements of pipe anchors and guides. Chapter 43 contains information on flexible pipe connectors and resilient pipe supports, anchors, and guides, which should help resolve any piping noise transmission problems.

OPERATION AND MAINTENANCE MANAGEMENT

Terminology .............................................................. 37.1
Quantitative Management Concept .............................. 37.1
Documentation ......................................................... 37.2
Knowledge and Skills ................................................ 37.3

Although mechanical maintenance was once the responsibility of trained technical personnel, increasingly sophisticated systems and equipment require overall management programs to handle organization, staffing, planning, and control. These programs should meet present and future personnel and technical requirements. They must also meet system availability and energy use requirements. Additionally, they must upgrade management and operator skills, and increase communication among those who benefit from cost-effective operation and maintenance.

Good maintenance management planning includes proper cost analysis and a process to ensure that occupant comfort, energy planning, and safety and security systems are optimal for all facilities. Appropriate technical expertise, whether in-house or contracted, is also important. This chapter addresses the following issues:

- Cost-effectiveness
- Commissioning
- Management approaches according to the criticality of buildings or systems
- Documentation and record keeping
- Condition monitoring and maintenance
- Operation and maintenance responsibilities of designers, contractors, manufacturers/suppliers, and owners

Operation and maintenance of all HVAC&R systems should be considered during the original design of a building. Any successful operation and maintenance program must include proper documentation of the design intent and criteria. ASHRAE Guideline 4 provides a methodology to properly document HVAC systems. Newly installed systems must be commissioned to ensure that they are functioning as designed. ASHRAE Guideline 1 provides the methods and procedures for HVAC system commissioning. It is then the responsibility of the management and operational staff to retain the design function throughout the life of the building. Existing systems may need to be recommissioned to accommodate changes.

TERMINOLOGY

System operation defines the parameters under which the building or systems operator can adjust components of the system to satisfy the tenant comfort or process requirements and the strategy for optimum energy use and minimum maintenance.

The maintenance program defines maintenance in terms of time and resource allocation. It documents the objectives, establishes evaluation criteria, and commits the maintenance department to basic areas of performance, such as prompt response to mechanical failure and attention to planned functions that protect capital investment and minimize downtime or failure response.

Failure response classifies maintenance department resources expended or reserved to handle interruptions in the operation or function of a system or equipment covered by the maintenance program. This classification includes two response types—repair and service.

Repair is to make good, or to restore to good or sound condition with the following constraints: (1) operation must be fully restored without embellishment, and (2) failure must trigger the response.

Service provides what is necessary to effect a maintenance program short of repair. It is usually based on manufacturers’ recommended procedures.

Planned maintenance classifies maintenance department resources that are invested in prudently selected functions at specified intervals. All functions and resources within this classification must be planned, budgeted, and scheduled. Planned maintenance embodies two concepts—preventive and corrective maintenance.

Preventive maintenance classifies resources allotted to ensure proper operation of a system or equipment under the maintenance program. Durability, reliability, efficiency, and safety are the principal objectives.

Corrective maintenance classifies resources, expended or reserved, for predicting and correcting conditions of impending failure. Corrective action is strictly remedial and always performed before failure occurs. An identical procedure performed in response to failure is classified as a repair. Corrective action may be taken during a shutdown caused by failure, provided the action is optional and unrelated.

Predictive maintenance is a function of corrective maintenance. Statistically supported objective judgment is implied. Nondestructive testing, chemical analysis, vibration and noise monitoring, and routine visual inspection and logging are classified under this function, provided that the item tested or inspected is part of the planned maintenance program.

Durability is the average expected service life of a system or facility. Table 3 in Chapter 35 lists median years of service life of various equipment. Individual manufacturers quantify durability as design life, which is the average number of hours of operation before failure, extrapolated from accelerated life tests and from stressing critical components to economic destruction.

Reliability is the probability that a system or facility will perform its intended function for a specified period of time when used under specific conditions and environment.

QUANTITATIVE MANAGEMENT CONCEPT

The following life-cycle management concept is recommended for operation and maintenance program planning. The concept can be used during the construction cycle as well as for day-to-day operation and maintenance management. Derived from value engineering, this life-cycle concept of management (see Figure 1) involves three interdependent dimensions: effectiveness (value), durability (time), and life-cycle cost (money). Their numerical values are affected by the type and extent of the operation and maintenance programs.

System effectiveness is the ability of a system to perform its intended use in terms of performance, availability, and dependability. To be perfectly effective, a facility must provide the required services satisfactorily and must operate dependably without failure.
for the given period. Mathematically, effectiveness $E$ is the product of capability $C$ and dependability $D$:

$$E = CD$$  (1)

Effectiveness may be assigned a numerical value according to the type of service required to meet a functional need. Table 1 is a guide for assigning effectiveness values. Note: The values given in this table are examples only, and values must be developed for each project to create proper relationships between the different systems in each facility.

**Capability** is the measure of a system’s ability to satisfactorily provide required service. It is the probability of meeting functional requirements, provided the system is operated under previously designated operating conditions. An example of capability is the ability of a heating system to cope with the heating load at the design winter temperature. The capability must be verified when the system is first commissioned and whenever the functional requirements change.

Capability can be calculated from the time $N$ the system cannot meet the requirements and the time $Y$ it is expected to operate in one year:

$$C = 1 - (N/Y)$$  (2)

**Dependability** is the measure of a system’s condition. Assuming the system was operative at the beginning of its service life, dependability is the probability of its operating at any other given time until the end of its life. For those systems that cannot be repaired during use, dependability is the probability that there will be no failure during use. For systems that can be repaired, dependability is governed by the ease and rapidity in which repairs can be made. This ease is the system maintainability, defined below.

Dependability $D$ can be expressed as a product of reliability $R$ and maintainability $M$:

$$D = RM$$  (3)

Reliability implies that a system will perform its function without failure for a desired portion of a specified time period. Reliability of two or more systems is calculated as follows:

1. If the systems are arranged in **series**, where the output of one is the input of the next [Figure 2], their combined reliability is

$$R = R_1 R_2 \ldots R_n$$  (4)

2. If the systems are arranged in **parallel**, such as dual pumping system with automatic changeover on failure of one of the two pumps [Figure 3], their combined reliability is calculated from the following equation:

$$R = 1 - (1 - R_1)(1 - R_2) \ldots (1 - R_n)$$  (5)

**Maintainability** is the ease and rapidity with which a system can be repaired. It complements reliability by defining the specific time that a system can operate in a fully restored condition. The value of maintainability is calculated from the time $B$ the system is being repaired in regular occupancy and the time $Y$ the system is expected to operate in one year.

$$M = 1 - (B/Y)$$  (6)

### DOCUMENTATION

Operation and maintenance documentation should be prepared as outlined in ASHRAE Guideline 4. Information should be documented as soon as it becomes available. This supports design and construction activities and the training of operation and maintenance staff in preparation for system commissioning.

A complete operation and maintenance documentation package consists of the following documents:

- **Operation and maintenance document directory.** The operation and maintenance document directory should provide easy access to information in the operation and maintenance documentation, and information should be well organized and clearly identified.
- **Emergency information.** Emergency information should be immediately available during emergency situations and should have emergency and staff and/or agency notification procedures.
- **Operating manual.** The operating manual should contain the following information:
  1. General information
     A. Building function
     B. Building description
     C. Operating standards and logs

   C. Seasonal start-up and shutdown
   D. Special procedures
   E. Basic troubleshooting

Maintenance manual. The maintenance manual should contain the following information:

I. Equipment data sheets
   A. General data
   B. Warranty

II. Maintenance program information
   A. Installation, operation, and maintenance instructions
   B. Spare parts inventory
   C. Preventive maintenance actions
   D. Schedule of actions
   E. Action descriptions
   F. History

Test reports. The test reports document the observed performance during start-up and commissioning and allows compilation throughout the service life of the facility.

Construction documents. Copies of the construction documents should be included.

  All the above documents should be available to the entire facility department.

MAINTENANCE MANAGEMENT

Maintenance management is the planning, implementation and review of maintenance activities. Myriad levels of maintenance management can be established. These levels are usually determined by their cost-effectiveness and by health and safety concerns. Cost-effectiveness is the balance between system effectiveness [e.g., maintenance levels, equipment (system) availability, reliability, maintainability, and performance] and life-cycle costs.

Three types of maintenance programs that can be adopted are (1) run-to-failure, (2) preventive maintenance, and (3) predictive maintenance. In run-to-failure, no money is spent on maintenance until equipment or systems break down. Predictive maintenance is maintenance that is scheduled, either by run time or by the calendar. Predictive maintenance is based on equipment monitoring and the use of condition and performance indices to maximize repair intervals. Within each of these groups, many levels of effort can be applied, from cursory to detailed. Maintenance programs may incorporate features of all these approaches into a single program. Many arguments can be made about the cost-effectiveness of each of these programs.

HVAC&R maintenance and operating costs represent a significant portion of a facility’s operating cost. Therefore, the cost-effectiveness of maintenance management is paramount.

Proper operation and maintenance are important factors in providing good indoor air quality (IAQ) and ensuring that life safety systems operate as designed. The ultimate success of maintenance management is based on dedicated, trained, and accountable personnel; clearly defined goals and objectives; measurable benefits; management support; and constant examination and reexamination.

KNOWLEDGE AND SKILLS

To be effective and economical, operation and maintenance requires staff with the right combination of technical and managerial skills. Technical skills include not only the skills of operation and maintenance mechanics, but also the engineering skills of the physical plant engineer. Managerial skills include managing the facility in life-cycle terms and on a day-to-day basis. Management on this level may administer contracts with tenants, service contracts, and labor unions. Specialized contractual maintenance companies require yet another level of management.

Physical plant engineers require a variety of skills because they need to coordinate the equipment selected by the designer, the operating and maintenance personnel, and the requirements of the investment plan. Good physical plant engineering solutions are developed when the investment plan is being formulated and continue throughout the life of the facility.

LEVELS OF EFFORT

The criticality and complexity of the system to be operated and maintained must be considered. Building types range from houses to commercial offices, institutional buildings, processing plants, refrigerated storage facilities, and mission critical facilities. All installed systems, no matter how simple, should have a commissioning plan; this gives the building or system owner and operators a means of operating the system in the most economical manner, minimizing energy consumption and maintenance costs while meeting user requirements.

Uncomplicated Systems

Many systems have simple operating procedures such as changing a single-zone thermostat from heating to cooling to control temperature for building occupants. Maintenance procedures for this type of system are usually limited to those recommended by most manufacturers.

Most building managers call on-site maintenance staff to change filters, belts, and motors. However, cleaning of condenser and evaporator coils and assessment of refrigeration and control systems require a more qualified technician. In most small facilities, maintenance contractors provide this service on a maintenance program basis. The frequency of maintenance depends on hours of system use, proximity to major transportation routes (dirt accumulation), and type of operation in the facility.

Smaller facilities may also have complex control systems, especially when zoning is critical for a variety of load conditions. Whenever the operator cannot service and repair the systems or components installed, the owner should ensure that qualified contractors are used.

Dirty evaporator and condenser coils and filters require additional energy to operate due to higher pressures and inefficient heat transfer. The system must also operate longer to satisfy space conditions. Although these items are variable and difficult to quantify, proper unit and system maintenance improves system operation and equipment life cycles, regardless of system size.

Medium-Complexity Systems

The next level of systems is more complex, with several pieces of mechanical equipment acting together through a control system to provide a variety of comfort zones.

Commissioning is increasingly important with this type of system to ensure optimum comfort at minimal energy cost. Without detailed documentation, the operation staff cannot consider energy budgets when addressing building occupants’ comfort complaints.

To manage maintenance programs in medium-sized facilities, the programs must be detailed for the maintenance personnel as well. Maintenance programs should be implemented on a sequential basis to reduce the failure response required. Over time, the maintenance programs can be adjusted for the particular characteristics of the system. Computerized maintenance programs can assist management in overseeing the effectiveness of the program.

For medium-sized systems, some operation and maintenance personnel may be employed by the building owner or lessee. They
should have the technical knowledge to operate these systems if they observed a full system commissioning process. The operating personnel may also be responsible for system maintenance. The maintenance procedures for the system should be detailed in the commissioning documentation (with individual equipment maintenance frequency detailed in manufacturers’ literature). The maintenance program should be tailored to each specific building. Again, it may be necessary to contract out certain maintenance program functions for highly technical pieces of equipment should the staff not have the technical expertise.

**Complex Systems**

Other buildings, including those with central plants, require a management structure to hire, direct, and oversee two staffs—one of operation personnel, and the other of maintenance personnel.

The operations budget should be large enough to support computerized maintenance programs, which detail proper timing of system maintenance procedures so that all systems operate at maximum efficiency while maintaining occupant comfort. Annual and life-cycle cost planning are essential to ensure the most cost-effective operation and maintenance of these systems.

To facilitate proper commissioning, management should be involved with the design process and construction of the facility. Because facilities are long-term investments, any first-cost compromises must consider both life-cycle cost and the ability to satisfy occupant comfort while maintaining reasonable energy budgets.

Logged information can be used with proper database management systems as predictive maintenance to reduce failure response requirements. These systems may be used to indicate the weaknesses in the systems so that management can make appropriate decisions or system changes. Like small and medium-sized systems, large systems may require an outside contractor or manufacturer’s support for specific equipment.

**CONDITION MONITORING**

An important aspect of operation and maintenance engineering systems is the assessment of the condition of the equipment. For complex systems, it may be necessary to monitor several conditions (e.g., temperature, vibration, and load) so that an assessment of the overall condition can be made.

One of the most effective condition-monitoring practices is the routine operating plant inspection conducted by the technician during regularly scheduled plant tours. A technician’s knowledge, experience, and familiarity with the plant are invaluable tools in plant diagnostics. Plant familiarity, however, is lost with frequent technician staff changes.

Many physical parameters or conditions can be measured objectively using both special equipment and conventional building management system sensors. One such condition is vibration on rolling element bearings. The vibration data is captured using computers, and special software can analyze the data to determine whether shaft alignment is correct, whether there are excessively unbalanced forces in the rotating mass, the state of lubrication of the bearing, and/or faults with the fixed or moving bearing surfaces or rolling elements. Not only can this technique diagnose failures and repair requirements at an early stage, but it can also be used upon completion of a repair to ensure that the underlying cause of a failure has been removed.

Other condition-monitoring techniques include (1) using thermal infrared images of electrical connections to determine whether mechanical joints are tight, (2) analyzing oil and grease for contamination (e.g., water in fuel oil on diesel engines), (3) analyzing electrical current to diagnose motor winding faults, (4) measuring differential pressure across filter banks and heat exchangers to determine optimum change/cleaning frequency, and (5) measuring temperature differences for correct control valve response or chiller operation.

In some cases, multiple parameters are required. For example, to determine the degree of contamination of an air filter bank on a variable air volume (VAV) system, it is necessary to measure the differential pressure across the filter and interpret it in terms of the actual flow rate through the filter. This can be done either by forcing the fan on to high speed and then measuring the differential pressure, or by combining a flow rate signal with a differential pressure signal.

**CONDITION-BASED MAINTENANCE**

Condition-based maintenance is the concept of carrying out maintenance only on the basis of the condition(s) monitored and the interpretation of those conditions. This should result in performing maintenance work only when necessary; therefore, plant reliability will be optimized, and personnel productivity will improve.

Many repairs are a direct result of maintenance-induced failures occurring during scheduled maintenance. Condition-based maintenance prevents unnecessary, repetitive work. There can, however, be added costs involved in supplementary training and instrumentation.

Conditions may be monitored on an on/off basis where comparison can be made against some fixed known values (e.g., tabulated values of acceptable vibration). Generally more useful in engineering systems within buildings is trending over a period of time: either measuring the conditions at a regular interval so that a gradual deterioration can be tracked and remedial work can be planned in advance or, in some circumstances, monitoring on a continuous basis where deterioration can be rapid.

To continue with the example of air filters mentioned in the section on Condition Monitoring, in the case of a VAV system, assuming the main fan is drawing the air through the filter and is controlled to a fixed static pressure, the filter change criterion is a function of the maximum differential pressure the filter can withstand when fully loaded with dust (without bursting) and the energy consumption of the fan. It may be more economical to change the filter before the maximum pressure is reached if the rate of dust loading is slow. Also, monitoring it via the energy management system rather than changing on a fixed time interval means that if something occurs to rapidly accelerate the dust loading (e.g., nearby construction work), the system will alert the building management before the filters are overloaded and could potentially burst.

In a constant volume system (again assuming the main fan is drawing air through the filter), the change criterion is a function of the maximum differential pressure the filter can withstand and the drop in flow rate that can be tolerated by the system users. As the filter blocks, the energy consumption decreases and the filter efficiency improves. A fixed time interval for filter bank changing/cleaning is not optimum. Changing on the basis of a monitored condition should optimize the life of the filters and minimize the cost of labor for building cleaning and this aspect of plant maintenance.

**RESPONSIBILITIES**

The building owner should be apprised of the design intent of the system. The system design must include proper operation and maintenance information; flowcharts and instrumentation requirements must be indicated. The installing contractor must provide the director of operation and maintenance with an organized and comprehensive turnover of the system that has been installed.

An effective director should be able to organize, staff, train, plan, and control the operation and maintenance of a facility with the cooperation of senior management and all departments. A manager’s responsibilities include administering the operation and maintenance budget and protecting the life-cycle objectives. Before selecting a least-cost alternative, a manager should determine the consequential effect on durability and loss prevention (Loveley 1973).
NEW TECHNOLOGY

Operation and maintenance programs are based on the technology available at the time of their preparation. The programs should be adhered to throughout the required service life of the facility or system. In the course of the service life, a new technology may become available that would affect the operation and/or maintenance program. When this occurs, the switch from the existing to the new technology must be assessed in life-cycle terms. The existing technology must be assessed for the degree of loss due to shorter return on investment; the new technology must be assessed for (1) all initial and operation and maintenance cost, (2) the correlation between its service life and the remaining service life of the facility, and (3) the cost of conversion, including the revenue losses due to the associated downtime.

Chapter 38

Computer Applications

APPLICATION CONCEPTS

Current technology in the computer industry changes rapidly. By the time a computer is purchased and implemented, new technology may appear on the market that renders it obsolete. This situation, along with the need to share information and applications among various computers, makes a design that can readily adapt to change a necessity. An information system has an architecture in much the same way that a building does. If laid out properly, this architecture can accommodate the introduction of new technologies while allowing the continuing use of existing software.

Before choosing computer products, the business that the information system will serve must be understood. End users can best specify the principles most important to a particular business. The system and applications can then be selected to match the needs of the business, and a technical framework that supports a consistent computing environment can be established.

Standards take several forms. Industry standards, such as ISO, ANSI/IEEE, and SQL, are defined and recognized by industry groups. Proprietary standards are often formed where other standards are not applicable, such as in a company. De facto standards, such as the operating system software for personal computers, are another type of standard.

Hardware

The availability of inexpensive personal computers and workstations at prices affordable to any company has made in-house computing an attractive option for even the smallest firm. The obvious advantages of rapid turnaround and unlimited computing for a fixed investment are compelling.

A personal computer operates at low cost to allow interactive usage and storage for the tasks a user generally takes on. Data can be transferred to other computers. This combination can enable a firm to handle a larger number and variety of projects than would be possible with a central system alone.

But owning a computer incurs additional expenses, including maintenance, software, and personnel costs. Software must be either bought or developed, and although it may seem expensive to buy, it is almost always more expensive to develop. A firm should employ at least one person knowledgeable about the systems and the software, or have contractual access to such a person.

Personal and workstation computers offer the small office enormous power at low cost. These machines should be considered in the class of business machines, in that they offer more possibilities than technical analysis (see the section on General Productivity Tools).

Laptop computers are battery-powered, miniature personal computers that are fully functional and more or less portable. These computers are also called palmtops, portables, or notebooks depending on their size.

Any of the hardware options described here may be connected through a local-area network (LAN), or a wide-area network (WAN). When machines are thus connected, one or more of the computers may be used as a file server. Any computer, once connected locally or via telephone to the server, has access to common data and programs through the network. This method allows data stored in one logical database to be accessed from many separate computers without the necessity of copying the data onto numerous storage devices.

An emerging hardware technology is parallel processing. In this computing method, the processors in one or more networked computers are used in parallel, each solving a portion of a problem. A control program determines what processing power is needed and available for a particular computational task. The task is then assigned to a processor. When the computation is complete, the results are passed back. Depending on the system and the control program, several software program steps may be completed at the same time. This method shows great promise in the area of simulations, which tend to be computationally intensive and which may be easily divided into smaller pieces.

Personal digital assistants offer unique capabilities that were previously obtainable only through a combination of equipment (phone, facsimile machine, laptop computer, modem, and more).

Programmable calculators and personal organizers can be programmed to carry out operations of hundreds of steps. They can be outfitted with printers and/or connected to personal computers to exchange data. A range of commercial programs is available for these machines. Many programmable calculators have integral memory or plug-compatible memory modules. These machines can store user-created programs and can read in programs created in machine-readable form by the user or by a vendor.

The primary advantages of the programmable calculator are low cost and portability, although with a printer attached, the calculators are not nearly as portable. For field calculations, they are unexcelled but are being challenged by battery-powered, notebook-sized laptop computers, and even hand-held computers.

Many of these calculators have additional features, such as programmable calendars, alarm clocks, and even language interpreters, which allow them to serve also as personal organizers. In many cases programmable calculators perform the same functions...
as laptop computers. Likewise, some laptops are becoming nearly as small as programmable calculators.

Software Options

Software can be divided into four major categories: system software, languages, utilities, and application programs.

System software, otherwise known as the operating system, is the environment in which other programs run. It handles input and output (keyboard, video display, and printer) and file transfer between disks and memory; it also supports the operation of other programs. Operating system software can be obtained from the computer manufacturer or from software companies. The operating system is specific to a particular type of computer.

Languages are used to write computer programs. They range from assembly language, which involves coding at the machine instruction level, to high-level languages such as FORTRAN, BASIC, Pascal, C, C++, JAVA, J++, or SQL. Many high-level languages exist to satisfy various programming requirements. FORTRAN and C++ are useful for scientific or mathematical applications. BASIC established microcomputers (personal computers) as viable business machines. New dialects of BASIC are overcoming many of the language’s previous limitations. Pascal is a structured language originally designed for teaching programming. C and C++ are emerging as preferred standards for professional programming in many industries, including the HVAC industry, because they compile to very efficient and fast code, and the C source code from one computer can be recompiled with other C compilers to run on many types of machines. The major disadvantage of C is the high level of programming skill required to create programs. JAVA and J++ are favored programming languages for applications that run over computer networks such as the Internet. Structured query language (SQL) allows user-friendly requests to be made for the retrieval of database information.

Utility software programs perform standard organizing and data handling tasks for a specific computer, such as copying files from one disk to another, printing file directories, printing files, and merging files (splicing two or more files together in a specific order). Utility software generally performs one or two specific functions, while applications software is written to accomplish a particular task that can require many function and utility components.

HVAC application programs calculate such items as loads, energy, and piping design. General-purpose applications software, such as accounting and word processing programs, is discussed in the section on General Productivity Tools. Another specialized area of applications software is artificial intelligence, discussed in the section on Advanced Tools.

Purchased Software. PC software can be purchased from the manufacturers of computer equipment, software companies, distributors, and discount houses. Software price, level of support, return policies, and distribution method vary from vendor to vendor. Most software companies support their product in some way, although some companies have a poor reputation for supporting customers. Some vendors allow customers to try software and return it if it is not acceptable; others make demonstration or limited function versions available for a minimal charge.

Some vendors use copy protection schemes that prevent the user from running the software on more than one computer. Copy protection inconveniences the user, so the trend is to move away from this protection method. Upon purchase of PC software, the user is given a license with specific restrictions on how that software may be used, typically that it is to be used on only one computer. A separate, signed license is not common but is occasionally used. Because the distribution of unauthorized copies has been so costly to software companies, many are actively prosecuting illegal software use.

Before purchasing general-purpose software (e.g., spreadsheet, database, or word processor programs), the user should look into how the software runs and how easy it is to use. A full-service computer store may offer advice and demonstrations unavailable from mail-order or discount software sources. The user interface is important; some programs are difficult to operate and understand, while others are very easy to use. Computer magazines often publish comparisons of general-purpose software that can be used for a first appraisal. Once a package is chosen, the user may have difficulty changing to another.

Occasionally suppliers offer the program’s source code, which is a set of human-readable instructions in a computer language. Skilled programmers can modify a source code to change the operation of the program. This is not generally recommended, because once the program is changed, support must be supplied internally. Public Domain Software. Public domain software is available to the public either without charge or for a minimal charge (usually for maintenance and support). These programs are developed through government-supported projects, at universities, and by individuals. The source code for many public domain programs is available, though usually poorly supported. However, some programs are well documented and supported. Some programs offer only executable code to prevent unauthorized use of the source code in proprietary programs.

Public domain software can be obtained from the Internet, computer bulletin boards, other individuals, and companies that distribute it for a small duplication charge. Care should be used when obtaining public domain software because its origin is difficult to trace. Some public domain programs have computer viruses; programs on bulletin boards and the Internet are particularly suspect. A virus is a small program inserted into another program that can destroy stored data, lock up the computer, and otherwise cause problems.

Custom Programming. Three major strategies for obtaining custom programs are followed: (1) contracting to an outside firm, (2) using an outside firm to provide consultation and help, or (3) developing the programs internally.

Contracting to an outside firm for the entire programming effort should be considered if the host organization does not have the personnel or desire to support the software on an ongoing basis. Funds should be budgeted for the outside organization to support any modifications or enhancements that become necessary. Contracting outside is a good approach for an organization that does not want to get involved with programming. The main drawbacks are the expense and the lack of control over the program. Licensing and ownership issues should be carefully spelled out in the contract.

Using an outside firm to do the programming is practical if internal skill is insufficient for programming, but long-term support and maintenance of the software are to be done internally. Outside firms can provide the expertise to get a project going quickly. A good design specification is critical to the success of the software development.

Developing programs internally is viable only if the skills and resources are available. Internal projects are easier to control because the people involved are usually under one roof. Most of the major vendors of software-based HVAC systems develop the software internally with occasional consultation from outside firms.

No matter which approach is chosen, the user must provide a detailed functional design specification. The calculations, human interface, reports, user documents, and testing procedures should be carefully detailed and agreed on by all parties before the development begins. To create a useful software program, a thorough understanding of the subject matter and a solid knowledge of computer programming are required. Software testing should also be specified at the beginning of the project. Once the software is created, it should be thoroughly tested in a variety of operating conditions.
Computer Applications

With any of the development approaches, good, understandable documentation is required. If for any reason the software cannot be adequately supported, the program will have to be either abandoned, replaced, or recoded, causing a substantial drain on fiscal resources.

Custom programming should be used to create only programs or features unavailable with existing software: no matter how high the cost of existing software, custom software that produces comparable results will cost more in the long-run.

Sources for HVAC Programs. The ASHRAE Journal lists sources of HVAC-related software. This resource is available in print (ASHRAE 1999) or through the Internet at www.ashrae.org.

GENERAL PRODUCTIVITY TOOLS

Administrative Tools

Word Processing. Word processing programs range from simple, small programs for creating notes to full-featured, electronic publishing tools. Many word processing programs include spelling and grammar checkers, the ability to create indexes and table of contents, simple databases for merging addresses and other information, drawing and graphing tools, tables, spelling and grammar checkers, simple spreadsheets to perform arithmetic with columns of figures, and the ability to convert documents so they may be read on the Internet.

Specification Writing. The efficiency and flexibility of a computerized master specification in conjunction with a word processor make it a valuable tool for preparing project specifications. Those who use a master specification should standardize language to avoid repeated editing of text. A master specification is most beneficial to firms that do not specialize in unique, one-of-a-kind designs.

If the master can be used with only minor revisions for most specifications, the time spent on editing may be justifiable. In general, the larger the size and the greater the number of documents produced, the greater the savings in time and money compared to traditional preparation and typing. Even without a master specification, however, the writer and typist can save considerable time by copying from previous specifications with minor revisions.

Desktop Publishing. Many high-end word processors have the ability to import graphic images and to print in decorative typefaces, but the full capability to arrange page layouts and incorporate graphics is found only in desktop publishing programs. However, word processing programs continue to include more and more desktop publishing features.

Most desktop publishing programs are limited in their ability to create text and drawings; normally text is imported from a word processing program and images from separate drawing programs. High-resolution graphic displays for personal computers and laser printers have allowed the creation and printing of high-quality graphic images.

Management Planning and Decision Making. Computers are ideal for repetitive operations such as inventory control, accounting, purchasing, and project control, providing managers with up-to-date information. The ability to store and manipulate large amounts of data is a powerful basis for forecasting. With sufficient historical data, statistical methods can be used to forecast sales, inventory needs, production capability, personnel needs, and capital requirements. For example, econometric modeling may be included to help forecast the effects of varying inflation rates.

Much of the data required for such techniques may not be in company files and must be found elsewhere. Technical papers, market trends, industry reports, financial forecasts, codes, standards, regulatory data, and demographic or geographic data are examples of information that can be searched for by computer. In many cases, this information can be obtained on the Internet for a nominal or no user access fee. Management information systems should also have the capability to provide special or supporting information in case it becomes necessary to delve deeper into an operation.

Employee Records and Accounting. All corporate accounting functions, from payroll to aging accounts receivables to taxes, can be automated with a wide choice of engineering-specific accounting software on even the smallest PCs. A firm with unique accounting requirements may often meet them by developing specific applications, called templates or overlays, for common spreadsheet programs. Continuously updated financial reports needed for project evaluation and government use can be generated more readily by computer than by manual methods or off-site accounting services. Labor expenses for various projects or departments can easily be separated and monitored on a regular basis. Personnel records for each employee can also be maintained on a computer.

Project Scheduling and Job Costing. The success of any project, no matter what its size, depends on good scheduling and control to ensure that manpower and materials are where they are supposed to be at the proper time. Whenever portions of a project can be done simultaneously, are dependent on the completion of one or more prior parts, or must share a limited amount of manpower and equipment, a project scheduling technique such as critical path method (CPM) or program evaluation and review technique (PERT) can establish priorities. Current microcomputer programs can also perform personnel leveling to make the best use of available resources, and some may provide graphics suitable for client presentations as well.

Commercially available computerized scheduling techniques quickly provide updated schedules and priorities, even if the critical path changes due to a delay in one part of the job. This capability is valuable for determining whether scheduled completion dates and costs can be met and for finding possible alternatives. Once personnel, payroll, and accounting functions have been established on a computer, a history of project costs, manpower requirements, and material requirements can be maintained. The computer can categorize and tabulate them for future reference, permitting more accurate estimates for future projects.

Security and Integrity. While computers are generally reliable, provision must be made for potential loss of important data in the event of equipment failure, theft, sabotage, natural catastrophe, or a previously undiscovered problem in the software. The most common method of protection is periodic duplication of disk files onto tape, CD-ROM or other digital archival media. Duplication of the most important data files, such as the firm’s accounts, should take place with every posting. Duplicate files should be kept in a secure area, such as a fireproof vault on the premises or totally off-site.

Another security concern is unauthorized access to particular data. The implementation of a formal, written data security policy, no matter how minimal it is initially, is a critical step in the computerization of any firm. Careful planning is required to be sure that only authorized personnel have access to confidential files. Most major accounting packages, as well as many popular spreadsheet and database management programs, contain built-in safeguards, such as multilevel password protection, to help keep information secure. Some packages also contain a transactions log to track who has accessed a particular file and what functions were performed.

Design Tools

Spreadsheet Software. Spreadsheets are two- or three-dimensional electronic tables containing thousands of cells into which the user may enter labeling text, numbers, formulas, or even macrocommands. Macro-commands can transfer control to another program, automatically move the user around in the spreadsheet, jump to other spreadsheets or databases, or execute other programs and return with a value. Automatic recalculations of all cells defined by formulas following data entry keeps all areas of the spreadsheet current. Spreadsheets include the following advantages:
Many special-purpose HVAC application programs exist, including, proprietary equipment selection packages and microcomputer versions of public domain programs such as DOE-2, BLAST, TRNSYS, and other powerful simulation programs previously available only on large mainframe computers. Many non-HVAC advanced analysis programs are also available, including statistical and mathematical packages, specialty artificial intelligence or knowledge-based development shells, and neural network development programs.

Advanced Input and Output Options. Advanced input capabilities include digitizing of images and text, scanners, bar code input, pen-based input, downloading of data directly from portable field instruments, voice input, and facsimile (fax) machines.

While each character of text can be represented internally by a single byte of storage, graphic images are more difficult to store and manipulate; they can be represented in bitmap or in vector format. In the bitmap or raster representation, the image is decomposed into points in a rectangular array (pixels). Storage requires a minimum of one bit per pixel for monochrome images and several bits per pixel for color. In vector representation, only end points of line segments are stored (as numbers). While the output of bitmap images is simple on raster devices such as graphic printers, scaling of images does not always produce satisfactory output. Vector representations plot easily on pen plotters and scale to a high degree of accuracy, but must be converted to raster format for output on graphic printers.

Computer-aided design and other drawing programs use vector representation. Paint programs use bitmap images. Scanners can be used to duplicate an image that resides on paper and produce a raster representation (text and images are both in bitmap format). Paint programs can take scanned images directly and facilitate their manipulation by the user. It is possible to scan drawings into raster format, and then use conversion software to change the raster representation into vector form for use in CAD. Similarly, optical character recognition (OCR) software can take a raster image of text and convert it to individual text characters in the computer for input into word processing programs.

Fax equipment scans input images into raster format and sends the images bit-by-bit over telephone lines to a receiver, which prints them out as raster images. Computers, can capture incoming fax images, allowing either conversion to internal text form or manipulation of the images.

Just as input capabilities have improved, so have output options, including the porting of graphic routines to video cassette recorder (VCR) tapes for assembly into training tapes, direct 35 mm slide production, and direct transmission of output via fax machine. Newly available hardware and specialty software for laptops allow the user to preassemble and display an animated electronic slide show, digital images, or even CAD drawings using a special translucent output screen (LCD) that is placed on top of a traditional overhead projector. Certain hardware even allows the user to view a television image in a separate window while working on a document or spreadsheet. Such an application might be the precursor of a video-based energy management and control system (EMCS).

ENGINEERING DESIGN CALCULATIONS

Although computers are now widely used in the design process, most programs perform not design, but simulation. That is, the engineer proposes a design and the computer program calculates the consequences of that design. When alternatives are easily cataloged, a program may aid design by simulating a range of alternatives and then selecting the best according to predetermined criteria.

Thus, a program to calculate the cooling load of a building requires specifications for the building and its equipment; it then simulates the performance of that building under certain conditions of weather, occupancy, and scheduling. A duct-design program may
Computer Applications

actually size ductwork, but usually an engineer must still decide air quantities, duct routing, and so forth.

Since computer programs perform repetitive calculations rapidly, it is possible for the designer to explore a wide range of alternatives and use selection criteria based on annual energy costs or life-cycle costs.

Heating and Cooling Loads

The calculation of design thermal loads in a building is a necessary step in the selection of HVAC equipment for virtually any building project. To ensure that heating equipment can maintain satisfactory building temperature under all conditions, peak heating loads are usually calculated for steady-state conditions without solar or internal heat gains. This relatively simple calculation can be performed with or without a computer.

Peak cooling loads are more transient than heating loads. Radiative heat transfer in a space and thermal storage cause thermal loads to lag behind instantaneous heat gains and losses. Especially with cooling loads this lag can be important, as the peak is both reduced in magnitude and delayed in time compared to the heat gains that cause it. Early methods of calculating peak cooling loads tended to overestimate loads; this resulted in oversized cooling equipment with penalties of a high first cost and part-load operating inefficiencies. Today various calculation methods account for the transient nature of cooling loads. These are described in Chapters 27 and 28 of the 1997 ASHRAE Handbook—Fundamentals and in Load Calculation Principles (Pederson et al. 1998).

Characteristics of a Loads Program. In general, a loads program requires user input for most or all of the following:

- Full building description, including the construction of the walls, roof, windows, etc., and the geometry of the rooms, zones, and building. Shading geometries may also be included.
- Sensible and latent internal loads due to lights and equipment, and their corresponding operating schedules.
- Sensible and latent internal loads due to people.
- Indoor and outdoor design conditions.
- Geographic data such as latitude and elevation.
- Ventilation requirements and amount of infiltration.
- Number of zones per system and number of systems.

With this input, a load programs calculates both the heating and cooling loads as well as perform a psychrometric analysis. Output typically includes peak room and zone loads, supply air quantities, and total (coil) load.

Selecting a Loads Program. In addition to general characteristics, such as hardware and software requirements, type of interface (icon-based, menu-driven versus command-driven), availability of manuals and support, and cost, some loads program-specific characteristics should be considered when selecting a loads program. The following are among the items to be considered:

- Type of building to be analyzed—residential versus commercial. Residential load programs tend to be simpler to use than the more general-purpose programs meant for commercial and industrial use. However, residential-only programs have limited abilities.
- Method of calculation for the cooling load, as discussed previously in this section.
- Program limits on such items as number of systems, zones, rooms, and surfaces per room.
- Sophistication of modeling techniques, for example, the capability of handling exterior or interior shading devices, tilted walls, daylighting, and skylights.
- Units of input and output.
- Complexity of program. In general, the more sophisticated and flexible programs require more input and are somewhat more difficult to use than the simpler programs.
- Capability of handling the system under investigation.

Duct Design

Two major needs exist in duct design: sizing and flow distribution. Duct sizing and equipment selection are part of any new duct design. Flow distribution is the calculation of flows through the duct sections and terminals for an existing system with known cross sections and fan characteristics.

Duct Sizing. Two major approaches to computerized duct sizing are followed: (1) application of manual procedures, which, although computerized, are still limited in capability, and (2) optimization. Duct design methods are described in Chapter 32 of the 1997 ASHRAE Handbook—Fundamentals.

Selecting and Using a Program. Duct design involves laying out the ductwork, selecting the fittings, and sizing the ducts. Computer programs can address many constraints that require recomputation of the duct size. Computer printouts provide detailed documentation. Any calculation requires the preparation of accurate estimates of pressure losses in duct sections and the definition of the interrelations of velocity pressures, static pressures, total pressures, and fitting losses.

The general computer procedure is to designate nodes (the beginning and end of duct sections) by number. Details about each node (e.g., divided flow fitting and terminal) and each section of duct between nodes (maximum velocity, flow rate, length, fitting codes, size limitation, insulation, and acoustic liner) are used as input data (Figure 1).

Characteristics of a duct design program include the following:

- Calculations for supply, return, and exhaust
- Sizing by constant friction, velocity reduction, static regain, and constant velocity methods
- Analysis of existing ducts
- Inclusion of fitting codes for a variety of common fittings
- Identification of the duct run with the highest pressure loss, and tabulation of all individual losses in each run
- Printout of all input data for verification
- Provision for error messages
- Calculation and printout of airflow for each duct section
- Printout of velocity, fitting pressure loss, duct pressure loss, and total static pressure change for each duct section

![Fig. 1 Example of Duct System Node Designation](image)
- Graphic showing of a schematic or line diagram indicating duct size, shape, flow rate, and temperature in the ducts
- Calculation of heat gain/loss and correction of temperatures and flow rates, including possible resizing
- Specification of maximum velocities, size constraints, and insulation thicknesses
- Consideration of insulated or acoustically lined duct
- Bill of materials for sheet metal, insulation, and acoustic liner
- Acoustic calculations for each section
- File-sharing with other programs, such as spreadsheet and CAD

Because many duct design programs are available, the following factors should be considered in program selection:

- Maximum number of branches that can be calculated
- Maximum number of terminals that can be calculated
- Types of fittings that can be selected
- Number of different types of fittings that can be accommodated in each branch
- Ability of the program to balance pressure losses in branches
- Ability to handle two- and three-dimensional layouts
- Ability to size a double-duct system
- Ability to handle draw-through and blow-through systems
- Ability to prepare cost estimates
- Ability to calculate fan motor power
- Provision for determining acoustical requirements at each terminal
- Ability to update the fitting library

**Optimization Techniques for Duct Sizing.** For an optimized duct design, fan pressure and duct cross sections are selected by minimizing life-cycle cost, which is an objective function that includes initial cost and energy cost. Many constraints, including constant pressure balancing, acoustic restrictions, and size limitations, must be satisfied. Duct optimization is a mathematical programming problem with a nonlinear objective function and many nonlinear constraints. The solution must be taken from a set of standard diameters and standard equipment. Several numerical methods for duct optimization exist, such as the T-method (Tsal et al. 1988), coordinate descent (Tsal and Chechik 1968), Lagrange multipliers (Stoecker et al. 1971, Kovarik 1971), dynamic programming (Tsal and Chechik 1968), and reduced gradient (Arkin and Shitzer 1979).

**Flow Distribution.** Another problem is the prediction of airflows in each section of a pre-sized system with known fan characteristics. This is called the flow distribution or air duct simulation problem. Whenever a retrofit to existing ducts is considered, the need to calculate flow distribution occurs. An HVAC engineer may then ask the following questions:

- How will the retrofit influence the flow at existing terminals?
- Is it possible to change only the motor and leave the fan?
- What is the new working point on the fan performance curve?
- Which duct sizes should be changed?
- What are the new duct sizes and what are the flows in the ducts with fully opened dampers?
- What is the best way to connect additional diffusers to an existing system?

A simulation program can help answer these questions. It can also analyze the efficiency of a control system effectively, check the performance of a number of parallel fans if one is not running, and predict the flows during field air balancing. The T-method (Tsal et al. 1988) and the gradient steepest descent method (Tsai and Chechik 1968) have been used for simulating a duct system.

**Piping Design**

Sizing programs normally size the piping and estimate pump pressure based on velocity and pressure drop limits. Some consider heat gain or loss from piping sections. Several programs produce a bill of materials or cost estimate for the piping. Piping flexibility programs assist in stress and deflection analysis. Many of the piping design programs can account for thermal effects in pipe sizing, as well as deflections, stresses, and moments.

Programs for the analysis of refrigerant piping layouts are also available. These programs aid in installing properly sized pipes or in troubleshooting those already installed. Some programs are generic—they use the physical properties of refrigerants along with system practices to give pipe sizes that may be used. Other programs “mix and match” evaporators and condensers from a particular manufacturer and recommend appropriate pipe sizes.

The general technique for computerizing piping design problems is similar to that for duct design. A typical piping problem in its nodal representation is shown in **Figure 2**.

Useful piping programs do the following:

- Provide sufficient design information
- Perform calculations for both open and closed systems
- Calculate the flow, pipe size, and pressure drop in each section
- Handle three-dimensional piping systems
- Cover a wide selection of commonly used valves and fittings, including solenoid and pressure-regulating valves
- Consider different piping materials such as steel, copper, and plastic by including generalized friction factor routines
- Accommodate liquids, gases, and steam by providing property information for a multiplicity of fluids
- Calculate pump capacity and pressure required for liquids
- Calculate the available terminal pressure for nonreturn pipes
- Calculate the required expansion tank size
- Estimate heat gain/loss for each portion of the system
- Prepare a cost estimate, including costs of pipe, insulation materials, and associated labor
- Print a bill of materials
- Calculate balance valve requirements
- Perform a pipe flexibility analysis
- Perform a stress analysis for the piping
- Print a graphic display of the pipe network
- Allow customizing of specific design parameters and conditions, such as maximum and minimum velocities, maximum pressure drops, condensing temperature, superheat temperature, and subcooling temperature
- Allow piping to be evaluated for off-design conditions
- Provide links to other programs, such as equipment simulation programs

Limiting factors to consider, in piping program selection include the following:

- Maximum number of terminals program can accommodate

![Fig. 2 Example of Nodes for Piping System](image)
Computer Applications

• Maximum number of circuits program can handle
• Maximum number of nodes each circuit can have
• Maximum number of nodes program can handle
• Compressibility effects for gases and steam
• Provision for two-phase fluids

Acoustic Calculations

Chapter 46 summarizes sound generation and attenuation in HVAC applications. Applying this data and methodology often requires a large amount of computation. All sound generation mechanisms and sound transmission paths are potential candidates for analysis. Adding to the computational work load is the need to extend the analysis over, at a minimum, octave bands 1 through 8 (63 Hz through 8 kHz). A computer can save time and reduce the difficulty in analyzing any noise situation, but the designer should be wary of using unfamiliar software.

Caution and critical acceptance of analytical results are mandatory, at all frequencies, but particularly at low frequencies. Not all manufacturers of equipment and sound control devices provide data below 125 Hz. Thus, the HVAC designer conducting the analysis and the programmer developing the software must make assumptions based on experience for these critical low-frequency ranges.

The designer/analyst should be well satisfied if predictions are within 5 dB of field-measured results. In the low-frequency rumble regions, results within 10 dB are often as accurate as can be expected, particularly in areas of fan discharge. Conservative analysis and application of the results is necessary, especially if the acoustic environment of the space being served is critical.

Several currently available acoustics programs are generally easy to use, but they are often less detailed than the custom programs developed by acoustic consultants for their own use. Acoustics programs are designed for comparative sound studies and allow the design of comparatively quiet systems. Acoustic analysis should address the following key areas of the HVAC system:

• Sound generation by HVAC equipment
• Sound attenuation and regeneration in duct elements
• Wall and floor sound attenuation
• Ceiling sound attenuation
• Sound break-out or break-in from ducts or casings
• Room absorption effect (relation of sound power criteria to sound pressure experienced)

Algorithm-based programs are preferred because they cover more situations (see Chapter 46). However, assumptions are an essential ingredient of algorithms. These basic algorithms, along with sound data from the acoustics laboratories of equipment manufacturers, are incorporated to various degrees in acoustics programs. The HVAC equipment sound levels in acoustics programs should come from the manufacturer and be based on measured data, because there is a wide variation in the sound generated by similar pieces of equipment. Some generic equipment sound generation data, which may be used as a last resort in the absence of specific measured data, are found in Chapter 46. Whenever possible, equipment sound power data by octave band (including 32 Hz and 63 Hz) should be obtained for the path under study. A good sound prediction program relates all performance data.

Other more specialized acoustics programs are also available. Various manufacturers provide equipment selection programs that not only select the optimum equipment for a specific application, but also provide associated sound power data by octave bands. These programs can help in the design of a specific aspect of a job. Data from these programs should be incorporated in the general acoustic analysis. For example, duct design programs may contain sound predictions for discharge airborne sound based on the discharge sound power of the fans, noise generation/attenuation of duct fittings, attenuation and end reflections of variable air volume (VAV) terminals, attenuation of ceiling tile, and room effect. VAV terminal selection programs generally contain subprograms that estimate the space NC level near the VAV unit in the occupied space. However, projected space NC levels alone may not be acceptable substitutes for octave-band data. The designer/analyst should be aware of assumptions, such as room effect, made by the manufacturer in the presentation of acoustical data.

Predictive acoustic software allows designers to look at HVAC-generated sound in a realistic, affordable time frame. HVAC-oriented acoustic consultants generally assist designers by providing cost-effective sound control ideas for sound-critical applications.

Refrigerant Properties

REFPROP (NIST 1996) is a program that allows the user to examine thermodynamic and transport properties for thirty-eight pure refrigerants and blends. It may be used in an interactive mode. Since the source code is included, it may also be used as part of a program that requires refrigerant properties. A number of other refrigerant property programs are also available from sources such as universities. Refrigerant properties that the user may find useful include, enthalpy, entropy, viscosity, and thermal conductivity.

Ventilation

Several ventilation programs aid the designer in satisfying requirements of ASHRAE Standard 62, Ventilation for Acceptable Indoor Air Quality. As with any computer program, the user must qualify the program’s technical capabilities, such as

• Ventilation requirements by application
• Calculation of the Multiple Space equation in Standard 62
• Use of ventilation effectiveness
• Application for spaces with intermittent or variable occupancy

In addition to technical capabilities the units of input and output and the ability to interface with programs for input or outputs should also be examined.

Equipment Selection and Simulation

Three types of equipment-related computer programs are available—equipment selection, equipment optimization, and equipment simulation programs.

Equipment selection programs are basically computerized catalogs. The program locates an existing equipment model that satisfies the entered criteria. The output is a model number, performance data, and sometimes alternative selections.

Equipment optimization programs display all equipment alternatives and let the user establish ranges of performance data or first cost to narrow the selection. The user continues to narrow the performance ranges until the best selection is found. The performance data used for optimizing selections vary by product family.

Equipment simulation programs calculate the full- and part-load performance of specific equipment over time, generally one year. The calculated performance is matched against an equipment load profile to determine energy requirements. Utility rate structures and related economic data are then used to project equipment operating cost, life-cycle cost, and comparative payback. Before accepting output from an equipment simulation program, the user must understand the assumptions made, especially those assumptions concerning load profile and weather.

Some advantages of equipment programs include the following:

• High speed and accuracy of the selection procedure
• Pertinent data presented in an orderly fashion
• More consistent selections than with manual procedures
• More extensive selection capability
• Multiple or alternate solutions
• Small changes in specifications or operating parameters easily and quickly evaluated
• Data-sharing with other programs, such as spreadsheets and CAD
Simulation programs have the advantage of (1) projecting part-load performance quickly and accurately, (2) establishing minimum part-load performance, and (3) projecting operating costs and payback-associated higher performance product options. Programs for nearly every type of HVAC equipment are available, and industry standards apply to the many of them. The more common programs and their optimization parameters include the following:

<table>
<thead>
<tr>
<th>Equipment Type</th>
<th>Optimization Parameters</th>
</tr>
</thead>
<tbody>
<tr>
<td>Air distribution units</td>
<td>Pressure drop, first cost, sound, throw</td>
</tr>
<tr>
<td>Air-handling units, rooftop units</td>
<td>Power, first cost, sound, filtration, footprint, heating and cooling capacity</td>
</tr>
<tr>
<td>Boilers</td>
<td>First cost, efficiency, stack losses</td>
</tr>
<tr>
<td>Cooling towers</td>
<td>First cost, design capacity, power, flow rate, air temperatures</td>
</tr>
<tr>
<td>Chillers</td>
<td>Power input, condenser pressure, evaporator pressure, capacity, first cost, compressor size, evaporator size, condenser size</td>
</tr>
<tr>
<td>Coils</td>
<td>Capacity, first cost, fluid pressure drop, air pressure drop, rows, fin spacing</td>
</tr>
<tr>
<td>Fan coils</td>
<td>Capacity, first cost, sound, power</td>
</tr>
<tr>

<tr>
<td>Pumps</td>
<td>Capacity, pressure, impeller size, first cost, power</td>
</tr>
<tr>
<td>Air terminal units (variable and constant volume flow)</td>
<td>Volume flow rate, air pressure drop, sound, first cost</td>
</tr>
</tbody>
</table>

Some selection programs are quite versatile. For example, coil selection programs can select steam, hot water, chilled water, and refrigerant (direct expansion) coils. Generally, they select coils according to procedures in ARI Standards 410 and 430.

Chiller and refrigeration equipment selection programs can choose optimal equipment based on such factors as lowest first cost, highest efficiency, best load factor, and best life-cycle performance. In addition, some manufacturers offer modular equipment for customizing their product. This type of equipment is suited for computer selection.

However, equipment selection programs have limitations. The logic of most manufacturers, programs is proprietary and not available to the user. All programs incorporate built-in approximations or assumptions, some of which may not be known to the user. Equipment selection programs should be qualified before use.

**SIMULATION PROGRAMS**

**Energy and System Simulation**

Building energy simulation programs in contrast to peak load calculation programs integrate loads over time (usually a year), consider the systems serving the loads, and calculate the energy required by the equipment. Most energy programs simulate the performance of already designed systems, although some programs make selections formerly left to the designer, such as equipment size, air volume, and fan power. Energy programs are necessary for making decisions regarding building energy use and, along with life-cycle cost routines, quantifying the impact of proposed energy conservation measures during the design phase. In new building design, energy programs help determine the appropriate type and size of equipment; they can also be used to explore the effects of design trade-offs and evaluate the benefits of innovative control strategies and the efficiency of new equipment.

Energy programs that track building energy use accurately can help determine whether a building is operating efficiently or wastefully. They can also allocate costs from a central heating/cooling plant among customers of the plant. However, such programs must be adequately calibrated to data measured from the building under consideration.

**Characteristics of Building Energy Simulation.** Most programs simulate a wide range of buildings, mechanical equipment, and control options. However, computational results differ substantially from program to program. For example, the shading effect from overhangs, side projections, and adjacent buildings is frequently a factor in the energy consumption of a building; however, the diversity of approaches to the load calculation results in a wide range of answers.

The choice of weather data also influences the load calculation. Depending on the requirements of each program, the following types of weather data are used:

- Typical hourly data for one year only, from averaged weather data
- Typical hourly data for one year, as well as design conditions for typical design days
- Reduced data, commonly a typical day or days per month for the year
- Typical reduced data, non-serial or bin format
- Actual hourly data, recorded on-site or nearby, for analysis where the simulation is being compared to actual utility billing data or measured hourly data.

Both air-side and energy conversion simulations are required to handle the wide variations among central heating, ventilation, and air conditioning. For proper estimation of energy use, simulations must be performed for each design combination, operating scheme, and control sequence.

**Simulation Techniques.** Two methods are currently used to simulate energy systems: the fixed schematic technique and the component relation technique.

The **fixed-schematic-with-options technique**, which is the most prevalent program, involves writing a calculation procedure that defines a given set of systems. The schematic is then fixed, with the user’s options usually limited to equipment performance characteristics, fuel types, and the choice of certain components.

The **component relation technique** differs from the fixed schematic in that it is organized around components rather than systems. Each component is described mathematically and placed in a library. Input includes the definition of the schematic, as well as equipment characteristics and capacities. Once all components have been identified and a mathematical model for each has been formulated, the components may be connected together and information may be transferred between them. Although this approach has certain inefficiencies because of its more general organization, the component relation technique does offer versatility in defining configurations.

**Selecting an Energy Program.** In selecting an energy analysis program, factors such as cost, availability, ease of use, technical support, and accuracy are important. However, another major concern is whether the program will do what is expected of it. It should be sensitive to the parameters of concern, and its output should include the necessary data. For other considerations, see Chapter 30 of the 1997 ASHRAE Handbook—Fundamentals.

Time can be saved if the initial input file for an energy program can also be used for load calculations. Some programs interface directly with computer-aided design (CAD) files, greatly reducing the time needed to create an energy program input file.

**Comparisons of Energy Programs.** Many comparisons, verifications, and validations of simulation programs are reported in the literature (see the section on Bibliography). Conclusions from these studies can be summarized as follows:

- The results obtained by using several computer programs on the same building range from good agreement to no agreement at all.
- The degree of agreement depends on the interpretations of the
program user and the ability of the computer programs to model the building.

- Several people using several programs on the same building will probably not agree on the results of an energy analysis.
- The same person using different programs on the same building may or may not find good agreement, depending on the complexity of the building and its systems and on the ability of the computer programs to model the specific conditions in that building.
- Forward computer simulation programs, which calculate the performance of a building given a set of descriptive inputs, weather conditions, and occupancy conditions, are best used for design.
- Calibration of hourly forward computer simulation programs is possible, but can require considerable effort for a moderately complex commercial office building. Detailed information concerning scheduled use, equipment set points, and even certain on-site measurements may be necessary for a closely calibrated model. Special-purpose graphic plots are useful in calibrating a simulation program with data from monthly, daily, or hourly measurements.
- Inverse, empirical, or system parameter identification models may also be useful in determining the characteristics of building energy usage. Such models can determine the relevant building parameters from a given set of actual performance data. This procedure is the inverse of the traditional building modeling approach, hence the name.

**Energy Programs to Model Existing Buildings.** Many programs are available and they vary widely in cost, degree of complexity, and ease of use. A general procedure should be followed in energy analysis of existing buildings. First, ensure your energy consumption data must be obtained for a one- to two-year period. For electricity, these data usually consist of metered electrical energy consumption and demand on at least a month-by-month basis. For natural gas, the data are in a similar form and are almost always on a monthly basis. For both electricity and natural gas, it is helpful to record the dates when the meters were read. These dates are important in weather normalization for determining average billing period temperatures. For other types of fuel, such as oil and coal, the only data available may be the delivery amounts and dates.

Unless fuel use is metered or measured daily or monthly, consumption for any specific period shorter than one season or year is difficult to determine. The data should be converted to a per-day usage or adjusted to account for differences in the length of metering periods. The data tell how much energy went into the building on a gross basis. Unless extensive submetering is used, it is nearly impossible to determine when and how that energy was used and what it was used for. It may be necessary to install such meters to determine energy use.

The thermal and electricity usage characteristics of buildings and their energy consumption as a time-varying function of ambient conditions and occupancy must also be determined. Most computer programs can use as much detailed information about the building and its mechanical and electrical systems as is available. Where the energy implications of these details are significant, it is worth the effort of obtaining them. Testing fans for air quantities, pressures, control set points, and actions can provide valuable information on deviations from design conditions. Test information on pumps can also be useful.

Data on building occupancy are among the most difficult to obtain. Since most energy analysis computer programs simulate the building on an hourly basis for a one-year period, it is necessary to know how the building is used for each of those hours. Frequent observation of the building during days, nights, and weekends shows which energy-consuming equipment is being used and to what degree. Measured, submetered hourly data for at least one week is needed to begin to understand weekday/weekend schedule-dependent loads.

**Weather data.** Usually one year of hour-by-hour weather data, are necessary for simulation. The actual weather data for the year in which energy consumption data were recorded significantly improves the simulation of an existing building. Where the energy consuming nature of the building is related more to internal than to external loads, the selection of weather data is less important; however, with residential buildings or buildings with large outside ambient air loads, the selection of weather data can affect results significantly. The purpose of the simulation should also be considered when choosing weather data: i.e., either specific year data, data representative of long-term averages, or data showing temperature extremes may be needed, depending on the goal of the simulation.

Usually the results of the first computer runs do not agree with the actual metered energy consumption data. The following are possible reasons for this discrepancy:

- Insufficient understanding of the energy-consuming systems that create the greatest use
- Inaccurate information on occupancy and time of building use
- Inappropriate design information on air quantities, set points, and control sequences

The input building description must be adjusted and trial runs continued until the results approximate actual energy use. Matching the metered energy consumption precisely is difficult; in any month, results within 10% are considered adequate.

The following techniques for calibrating a simulation program to measured data from a building should be considered:

- Matching submetered loads or 24-hour day profiles of simulated whole-building electric loads to measured data
- Matching x-y scatter plots of simulated daily whole-building thermal loads versus average daily temperature to measured data
- Matching simulated monthly energy use and demand profiles to utility billing data

Having a simulation of the building as it is being used permits subsequent computer runs to evaluate the energy impact of various alternatives or modifications. The evaluation may be accomplished simply by changing the input parameters and running the program again. The impacts of the various alternatives may then be compared and an appropriate one selected.

**Computational Fluid Dynamics**

Computational fluid dynamics (CFD) is a technique for simulation, study, analysis, and prediction of fluid flow and heat transfer in well defined spaces with boundaries. It is based on equations that govern the physical behavior and the appropriate equation of state. Usually these equations are in the form of nonlinear partial differential equations relating velocities, pressure, temperature, and some scalar variables to space directions, and time. Initial and boundary conditions are specified and numerical methods such as finite difference, finite volume, or finite element analysis methods are used to solve these equations. The domain (typically space) is divided (discretized) into cells or elements, then equations are solved for each of the discrete cells. Upon solving these equations, the dependent variables (velocities, pressure, temperature, and scalar) are made available at the nodes.

CFD analysis can be successfully applied to a variety of tasks including the location of airflow inlets/outlets in a space, velocities required, flow pattern determination, temperature distribution in space, and smoke movement and buildup in a space with fire.

**GRAPHICS APPLICATIONS**

**Computer-Aided Design**

CAD (which refers to computer-aided drafting at times and to computer-aided design at other times) is a subset of CADD
(computer-aided design and drafting). CADD encompasses the creation of building data models and the storing and use of attributes of the graphic elements. Drafting, or the creation of construction documents, is becoming a by-product of the design process. The distinction between engineers and drafters in engineering firms is decreasing as design and production work becomes unified. In this section, CADD refers to all aspects of design.

Single-building data model: In this section, CADD refers to all aspects of design. The use of CADD is decreasing as design and production work becomes unified. The distinction between engineers and drafters in engineering firms is decreasing as design and production work becomes unified. In this section, CADD refers to all aspects of design. Computer-aided design (CAD) allows the development of a single-building data model that integrates complex, three-dimensional (3D) building data into one common location. Engineers can access such building information as room volumes, percentage of glazing, building orientation, and lighting. This information can then be electronically passed on to third-party analysis programs such as load calculation or distribution analysis. Considering the building data model is drawn in true dimensional size, the information is accurate and complete. The architect or engineer can modify the building model at any phase of the design and provide instantaneous updates. Reiterations of analysis can be accomplished at any phase of the building’s life cycle.

Computer-generated design models can also help the designer visualize the building and its systems and check for interferences, such as the structure and ductwork occupying the same space. Some software packages now perform interference checking themselves. This layering feature also helps an HVAC designer coordinate interdisciplinary and multidiscipline designs and simplify modifications.

In addition to the concept of the single building data model, the Internet is influencing work flow in the engineering community. Software applications allow users to design projects and share building model data via the Internet on a global scale. These applications can also be used for simple viewing and redlining as well. Computer-aided design automates (1) material and cost estimating, (2) design and analysis of HVAC, (3) visualization and interference checking, and even (4) manufacturing of HVAC components such as ductwork.

Computer-generated drawings of building parts can be linked to non-graphic characteristics, which can be extracted for reports, schedules, and specifications. For instance, an architectural designer can draw wall partitions and windows, and then have the computer automatically tabulate the number and size of windows, the areas and lengths of walls, and the areas and volumes of rooms and zones. Similarly, the building data model can store information for later use in reports, schedules, design procedures, or drawing notes. For example, the airflow, voltage, weight, manufacturer, model number, cost, and other data about a fan displayed on a drawing can be stored and associated with the fan in the data model. Conversely, the graphics-to-data links allow the designer to enhance graphic items having a particular characteristic by searching for that characteristic in the data files and then making the associated graphics brighter, bolder, or different-colored in the display.

HVAC models and their associated data can be used by building owners and maintenance personnel for ongoing facilities management, strategic planning, and maintenance. For instance, an air-handling unit can be associated with a preventative maintenance schedule in a separate facility management application. Models are useful for computer-aided manufacturing such as duct construction. The three-dimensional building data model can also aid in the development of sections and details for building drawings. CAD programs can also automate the cross-referencing of drawings, drawing notations, and building documents.

Computer Graphics and Modeling

Computer graphics programs may be used to create and manipulate pictorial information between the computer and the user. Combining text with computer graphics enables the design engineer to quickly evaluate design alternatives. Computers can pictorially simulate design problems with three-dimensional color displays that can predict the performance of mechanical systems before they are constructed. Simulation graphics software is also used to evaluate design conditions that cannot ordinarily be tested with scale models due to high costs or time constraints. Product manufacturability and economic feasibility may thus be determined without the construction of a working prototype.

Integrated CADD and expert systems can help the building designer and planner with construction design drawings and with construction simulation for planning and scheduling complex building construction scenarios (Potter 1987).

A simple yet helpful tool available to the HVAC engineer is the graphic representation of thermodynamic properties and thermodynamic cycle analysis. These programs may be as simple as a computer-generated psychrometric chart with cross-hair cursor retrieval of properties and computer display zooming or magnification of chart areas for easier data retrieval. More complex software graphically represent thermodynamic cyclic paths overlaid on two- or three-dimensional thermodynamic property graphs. With a simultaneous graphic display of the calculated results of Carnot efficiency and COP, the user can understand more readily the cycle fundamentals and the practicality of the cycle synthesis.

Typical piping and duct system software produces large amounts of data to be analyzed. Pictorially enhanced simulation output of system curves, pump curves, and load curves speeds the sizing and selection process. What-if scenarios with numeric/graphic output increase the designer’s understanding of the system and help avoid design problems that may otherwise come to light only after installation. Graphic-assisted fan and duct system design and analysis programs are also available to designers.

Airflow analysis of flow patterns and air streamlines is done by solving the fundamental equations of fluid mechanics. Finite element and finite volume modeling techniques are used to produce two- or three-dimensional pictorial-assisted displays, with the velocity vectors and velocity pressures at individual nodes solved and numerically displayed. An example of pictorial output is shown in Figures 4.8 and 4.9 of Chapter 4. Clean Spaces, where calculated airflow streamlines have been overlaid on the computer against a two-dimensional graphic of the clean room. With this display, the clean room designer can see potential problems in the configuration, such as the circular flow pattern in the lower left and right.

While research has shown good correlation between flow modeling by computer and flow modeling done in simple mock-ups, modeling software should not be considered a panacea for design; simulation of flow around complex shapes is still being developed, as are improved simulations of low Reynolds number flow.

MONITORING AND CONTROL

A control system performs two primary functions—monitoring (also referred to as data acquisition or data gathering) and control (also referred to as device control). A control consists of a set of measured (monitored) parameters, a set of controlled parameters, and a control function which translates the measurement data into control signals applied to controlled parameters.

Supervisory control is the total monitoring and overall control of the local subsystems. Overall control includes functions such as manual overrides, optimizing modification or discharge local loop set points, optimizing start-stop of subsystems, and controlled interaction between subsystems. Total system monitoring includes functions such as alarm reporting, energy measurement and calculation, logs, and trend reports.

Supervisory control has been called a building automation system (BAS) when the primary focus was on automating as much as possible to save labor. It has been called an energy monitoring and control system (EMCS) when the focus was on saving energy by both automatic control and manual control with the aid of energy monitoring. It has been called an energy management system (EMS) when the focus was on saving energy by specific
automatic control programs. It has been called a facility management system (FMS) when the scope of control went beyond HVAC control and/or beyond a single building, such as including fire, security, or manufacturing systems. Building automation system (BAS) has become the most popular term for description of a computerized control in buildings that may provide one or more of the above functions.

**Standard and Open Protocols**

Standard protocols such as BACnet are developed in committee by professional societies, open protocols are created by manufacturers but available for all to use, and proprietary protocols are developed by manufacturers but not freely distributed. User needs should be determined prior to selecting a particular protocol for a given application.

BACnet, the ASHRAE Building Automation and Control Networking Protocol, provides mechanisms by which computerized equipment for a variety of building control functions may exchange information regardless of the particular building service it performs (ASHRAE Standard 135). As a result, the BACnet protocol may be used by head-end computers, general-purpose direct digital controllers, and application specific or unitary controllers.

BACnet is based on a four-layer collapsed architecture that corresponds to the physical, data link, network, and application layers of the ISO/OSI (International Standards Organization/Open Systems Interconnection) model. The application layer and a simple network layer are defined in the BACnet standard.

The physical layer provides a means of connecting devices and transmitting the electronic signals that convey the data.

The data link layer organizes the data into frames or packets, regulates access to the medium, provides addressing, and handles some error recovery and flow control.

Functions provided by the network layer include translation of global addresses to local addresses, routing messages through one or more networks, accommodating differences in network types and in the maximum message size permitted by those networks, sequencing, flow control, error control, and multiplexing. BACnet is designed so that there is only one logical path between devices, thus eliminating the need for optimal path routing algorithms.

The presentation layer provides a way for communicating partners to negotiate the transfer syntax that will be used to conduct the communication. This transfer syntax is a translation from the abstract user view of data at the application layer to sequences of octets treated as data at the lower layers.

The application layer of the protocol provides the communication services required by the applications to perform their functions, in this case monitoring and control of the HVAC&R and other building functions.

Building automation system networks are local area networks even though some applications must exchange information with devices in a building that is very far away. This long-distance communication is typically done through telephone networks. The use of the Internet is becoming a popular, low-cost alternative to phones. The routing, relaying, and guaranteed delivery issues are handled by the telephone system and can be considered external to the BAS network. BAS devices are static. They do not move from place to place, and the functions that they are asked to perform do not change in the sense that a manufacturing device may make one kind of part today and some very different part tomorrow. These are among the features of BAS networks that can be used to evaluate the appropriateness of the layers in the OSI model.

**APPLICATIONS OF ARTIFICIAL INTELLIGENCE**

Artificial intelligence (AI) applications range from systems that learn, reason, and recognize speech like human beings to those that can help make decisions based on incomplete, uncertain, and/or complicated information. Artificial intelligence techniques are generally used in three areas—design, control, and diagnosis. The following sections discuss some of the technology of interest to engineers.

**Knowledge-Based Systems.** Knowledge-based systems (KBSs), often called expert systems, can make decisions similar to those made by human experts. They typically use facts, if-then rules, and/or models to make decisions. Most KBS tools can also link with other programs, access databases, and import graphics. An expert system shell is usually a complete development package that includes rule and database development tools, debugging facilities, and good user interfaces. Some shells take advantage of windowing environments and incorporate object oriented features, hypertext, and graphics. Haberl et al. (1995), Shams et al. (1994a,b) and Nielsen and Walters (1988) discuss KBS in detail.

Knowledge-based systems are used to make decisions, diagnose faults, monitor and control operation, and develop tutorials. Some HVAC applications include KBSs that select HVAC equipment for small office buildings (Shams et al. 1994a,b), analyze building energy consumption (Haberl et al. 1988), recommend energy conservation options (Meadows and Brothers 1989), help with the conceptual design of building energy systems (Doheny and Monaghan 1987, Mayer et al. 1991), incorporate building regulations into design (Corkick et al. 1990), monitor HVAC equipment (Kaler 1990), manage cooling loads (Potter et al. 1991), and diagnose HVAC equipment problems.

**Case-Based Reasoning.** Case-based reasoning (CBR) techniques use search methods to find a match between entered information and a previous case on file in a case library. This technique is gaining popularity because it requires less programming maintenance than a rule-based system. Generally the user is only required to answer a few questions and the program seeks to match parameters to the cases on file. While not as generic in providing solutions as rule-based systems, CBR tools increase in general applicability each time a new case is added. When a match is found, the solution for the previous case is presented to the user. The most obvious application of CBR is at help desks, where many of the cases handled are similar.

**Knowledge Discovery.** Modern computing technologies have gathered and stored large amounts of data. Traditional methods of analysis, especially those involving human expertise, often can not be used to find useful knowledge hidden in this data. Knowledge discovery in databases (KDD), also called data mining, describes the tools used to intelligently and automatically discover information in large databases. Some of these tools include classification and clustering techniques, trend and deviation analysis, dependency derivation, and inductive rule learning. More information can be found in Fayyad et al. (1996).

**Artificial Neural Networks.** Artificial neural networks (ANNs) are collections of small individually interconnected processing units. Information is passed between these units along interconnections. An incoming, connection has two values associated with it: an input value and a weight. The output of the unit is a function of the summed values. ANNs, while represented on computers, are not programmed to perform specific tasks. Instead, they are trained with repeated data sets until they learn the patterns presented to them. Once the net is trained, new patterns may be presented to it for classification.

Numerous techniques and architectures are available for implementing neural nets, which are detailed by Wasserman (1989). Specialized neural computers are currently being developed, but most neural nets can be implemented by software. Some of the areas in which ANNs have been successful include speech recognition, image enhancement, pattern association, global optimization problems, and predicting building energy usage (Haberl et al. 1996).

**Fuzzy Logic.** This form of logic is based on the concept of the fuzzy set. Membership in fuzzy sets is expressed in probabilities or
degrees of truth, i.e., as a continuum of values ranging from 0 to 1. According to fuzzy-logic theorists, classical logic oversimplifies the concept of set membership by flatly including or excluding an individual, whereas fuzzy logic expresses the extent to which an individual pertains to a set. For example, under classical logic, the theoretical tree $x$ is a member of the set of tall trees; in contrast, under fuzzy logic, $x$ pertains partly to the set of tall trees and can be described as fairly tall.

Fuzzy logic is used as a form of data processing by advanced computers. In less complex information processors, the possibility that a particular event will occur is expressed as a certainty (either false or true) represented by the binary digits 0 or 1. Fuzzy-logic, in contrast, breaks down the chance of the occurrence into varying degrees of truthfulness or falsehood (e.g., will occur, probably will occur, might occur, might not occur, etc.). This allows the outcome of an event to be expressed as a possibility. Moreover, as additional data is gathered, many fuzzy-logic systems are able to adjust continuously the values assigned to different possibilities. Because some fuzzy-logic systems appear able to learn from their mistakes and mimic human thought processes, they are often considered a crude form of artificial intelligence.

INTERNET

The Internet originated in 1969 as an experimental project of the Advanced Research Project Agency (ARPA), and was called ARPANET. From its inception, the network was designed to be a decentralized, self-maintaining series of redundant links between computers and computer networks, capable of rapidly transmitting communications without direct human involvement or control, and with the automatic ability to re-route communications if one or more individual links were damaged or otherwise unavailable. Among other goals, this redundancy of linked computers was designed to allow vital research and communications to continue even if portions of the network were damaged, say, in a war.

Messages between computers on the Internet do not necessarily travel entirely along the same path. The Internet uses packet switching communication protocols that allow individual messages to be subdivided into smaller packets. These are then sent independently to the destination and automatically reassembled by the receiving computer. While all packets of a given message often travel along the same path to the destination, if computers along the route become overloaded, packets can be rerouted to less loaded computers.

No single entity—academic, corporate, governmental, or nonprofit—administers the Internet. It exists and functions as a result of the fact that hundreds of thousands of separate operators of computers and computer networks independently decided to use common data transfer protocols to exchange communications and information with other computers. No centralized storage location, control point, or communications channel exists for the Internet, and no single entity can control all of the information conveyed on the Internet.

Communication over the Internet

The most common methods of communications on the Internet (as well as within the major on-line services) can be grouped into six categories:

1. One-to-one messaging (such as e-mail)
2. One-to-many messaging (such as listserv)
3. Distributed message databases (such as USENET news groups)
4. Real time communication (such as Internet Relay Chat)
5. Real time remote computer use (such as telnet)
6. Remote information retrieval (such as ftp, gopher, and the World Wide Web)

Most of these methods of communication can be used to transmit text, data, computer programs, sound, visual images (i.e., pictures), and moving video images.

Electronic mail, or e-mail, is comparable to sending a letter. The Internet also contains automatic mailing list services (such as listservs) that allow communications about particular subjects of interest to a group of people. Similar in function to listservs—but quite different in how communications are transmitted—are distributed message databases such as USENET news groups. Like listservs, newsgroups are open discussions and exchanges on particular topics. Users, however, need not subscribe to the discussion mailing list in advance, but can instead access the database at any time. Some USENET newsgroups are moderated but most are open access. The dissemination of messages to USENET servers around the world is an automated process that does not require direct human intervention or review.

In addition to transmitting messages that can be later read or accessed, individuals on the Internet can communicate in real time with other people on the Internet. In its simplest forms, talk allows one-to-one communications and Internet Relay Chat (or IRC) allows two or more to type messages to each other that almost immediately appear on the other computer screens.

Real time remote computer use is another method to access and control remote computers in real time using telnet. For example, a researcher at a university could use the computing power of a supercomputer located at a different university. A student can use telnet to connect to a remote library to access the library’s on-line card catalog program.

Information on the Internet is located and retrieved by three primary methods: ftp, gopher, and the World Wide Web.

A file transfer protocol (ftp) allows the user to transfer one or more files between the local computer and a remote computer. Another approach uses a program and format named gopher to guide a search through the resources available on a remote computer.

World Wide Web

A third approach, and the most well-known on the Internet, is the World Wide Web (WWW). The web serves as the platform for a global, on-line store of knowledge. Though information on the web is contained in individual computer connected to the Internet through WWW protocols. It is currently the most advanced information system developed on the Internet, and embraces most information in previous networked information such as ftp, gopher, and Usenet.

Placing information or publishing on the web simply requires a computer running WWW server software. The computer can be as simple as a small personal computer or as complex as multi-million dollar computers occupying a small building. Many web publishers choose to lease disk storage space from a service that has the necessary computer facilities, eliminating the need for owning any equipment. Web publishers may make their web sites open to all Internet users, or close them, thus making the information accessible only to those authorized.

Searching the Web. Various search engines allow users to search for web sites that contain desired information, or to search for key words. For example, a user looking for information on evaporative cooling would type the words “evaporative cooling” into a search engine. The engine then searches the web and presents a list linked to sites that contain this text. The user can browse through the information on each site until the desired material is found.

Common Standards. The web links together disparate information by setting common information storage formats called hyper-text markup language (HTML) and a common language for the exchange of web documents, hypertext transfer protocol (HTTP). Although the information itself may be in many different formats, and stored on computers which are not otherwise compatible, the basic web standards provide a basic set of standards which allow communication and exchange of information. The web can display
Computer Applications

38.13

HTML documents containing text, images, sound, animation, and moving video. Any HTML document can include links to other types of information or resources, even if the information is stored on numerous computers all around the world.

No single authority controls the Internet as a whole. The Internet Society, or ISOC, is a voluntary membership organization whose purpose is to promote global information exchange through Internet technology. The Internet Architecture Board (IAB) develops standards for the ways computers and software talk to each other. The IAB also keeps track of information that must remain unique. For example, each computer on the Internet has a unique 32-bit address; no other computer has the same address. The IAB does not actually assign the addresses, but it makes the rules about how to assign addresses.

**Collaborative Design.** The Internet is revolutionizing how project teams collaborate. Sharing or jointly developing drawings or documents can take place efficiently with collaborators around the world. In a similar manner, geographically dispersed teams can now design and develop software. Numerous coordination issues comprise the collaborative design process. Methods of sharing data, such as distributed databases, revision and developmental accounting, and security concerns associated with the transmission of design information must be considered carefully.

**ASHRAE DEVELOPED SOFTWARE**

ASHRAE has funded the development of several software programs. These applications range from database retrieval for use in HVAC&R calculations to demonstration versions of advanced tools. They may be obtained via the Bookstore on the ASHRAE website at www.ashrae.org.

BUILDING ENERGY MONITORING

CHAPTER 39

REASONS FOR ENERGY MONITORING

Monitoring projects can be broadly categorized by goals, objectives, experimental approach, level of monitoring detail, and uses.

Energy End Use

Energy end-use projects focus on individual energy systems in particular buildings, typically for large samples. Monitoring usually requires separate meters or data collection channels for each end use, and analysts must account for all factors that may affect energy use. Examples of this approach include detailed utility load research efforts, evaluation of utility incentive programs, and end-use calibration of computer simulations. Depending on the project objectives, the frequency of data collection may range from one-time measurements of full-load operation to continuous time-series measurements.

Specific Technology Assessment

Specific technology assessment projects monitor the field performance of specific equipment or technologies that affect building energy use, such as envelope retrofit measures, major end uses (e.g., lighting), or mechanical equipment.

The typical goal of retrofit performance monitoring projects is to estimate savings resulting from the retrofit despite potentially significant variation in indoor/outdoor conditions, building characteristics, and occupant behavior unrelated to the retrofit. The frequency and complexity of data collection depend on project objectives and site-specific conditions. Projects in this category assess variations in performance between different buildings or for the same building before and after the retrofit.

Field tests of end-use equipment are characterized by detailed monitoring of all critical performance parameters and operational modes. In evaluating energy efficiency improvements, it is preferable to measure in situ performance. Although manufacturers’ data and laboratory performance measurements can provide excellent data for sizing and selecting equipment, the installed performance can vary significantly from that at design conditions. The project scope may include reliability, maintenance, design, energy efficiency, sizing, and environmental effects (Phelan et al. 1997a,b).
Table 1 Characteristics of Major Monitoring Project Types

<table>
<thead>
<tr>
<th>Project Type</th>
<th>Goals and Objectives</th>
<th>General Approach</th>
<th>Level of Detail</th>
<th>Uses</th>
</tr>
</thead>
<tbody>
<tr>
<td>Energy end use</td>
<td>Determine characteristics of specific energy end uses in building.</td>
<td>Often uses large, statistically designed sample. Monitor energy demand or use profile of each end use of interest.</td>
<td>Detailed data on end uses metered. Collect building and operating data that affect end use.</td>
<td>Load forecasting by end use. Identify and confirm energy conservation or demand-side management opportunities. Simulation calculations. Rate design.</td>
</tr>
<tr>
<td>Specific technology assessment</td>
<td>Measure field performance of building system technology or retrofit measure in individual buildings.</td>
<td>Characterize individual building or technology, occupant behavior, and operation. Account and correct for variations.</td>
<td>Uses detailed audit, submetering, indoor, outdoor, and occupant surveys. May use weekly, hourly, or short-term data.</td>
<td>Technology evaluation. Retrofit performance. Validate models and predictions.</td>
</tr>
<tr>
<td>Energy savings measurement and verification</td>
<td>Estimate the impact of a retrofit or other building alteration, in order to serve as the basis for payments.</td>
<td>Preretrofit consumption is used to create a baseline model. Postretrofit consumption is measured; the difference between the two is savings.</td>
<td>Varies substantially, including verification of potential to provide savings, retrofit isolation, whole-building, or calibrated simulation.</td>
<td>Focused on specific building component or system. Amount and frequency of data varies widely between projects.</td>
</tr>
<tr>
<td>Building operation and diagnostics</td>
<td>Solve problems. Measure physical or operating parameters that affect energy use or that are needed to model building or system performance.</td>
<td>Typically uses one-time and/or short-term measurement with special methods, such as infrared imaging, flame gas analysis, blower door, or coheating.</td>
<td>Focused on specific building component or system. Amount and frequency of data varies widely between projects.</td>
<td>Energy audit. Identify and solve operation and maintenance, indoor air quality, or system problems. Provide input for models. Building commissioning.</td>
</tr>

### Savings Measurement and Verification (M&V)

Accountability is increasingly necessary in energy performance retrofits, whether they are performed as part of an energy savings performance contract (ESPC) or performed directly by the owner. In either case, savings measurement and verification (M&V) is an important part of the project. Measurement and verification is based on comparing the energy use after a retrofit to what it would have been without the retrofit. Because the actual energy savings cannot be measured directly, the appropriate role of energy monitoring methodology is to:

- Accurately define baseline conditions and assumptions
- Confirm that the proper equipment and systems were installed and that they have the potential to generate the predicted energy savings
- Take post retrofit measurements
- Estimate the energy savings achieved

See IPMVP (1997) for more information on M&V for performance contracting.

### Building Diagnostics

Diagnostic projects measure physical and operating parameters that determine the energy use of buildings and systems. Usually, the project goal is to determine the cause of problems, provide parameters to model energy performance, or isolate the effects of components. Diagnostic tests frequently involve one-time measurements or short-term monitoring. To give insight, the frequency of measurement must be several times faster than the rate of change of the effect being monitored. Some diagnostic tests require intermittent, ongoing data collection.

The residential sector, particularly single-family dwellings, has a large number of diagnostic measurement procedures. Typical measurements for single-family residences include (1) flue gas analysis to determine steady-state furnace combustion efficiency and the efficiency of other end uses, such as air conditioners, refrigerators, and water heaters; (2) fan pressurization tests to measure and locate building envelope air leakage (ASTM Standard E 779) and tests to measure air tightness of air distribution systems (Modera 1989; Robinson and Lamb 1989); and (3) infrared thermography to locate thermal defects in the building envelope and other methods to determine overall building envelope parameters (Subbarao 1988).

Energy systems in multifamily buildings can be much more complex than those in single-family homes, but the types of diagnostics are similar: combustion equipment diagnostics, air leakage measurements, and infrared thermography to identify thermal defects or moisture problems (DeCicco 1995). Some techniques are designed to determine the operating efficiency of steam and hot water boilers and to measure the air leakage between apartments.

In research, diagnostic techniques have been designed to measure the overall airtightness of building envelopes and the thermal performance of walls (Persily and Grot 1988). Practicing engineers also employ a host of monitoring techniques to aid in the diagnostics and analysis of equipment energy performance. Portable data loggers are often used to collect time-synchronized distributed data, allowing multiple data sets (such as chiller performance and ambient conditions) to be collected and quickly analyzed. Similar short-term monitoring procedures are used to provide more detailed and complete building system commissioning. Short-term in situ tests have also been developed for pumps, fans, and chillers (Phelan et al. 1997a, 1997b).

Diagnostics are also well suited to support the development and implementation of building energy management programs (see Chapter 34). In this role, diagnostic measurements can be used in conjunction with energy audits to identify existing energy usage patterns, to determine energy performance parameters of building systems and equipment, and to identify and quantify areas of inefficient energy usage (Misuriello 1988). Diagnostic measurement projects can generally be designed using procedures adapted to specific project requirements (see the section on Steps for Project Design and Implementation).

Equipment for diagnostic measurement may be installed temporarily or permanently to aid energy management efforts. Designers should consider providing permanent or portable check metering of major electrical loads in new building designs. The same concept can be extended to fuel and thermal energy use.

### PROTOCOLS FOR PERFORMANCE MONITORING

Examples of procedures (protocols) for evaluating energy savings for projects involving retrofit of existing building energy systems are presented here. These protocols should also be useful to those interested in more general building energy monitoring.

Building monitoring has been significantly simplified and made more professional in recent years by the development of fairly...
Building Energy Monitoring

standardized monitoring protocols. Although there may be no way
to define a protocol to encompass all types of monitoring applica-
tions, repeatable and understandable methods of measuring and
verifying retrofit savings are needed. However, following a proto-
col does not take the place of adequate project planning and careful
assessment of project objectives and constraints.

Residential Retrofit Monitoring

Protocols for residential building retrofit performance can
answer specific questions associated with the actual measured per-
formance. For example, Ternes (1986) developed a single-family
retrofit monitoring protocol, which consists of a data specification
guideline that identifies important parameters to be measured. Both
one-time and time-sequential data parameters are covered, and the
parameters are defined carefully to ensure consistency and compa-
rability between experiments. Discrepancies between predicted and
actual performance, as measured by the energy bill, are common.
This protocol improves on billing data methods in two ways: (1)
internal temperature is monitored, which eliminates a major un-
known variable in data interpretation; and (2) data are taken more
frequently than monthly, which potentially shortens the monitoring
duration. Utility bill analysis generally requires a full season of pre-
retrofit and postretrofit data. The single-family retrofit protocol may
require only a single season.

Ternes (1986) identified both a minimum set of data, which must
be collected in all field studies that use the protocol, and optional
extensions to the minimum data set that can be used to study addi-
tional issues. See Table 2 for details. Szydlocwski and Diamond
(1989) have developed a similar method for multifamily buildings.

The single-family retrofit monitoring protocol recommends a
before-after experimental design, and the minimum data set allows
performance to be measured on a normalized basis with weekly
time-series data. (Some researchers recommend daily.) The proto-
col also allows hourly recording intervals for time-integrated
parameters—an extension of the basic data requirements in the min-
imum data set. The minimum data set may also be extended through
optional data parameter sets for users seeking more information.

The data parameters in this protocol have been grouped into four
data sets: basic, occupant behavior, microclimate, and distribution
system (Table 2). The minimum data set consists of a weekly
option of the basic data parameter set. Time-sequential measure-
ments are monitored continuously throughout the field study
period. These are all time-integrated parameters (i.e., the appropri-
ate average value of a parameter over the recording period, rather
than the instantaneous values).

This protocol also addresses instrumentation installation, accu-
curacy, and measurement frequency and expected ranges for all time-
sequential parameters (Table 3). The minimum data set (weekly
option of the basic data) must always be collected. At the user’s
discretion, hourly data may be collected, which allows two optional
parameters to be monitored. Parameters from the optional data sets
may be chosen, or other data not described in the protocol added, to
arrive at the final data set.

This protocol has standardized the experimental design and
data collection specifications, enabling independent researchers to
compare project results more readily. Moreover, including both
minimum and optional data sets and two recording intervals
accommodates projects of varying financial resources.

Commercial Retrofit Monitoring

Several related guidelines have been created for the particular
application of retrofit savings (M&V). The International Perfor-
mane Measurement and Verification Protocol (IPMVP 1997)
provides guidance to buyers, sellers, and financiers of energy
projects on quantifying energy savings performance of energy ret-
rofits. The Federal Energy Management Program has produced
guidelines specific to federal projects but having many procedures
that could be used for calculating retrofit savings in nonfederal
buildings (Schiller 1996).

On a more detailed level, ASHRAE research project RP-827
resulted in separate guidelines for the in situ testing of chillers, fans,
and pumps to evaluate installed energy efficiency (Phelan et al.
1997a,b). The guidelines specify the physical characteristics to be
measured; the number, range, and accuracy of data points required;
methods of artificial loading; and calculation equations with a rig-
orous uncertainty analysis.

In addition to these specialized protocols for particular monitor-
ing applications, a number of specific laboratory and field measure-
ment standards exist (see Chapter 54), and many monitoring source
books are in circulation.

As a final example, a protocol has been developed for use in field
monitoring studies of energy improvements (retrofits) for commer-
cial buildings (MacDonald et al. 1989). Similar to the residential
protocol, it addresses data requirements for monitoring studies.
Commercial buildings are more complex, with a diverse array of
potential efficiency improvements. Consequently, the approach to
specifying measurement procedures, describing buildings, and
determining the range of analysis must differ.

The strategy used for this protocol is to specify data require-
ments, analysis, performance data with optional extensions, and a
building core data set that describes the field performance of effi-
ciency improvements. This protocol requires a description of the
approach used for analyzing building energy performance. The nec-
essary performance data, including identification of a minimum
minimum data set, are outlined in Table 4.
Commercial New Construction Monitoring

New building construction offers the potential for monitoring building subsystem energy consumption at a reasonable cost. The information obtained by monitoring operating hours or direct energy consumption can benefit building owners and managers by:

- Alerting them to inefficient or improper operation of equipment
- Providing data that can be useful in determining the benefits of alternative operating strategies or replacement equipment
- Evaluating costs of operation for extending occupancy hours for special conditions or events
- Demonstrating the effects of poor maintenance or identifying when maintenance procedures are not being followed
- Diagnosing power quality problems
- Submetering tenants

In order to provide the data necessary to improve building systems operation, monitoring should be considered for boilers, chillers, heat pumps, air-handling unit fans, major exhaust fans, major pumps, comfort cooling compressors, lighting panels, electric heaters, receptacle panels, substations, motor control centers, major feeders, service water heaters, process loads, and computer rooms.

The construction documents may include provisions for various meters to monitor equipment and system operation. Some equipment can be specified to have factory-installed hour meters that record the actual operating hours of the equipment. Hour meters can also be easily field installed on any electrical motor.

More sophisticated power monitoring systems, with electrical switchgear, substations, switchboards, and motor control centers, can be specified. These systems can monitor energy demand, energy consumption, power factor, neutral current, etc., and can be linked to a personal computer. These same systems can be installed on

circuits to existing or retrofit fans, chillers, lighting panels, etc. Some equipment commonly used for improving system efficiency, such as variable-frequency drives, can be provided with capability to monitor kW output, kWh consumed, and other variables.

Use of central energy management control systems (e.g., direct digital control systems) for monitoring is particularly appropriate in new construction. These systems can monitor and record system status, steam flow, gas flow, water flow, energy consumption, demand, and hours of operation, as well as start and stop building systems, control lighting, and print alarms when systems are not operating within specified limits. Initial specification of the new control system should include sensors and trend logging and reporting functions.

COMMON MONITORING ISSUES

The key issues in monitoring are the accuracy and reliability of the data. Projects have been compromised by inaccurate or missing data. Periodic sensor calibration and ongoing data verification ensure the reliability and quality of the collected data.

Field monitoring projects also require effective management of various professional skills. Project staff must understand the building systems being examined, data management, data acquisition, and sensor technology. In addition to data collection, processing, and analysis, the logistics of field monitoring projects require the coordination of equipment procurement, delivery, and installation.

Planning

Many common problems in monitoring projects can be avoided by effective and comprehensive planning.

Project Goals. Project goals and data requirements should be established before hardware is selected. Unfortunately, projects are often driven by the selection of hardware rather than by project objectives, either because monitoring hardware must be ordered several months before data collection begins or because project initiation procedures are lacking. As a result, the hardware may be inappropriate for the particular monitoring task, or critical data points may be overlooked.

Project Cost and Resources. After goal setting, the feasibility of the anticipated project should be reviewed in light of available resources. Projects to which significant resources can be devoted usually involve different approaches from those for which resources are more limited. This issue should be addressed early on and reviewed throughout the course of the project. Although it is difficult to assess with certainty the cost of an anticipated project at this early stage, rough estimates can be quite helpful.

Data Products. It is important to establish the format and content of the data products before selecting data points. Failure to plan these data products first may lead to failure to answer critical questions.

Data Management. Failure to anticipate the (typically) large amounts of data collected can lead to major difficulties. The computer and personnel resources needed to verify, retrieve, analyze, and archive data can be estimated based on experience with previous projects.

Commitment. Many projects require a long-term commitment of personnel and resources. Project success depends on long-term, daily attention to detail and on staff continuity.

Accuracy Requirements. The accuracy requirements of the final data and the experimental design needed to meet these requirements should be determined early on. After the required accuracy is specified, the sample size (number of buildings, control buildings, or pieces of equipment) must be chosen, and the required measurement precision (including error propagation into the final data products) must be determined. Because trade-offs must usually be made between cost and accuracy, this process is often iterative. It is further complicated by a large number of independent variables (occupants, operating modes) and the stochastic nature of many variables (weather).

Advice. Expert advice should be sought from others who have experience with the type of monitoring envisioned.

Implementation and Verification

The following steps can facilitate smooth project implementation and data verification:

• Calibrate sensors before installation. Spot-check the calibration on site. During long-term monitoring projects, recalibrate sensors periodically. National Institute of Standards and Technology (NIST) standards should be used in all calibration procedures, which are listed in IPMVP (1997).

• Track sensor performance on a regular basis. Quick detection of sensor failure or calibration problems is essential. Ideally, this should be an automated or a daily task. The value of data is high because it may be difficult or impossible to reconstruct.

• Generate and review data on a timely, periodic basis. Problems often occur in developing final data products. These problems include missing data from failed sensors, data points not installed due to planning oversights, and anomalous data for which there are no explanatory records. If data products are specified as part of general project planning and produced periodically, production problems can be identified and resolved as they occur. Automating the process of checking data reliability and accuracy can be invaluable in keeping the project on track and in preventing sensor failure and data loss.

Data Analysis and Reporting

For most projects, the collected data must be analyzed and put into reports. Because the objective of the project is to translate these data into information and ultimately into knowledge and action, the importance of this step cannot be overemphasized. Clear, convenient, and informative formats should be devised in the planning stages and adhered to throughout the project.

Close attention must be paid to resource allocation to ensure that adequate resources are dedicated to verification, management, and analysis of the data and to ongoing maintenance of the monitoring equipment. As a quality control procedure and to make data analysis more manageable, these activities should be ongoing. The data analysis should be carefully defined before the project begins.

STEPS FOR PROJECT DESIGN AND IMPLEMENTATION

This section describes a methodology for designing effective field monitoring projects. The task components and relationships among the nine activities constituting this methodology are identified in Figure 1. The activities fall into four categories: project management, project development, resolution and feedback, and production quality and data transfer. Field monitoring projects vary in terms of resources, goals and objectives, data product requirements, and other variables, which affects how the methodology should be applied. Nonetheless, the methodology provides a proper framework for advance planning, which minimizes or helps prevent project implementation problems.

An iterative approach to planning activities is best. The scope, accuracy, and techniques can be adjusted based on cost estimates and resource assessments. The initial design should be performed simply and quickly to estimate cost and evaluate resources. An iterative approach to project planning is also necessary when the desired levels of instrumentation exceed the resources available for the project. The planning process should identify and resolve any trade-offs necessary to execute the project within a given budget. In many instances, it is preferable to reduce the scope of the project...
Part One: Identify Project Goals and Objectives

One of the most frequent oversights in project planning is failure to reserve sufficient time and resources for later analysis and reporting of data. Unanticipated additional costs associated with data collection and problem resolution should not jeopardize these resources.

Part One: Identify Project Goals and Objectives

Start with a clear understanding of the decision to be made or action to be taken as a result of the project. The goals and objectives statement determines the overall direction and scope of the data collection and analysis effort. The statement should also list the questions to be answered by the empirical data, noting the error or uncertainty associated with the desired result. A realistic assessment of error is needed because requiring too small an uncertainty leads to an overly complex and expensive project. It is important in monitoring projects to resolve that a data acquisition plan will be developed and followed with a clear idea of the research questions to be answered.

Even if a project is not research-oriented, it is attempting to obtain some information, and this can be stated in the form of questions. Research questions can have varying scopes and levels of detail, addressing entire systems or specific components. Some examples of research questions follow:

- Measurement and verification: Have the contractors fulfilled their responsibilities in installing equipment capable of producing the agreed-upon energy savings?
- Classes of buildings: To an accuracy of 20%, how much energy has been saved by using a building construction/performance standard mandated in this state?
- Particular buildings: Has a lapse in building maintenance caused energy performance to degrade?
- Particular components: What is the average reduction in demand charges during summer peak periods due to the installation of an ice storage system in this building?

Research questions vary widely in technical complexity, generally taking one of the following three forms:

1. How does the building/component perform?
2. Why does the building/component perform as it does?
3. Which building/component should be targeted to achieve optimal cost-effectiveness?

Part Two: Specify Building Characteristics

The measured energy data will not be meaningful at a later date to people who were not involved in the project unless the characteristics of the building being monitored and its use have been documented. To meet this need, a data structure (e.g., a characteristic database) can be developed to describe the buildings.

Building characteristics can be collected at many levels of detail, but it is important to provide at least enough detail to document the following:

- General building configuration and envelope (particularly energy-related aspects)
- Building occupant information (number, occupancy schedule, activities)
- Internal loads
- Type and quantity of energy-using systems (including set-point temperatures)
- Any building changes that occur during the monitoring project

The minimum level of detail is known as summary characteristics data. Simulation level characteristics (detailed information collected for hourly simulation model input) may be desirable for some buildings. Regardless of the level of detail, the data should provide a context for analysts, who may not be familiar with the project, to understand the building and its energy use.

For occupied existing buildings, characteristics information should be collected in four areas:

- Building descriptive information characterizing key parameters affecting HVAC system performance
- Entrance interview information focusing on the energy-related behavior of building occupants prior to monitoring
- Exit interview information documenting physical or life-style changes at the test site that may affect data analysis

Part Three: Specify Data Products and Project Output

The objective of a monitoring project is typically not to produce data, but to answer a question. However, the data must be of high quality and must be presented to key decision makers and analysts in a convenient and informative format. The specific data products (the format and content of data reporting needed to meet the project goals and objectives) must be identified and evaluated for feasibility and usefulness. The final data products must be clearly specified, together with the minimum acceptable data requirements for the project. It is important to clearly define an analysis path showing what will be calculated and what data will be necessary to achieve desired results. Clear communication is critical to ensure that project requirements are satisfied and factors contributing to monitoring costs are understood.

Evaluation results can be presented in many forms, often as interim and final reports (possibly by heating and/or cooling season), technical notes, or technical papers. These documents must convey specific results of the field monitoring clearly and concisely. They should also contain estimates of the accuracy of the results.

The composition of data presentations and analysis summaries should be determined early to ensure that no critical parameters are overlooked (Hough et al. 1987). For instance, mock-ups of data tables, charts, and graphs can be used to identify requirements.
Previously reported results can be used to provide examples of useful output. Data products should also be prioritized to accommodate possible cost trade-offs or revisions resulting from error analysis (see Part Seven). A worksheet can be used to determine information needs and to help organize specific research questions and technology issues by project objectives. Next, specific data presentation formats should be determined.

It is important to identify the type and amount of comparative analysis and evaluation needed. For example, any need for data normalization for weather or usage profiles, along with the method to be employed, should be determined in advance.

Although requirements for the minimum acceptable data results can often be specified during planning, data analysis typically reveals further requirements. Thus, budget plans should include allowances and optional data product specifications to handle additional or unique project output requirements uncovered during data analysis.

Longer-term goals and future information needs should be anticipated and explained to project personnel. For example, a project may have short- and long-term data needs (e.g., demonstrating reductions in peak electrical demand versus demonstrating cost-effectiveness or reliability to a target audience). The initial results on demand reduction may not be the ultimate goal, but rather a step toward later presentations on cost reductions achieved. Thus, it is prudent to consider long-term and potential future data needs so that additional supporting information, such as photographs or testimonials, may be identified and obtained.

Part Four: Specify Monitoring Design Approach

A general monitoring design must be developed that defines two interacting factors—the number of buildings admitted to the study and the monitoring approach. A less detailed or precise approach can be considered if the number of buildings is increased, and vice versa. If the goal is related to a specific product, the monitoring design must isolate the effects of that product. Haberl et al. (1990) discuss monitoring designs. For the particular example of retrofit M&V, protocols have been written allowing a range of different monitoring methods, from retrofit verification to retrofit isolation (IPMVP 1997, Schiller 1996).

Specifying the monitoring design approach is particularly important because the total building performance is a complex function of several variables, all of which are subject to changes that are difficult to monitor and to translate into performance. Unless care is taken with measurement organization and accuracy, uncertainties and errors (noise) can make it difficult to detect performance changes of less than 20 to 30% (Fracastoro and Lyberg 1983).

In some cases, judgment may be required in selecting the number of buildings involved in the project. If an owner seeks information about a particular building, the choice is simple—the number of buildings in the experiment is fixed at one. However, for other monitoring applications, such as drawing conclusions regarding effects in a sample population of buildings, some degree of choice is involved. Generally, the error in the derived conclusions decreases as the square root of the number of buildings (Box 1978).

Accuracy requirements depend on the effect to be measured and on the specified experimental design and analysis methods. Without special measurements, energy savings of less than 20% of the total consumption are difficult to detect from an analysis of monthly utility bills. Year-to-year changes in weather conditions alone can cause a significant change in energy use for an average envelope-driven building. A specific project may be directed at

1. Fewer buildings or systems with more detailed measurements
2. Many buildings or systems with less detailed measurements
3. Many buildings or systems with more detailed measurements

For projects of the first type, accuracy requirements are usually resolved initially by determining the expected variations of measured quantities (dependent variables) about their average values in response to the expected variations of the independent variables. For buildings, a typical concern is the response of heating and cooling loads to changes in temperature or other weather variables. The response of building lighting energy use to daylighting systems using natural light is another example of the relationship between dependent and independent variables. The fluctuations in response are caused by (1) outside influences not quantified by the measured energy use data and (2) limitations and uncertainties associated with measurement equipment and procedures. Thus, accuracy must often be determined using statistical methods to describe mean tendencies of dependent variables.

For projects of the second and third types, the increased number of buildings allows improved confidence in the mean tendencies of the dependent responses of interest. Larger sample sizes are also needed for experimental designs with control groups, which are used to adjust for some outside influences. For further information, see Box (1978), Fracastoro and Lyberg (1983), and Hirst and Reed (1991).

Most monitoring procedures use one or more of the following general experimental approaches:

**On-Off.** If the retrofit or product can be activated or deactivated at will, energy consumption can be measured in a number of repeated on-off cycles. The on-period consumption is then compared to the off-period consumption (Woller 1989; Cohen et al. 1987).

**Before-After.** Building energy consumption is monitored before and after a new component or retrofit is installed. Changes in the weather and building operation during the two periods must be accounted for, often requiring a model-based analysis (Hirst et al. 1983; Fels 1986; Robison and Lambert 1989; Sharp and Mac-Donald 1990; Kissock et al. 1992).

**Test-Reference.** The building energy consumption data of two “identical” buildings, one with the product or retrofit that is being investigated, are compared. Because buildings cannot be identical (e.g., different air leakage distributions, insulation effectiveness, temperature settings, and solar exposure), measurements should be taken prior to installation as well in order to allow calibration. Once the product or retrofit is installed, any deviation from the calibration relationship can be attributed to the product or retrofit (Levins and Karnitz 1986; Fracastoro and Lyberg 1983).

**Simulated Occupancy.** In some cases, the desire to reduce noise can lead the experimenter to postulate certain standard profiles for temperature set points, internal gains, moisture release, or window manipulation and to introduce this profile into the building by computer-controlled devices. The reference is often given by the test-reference design. In this case, both occupant and weather variations are nearly eliminated in the comparison (Levins and Karnitz 1986).

**Nonexperimental Reference.** A reference for assessing the performance of a building can be derived nonexperimentally using (1) a normalized, stratified performance database—energy use per unit area classified by building type (MacDonald and Wasserman 1989) or (2) a reasonable standard building, simulated by a calculated hourly or bin-method calibrated building energy performance model subject to the same weather, equipment type, and occupancy as the monitored building.

**Engineering Field Test.** When the experiment is focused on testing a particular piece of equipment, the total building performance is not of primary interest. The building provides a realistic environment for testing the equipment for reliability, maintenance requirements, and comfort and noise levels, as well as energy usage. The energy consumption of mechanical equipment is significantly affected by the control strategy. Testing procedures should be designed to incorporate the control strategy of the equipment and its system (Phelan et al. 1997a, b). This type of monitoring and testing can also be used to calibrate computer simulation models of
as-built and as-operated buildings, which can then be used to evaluate whole-building energy consumption. The equipment may be extensively instrumented.

Some of the general advantages and disadvantages of these approaches are listed in Table 5 (Fracastoro and Lyberg 1983). Monitoring design choices have been successfully combined (e.g., the before-after and test-reference approaches). Questions to be considered in choosing a monitoring approach include the following:

• Can the building alteration being investigated be turned on and off at will? The on-off design offers considerable advantages.
• Are occupancy and occupant behavior critical? Changes in building type, use schedules, internal gains, temperature set points, and natural or forced ventilation practices should be considered because any one of these variables can ruin an experiment if it is not constant or accounted for.
• Are actual baseline energy performance data critical? In before-after designs, time must be allotted to characterize the before case as precisely as the after case. For instances in which heating and cooling systems are being evaluated, data may be required for a complete range of anticipated ambient conditions.
• Is it a test of an individual technology, or are multiple technologies installed as a package being tested? If the impacts of individual technologies are sought, detailed component data and careful model-based analyses are required.
• Does the technology have a single mode or multiple modes of operation? Can the modes be controlled to suit the experiment? If many modes are involved, it will be necessary to test over a variety of conditions and conduct model-based analysis (Phelan et al. 1997a,b).

Table 5  Advantages and Disadvantages of Common Experimental Approaches

<table>
<thead>
<tr>
<th>Mode</th>
<th>Advantages</th>
<th>Disadvantages</th>
</tr>
</thead>
<tbody>
<tr>
<td>Before-after</td>
<td>No reference building required. Same occupants implies smaller occupant variations. Modeling processes will be mostly identical before/after.</td>
<td>Weather different before/after. More than one heating/cooling season may be needed. Model is required to account for weather and other changes.</td>
</tr>
<tr>
<td>Test-reference</td>
<td>One season of data may be adequate. Small climate difference between buildings.</td>
<td>Reference building required. Calibration phase required (may extend testing to two seasons). Occupants in either or both buildings can change behavior.</td>
</tr>
<tr>
<td>On-off</td>
<td>No reference building required. One season may be adequate. Modeling processes will be mostly identical before/after. Most occupancy changes will be small.</td>
<td>Requires reversible product. Cycle may be too long if time constants are large. Model is required to account for weather differences in cycles. Dynamic model accounting for transients may be needed.</td>
</tr>
<tr>
<td>Simulated occupancy</td>
<td>Noise due to occupancy is eliminated. A variety of standard schedules can be studied.</td>
<td>Not “real” occupants. Expensive apparatus required. Extra cost of keeping building unoccupied.</td>
</tr>
<tr>
<td>Nonexperimental reference</td>
<td>Cost of actual reference building eliminated. With simulation, weather variation is eliminated.</td>
<td>Database may be lacking in strata entries. Simulation errors and definition of reference problematic. With database, weather changes usually not possible.</td>
</tr>
<tr>
<td>Engineering field test</td>
<td>Information focused on the product of interest. Minimal number of buildings required. Same occupants during the test.</td>
<td>Extensive instrumentation of product processes required. Models required to extrapolate to other buildings and climates. Occupancy effects not determined.</td>
</tr>

• Determine the independent variables and analysis constants to be measured in the field (e.g., fan power, lighting and receptacle power, indoor air temperature).
• Develop engineering calculations and equations (algorithms) necessary to convert field data to end products. This may include the use of statistical methods and simulation modeling.
• Specify detailed items, such as the frequency of data collection, the required range of independent variables to be captured in the data set, and the reasons certain data must be obtained at different intervals. For example, 15 min interval demand data is assembled into hourly data streams to match utility billing data.

Determine the proper NIST-traceable calibration standards for each sensor type to be used. For details, see the references cited in IPMVP (1997) for specific types of sensors. However, it is often impractical to implement standards in the field. For example, maintaining the length of straight ductwork required for an airflow sensor is usually difficult in the field, requiring compromise.

Algorithm inputs can be assumed values (such as the energy value of a unit volume of natural gas), one-time measurements (the leakage area of a house), or time-series measurements (fuel consumption and outside and inside temperatures at the site). The algorithms may pertain to (1) utility level aggregates of buildings, (2) particular whole-building performance, or (3) performance of instrumented components.

Chapter 30 of the 1997 ASHRAE Handbook—Fundamentals contains a lengthy discussion on inverse modeling procedures. In this chapter, the discussion will focus on analysis methods that can generally be classified as empirical or model-based.

Empirical Methods. Although empirical methods are the simplest, they can have large uncertainty and generate little or no information for small sample sizes. The simplest empirical methods are based on annual consumption values, tracking the annual numbers and looking for degradation. Questions about building performance relative to other buildings are based on comparing certain performance indices between the building and an appropriate reference. ASHRAE/IESNA Standard 105 gives an example of how a database could be established for this purpose.

For commercial buildings, the most common index is the energy use intensity (EUI), which is the annual consumption, either by fuel type or summed over all fuel types, divided by the conditioned floor area. Comparison is often made only on the basis of general building type, which can ignore potentially large variations in climate, the number of workers in a building, the number...
and type of computers in a building, and HVAC systems. Such variations can be accommodated to some degree by stratifying the database from which the reference EUI is chosen. Computer simulations are often used to set reasonable standards.

The Commercial Buildings Energy Consumption Survey database, summarized in EIA (1996) and in Chapter 34, has been used to develop an energy use benchmarking method for office buildings in the United States. The initial work in this area covered only electricity use, but the methods have been extended to cover all fuels for office buildings (Sharp 1996). The work showed that the electricity use of office buildings is most significantly explained by the number of workers in the building, the number of personal computers, whether the building is owner-occupied, and the number of operating hours each week. Only a subset of these parameters may be used to determine a benchmark within a specific census division.

Simple empirical methods that are applied to retrofit applications should include at least some periods of data on daily energy use and average daily temperature (recorded locally) to account for variations in occupancy and building schedules. Monthly EUI or billing data provide more information for empirical analysis and can be used for extended analysis of energy impacts of retrofit applications, for example, in conditional demand analysis (Hirst and Reed 1991). Monthly data can also be used to detect billing errors, improper equipment operation during unoccupied hours, and seasonal space-conditioning problems (Haberl and Komor 1990a, 1990b). Daily data are often used in these analyses, and raw hourly total building consumption data, when available, provide more detailed information on occupied versus unoccupied performance. Hourly, daily, monthly, and annual EUI across buildings can be directly compared when reduced to average power per unit area (power density). To avoid false correlations, the method of analysis should have statistical significance that can be traced to realistic parameters (Haberl et al. 1996).

Model-Based Methods. These techniques allow a wide range of additional data normalization to potentially improve the accuracy of comparisons and provide estimates of cause-effect relations. The analyst must carefully define the system and postulate a useful form of the governing energy balance/system performance equation or system of equations. Explicit terms are retained for equipment or processes of particular interest. As part of the data analysis, whole-building data (driving forces and thermal or energy response) are used to determine the model’s significant parameters. The parameters themselves can provide insight, although parameter interpretation can be difficult, particularly with time-integrated billing data methods. The model can then be used for a number of normalization processes as well as future diagnostic and control applications. Two general classes of models are used in analysis methods: time-integrated methods and dynamic techniques (Burch 1986; Balcomb et al. 1993).

Time-Integrated Methods. Based on algebraic calculation of the building energy balance, time-integrated methods are often used prior to data comparison to correct annual consumption for variations in outdoor temperature, internal gains, and internal temperature (Fels 1986; Busch et al. 1984; Haberl and Claridge 1987; Claridge et al. 1991). This type of correction is essential for most retrofit applications.

Time-integrated methods can be used with whole-building energy consumption data (billing data) or with metered end-use data. For example, standard time-integrated methods are often used to separately integrate end-use consumption data (heating, cooling, domestic water heating) for comparison and analysis. Time-integrated methods are generally reliable, as long as the following three conditions are accounted for:

- **Appropriate time step.** Generally, the time step should be as long as or longer than the response time of the building or building system for which energy use is being integrated. For example, the response of daylighting controls to natural illumination levels can be rapid, allowing short time steps for data integration. In contrast, the response of cooling system energy use to changes in cooling load can be comparatively slow. In this instance, either a time step long enough to average over these slow variations or a dynamic model should be used. In general, an appropriate time step should account for the physical behavior of the energy system(s) and the expression of this behavior in model parameters.

- **Linearity of model results.** Generally, time-integrated models should not be applied to data used to estimate nonlinear effects. Air infiltration, for example, is nonlinear when estimated using wind speed and indoor/outdoor temperature difference data in certain models. Estimation errors would result if these parameters were independently time-integrated and then used to calculate air infiltration. Such nonlinear effects should be modeled at each time step (each hour, for example).

- **End-use uniformity within data set.** End-use data sets should be uniform (i.e., should not inadvertently contain observations with measurements of end uses other than those intended). During mild weather, for example, HVAC systems may provide both heating and cooling over the course of a day, creating data observations of both heating and cooling measurements. In a time-integrated model of heating energy use, these cooling energy observations would lead to error. Such observations should be identified or otherwise flagged by their true end use.

For whole-building energy consumption data (billing data), reasonable results can be expected from heating analysis models when the building is dominantly responsive to inside-outside temperature differences. The billing data analysis method yields little of interest when internal gains are large compared to skin loads, as in large commercial buildings and industrial applications. Daily, weekly, and monthly whole-building heating season consumption integration steps have been employed (Fels 1986; Ternes 1986; Sharp and MacDonald 1990; Claridge et al. 1991). Cooling analysis results have been less reliable because cooling load is not strictly proportional to variable base cooling kelvin-days (Kissock et al. 1992; Haberl et al. 1996; Fels 1986). Problems also arise when solar gains are dominant and vary by season.

Dynamic Techniques. Dynamic models, both macrodynamic (whole-building model) and microdynamic (component-specific), offer great promise for reducing monitoring duration and increasing conclusion accuracy. Furthermore, individual effects from multiple measures and system interactions can be examined explicitly. Dynamic whole-building analysis is generally accompanied by detailed instrumentation of specific technologies. Dynamic techniques create a dynamic physical model for the building, adjusting the parameters of the model to fit the experimental data (Subbarao 1988; Duffy et al. 1988). In residential applications, computer-controlled electric heaters can be used to maintain a steady interior temperature overnight, extracting from this data an experimental value for the building steady-state load coefficient. A cool-down period can also be used to extract information on internal building mass thermal storage. Daytime data can be used to renormalize the response (computed from a microdynamic model) of the building to solar radiation, which is particularly appropriate for buildings with glazing areas of over 10% of the building floor area (Subbarao et al. 1986). Once the data with electric heaters have been taken, the building can be used as a dynamic calorimeter to assess the performance of auxiliary heating and cooling systems.

Similar techniques have been applied to commercial buildings (Norford et al. 1985; Burch et al. 1990). In these cases, delivered energy from the HVAC system must be monitored directly in lieu of using electric heaters. Because ventilation is a major variable term in the building energy balance, the outside airflow rate should also be monitored directly. Simultaneous heating and cooling, common

</table>

Note: Error figures are approximate for total energy use in a single building. All methods improve with selection of more buildings.

Accuracy can be improved by decreasing time step to weekly or daily. These methods are of little use when the outdoor temperature approaches the balance temperature.

Part Six: Specify Field Data Monitoring Points

Careful specification of field monitoring points is critical to identifying the variables that need to be monitored or measured in the field to produce the required data.

Because metering projects are often conducted in buildings with changing conditions, special consideration must be given to identifying and controlling significant changes in climate, systems, and operation during the monitoring period. Additional monitoring points may be required to measure variables that are assumed to be constant, insignificant, or related to other measured variables in order to draw sound conclusions from the measurements. Because the necessary data may be obtained in several ways, data analysts, equipment installers, and data acquisition system engineers should work together to develop tactics that best suit the project requirements. It is important to anticipate the need for supplemental measurements in response to project needs that may not become apparent until actual equipment installation occurs.

The cost of data collection is a nonlinear function of the number, accuracy, and duration of measurements that must be considered while planning within budget constraints. If the extent of data applications is unknown, such as in research projects, consideration should be given to the value of other concurrent measurements because the incremental cost of alternative analyses may be small.

For any project involving large amounts of data, data quality verification should be automated (Lopez and Haberl 1992). While this may require adding monitoring points to facilitate energy balances or redundancy checks, the added costs are likely to be offset by savings in data verification for large projects.

If multiple sites are to be monitored, common protocols for the selection and description of all field monitoring points should be established so that data can be more readily verified, normalized, compared, and averaged. Protocols also add consistency in selecting monitoring points. Pilot installations should be conducted to provide data for a test of the system and to ensure that the necessary data points have been properly specified and described.

General considerations in selecting monitoring equipment include the following:

- Evaluate the equipment thoroughly under actual test conditions before committing to large-scale procurement. Particular attention should be paid to any sensitivity to power outages and to protection against power surges and lightning.
- Consider local set up and testing of complex data acquisition systems that are to be installed in the field.
- Avoid data acquisition equipment that has not been proven (Sparks et al. 1992). Untested equipment, even if donated, may not be a good value.
- Consider the costs and benefits of remote data interrogation and programming.
- Evaluate quality and reliability of data loggers and instrumentation; these issues may be more important than cost, particularly when data acquisition sites are distant.
- Verify vendor claims by calling references or obtaining performance guarantees.
- Consider portable battery-powered data loggers in lieu of hardwired loggers if the monitoring budget is limited and the length of the monitoring period is less than a few months.
- Ensure that the monitoring equipment and installation methods are consistent with prevailing laws, building codes, and standards of good practice.

An examination of the analysis method will determine the data to be measured in the field. The simplest methods require no on-site instrumentation. As the methods become more complex, data channels increase. For engineering field tests conducted with dynamic techniques, up to 100 data channels may be required.

Particular attention must be paid to sensor location. For example, if the method requires an average indoor temperature, examine the potential for internal temperature variation; data from several temperature sensors must often be averaged. Alternatively, temperature sensors adjacent to HVAC thermostats detect the temperature to which the HVAC equipment reacts.

After the channel list is compiled, sensor accuracy and scan rates should be assigned. Some sensors, such as indoor and outdoor temperature sensors, may require low scan rates (once every 5 min). Others, such as total electric sensors, may contain high-frequency transients that require rapid sampling (many times per second). The maximum sampling rate is usually programmed into the logger, and averages are stored at a specified time step (hourly). Some loggers can scan different channels at different rates. The logger’s interrupt capability can also be used for rapid, infrequent transients. Interrupt channels signal the data logger to start monitoring an event only once it begins. In some cases, the on-line computation of derived quantities must be considered. For example, if heat flow in an air
duct is required, it can be computed from a differential temperature measurement multiplied by an air mass flow rate that was determined from a one-time measurement. However, it should be computed and totaled only when the fan is operating.

Once the required field data monitoring points are specified, these requirements should be clearly communicated to all members of the project team to ensure that the actual monitoring points are accurately described. This can be accomplished by publishing handbooks for measurement plan development and equipment installation and by outlining procedures for diagnostic tests and technology assessments.

Cost savings may be possible through the use of a building energy management system for data acquisition. This should be considered only when its sensors and their accuracy and limitations (scan rate, etc.) are thoroughly understood. When merging data from two data acquisition systems, problems may arise such as differing reliability and low data resolution (e.g., 1 kW resolution of a circuit that draws 10 kW fully loaded). These problems can often be avoided, however, by adding appropriate sensors and setting up custom trend logs with point, memory, and programming capacity.

**Scanning and Recording Intervals.** The frequency of data measurement and data storage can affect the accuracy of project output. Scanning differs from storage in that data channels may be read (scanned) many times per second, for example, while average data may be recorded and stored every 15 min. Most data loggers maintain temporary storage registers, accumulating an integrated average of channel readings from each scan. The average is then recorded at the specified interval.

The data scan rate must be sufficiently fast to ensure that all significant effects are monitored. The recording frequency required can vary by data channel. As mentioned previously, transient and/or random events are often best monitored using the interrupt capabilities of modern data loggers.

**Sensors and Data Acquisition Systems.** Sensors should be selected to obtain each measurement on the field data list. Next, conversion and proportion constants should be specified for each sensor type, and the accuracy, resolution, and repeatability of each sensor should be noted. Sensors should be calibrated before they are installed in the field, preferably with a NIST-traceable calibration procedure. They should be checked periodically for drift, recalibrated, and then postcalibrated at the conclusion of the experiment (Haberl et al. 1995). Calibration of instrumentation is particularly vital for flow and power measurement.

Because hardware needs vary considerably by project, specific selection guidelines are not provided here. However, general characteristics of data acquisition hardware components are shown in [Table 7]. Some typical concerns for selecting data acquisition hardware are outlined in [Table 8]. In general, data logger and instrumentation hardware should be standardized, with replacements available in the event of failure. It is also useful to consider redundant measurements for critical data components that are likely to fail include modems, flowmeters, shunt resistors on current transformers, and devices with moving parts (O’Neal et al. 1993). Also, certain measurements are more difficult to obtain accurately than others due to instrumentation limitations, as summarized in [Table 9].

Safety must be considered in equipment selection and installation. Installation teams of two or more individuals will reduce risks. When contemplating thermal metering, the presence of asbestos insulation on water piping should be determined. Properly licensed trades personnel, such as an electrician or welder, should be a fundamental part of any team installing electrical monitoring equipment.

In order to prevent inadvertent tampering, any occupants and maintenance personnel should be carefully briefed on what is being done and the purpose of sensors and equipment. Data loggers should have a dedicated (non-occupant-switchable) hard-wired power supply to prevent inadvertent power loss.

Part Seven: Resolve Data Product Accuracies

Data collected by the monitoring equipment is usually used for the following purposes:

- Direct reporting of the primary measurement data
- Reporting of secondary or deduced quantities (e.g., thermal energy consumed by a building, found by multiplying mass flow rate and temperature difference)
- Subsequent interpretation and analyses (e.g., to develop a statistical model of energy used by a building versus outdoor dry-bulb temperature)

In all three cases, the value of the measurements is dramatically increased if the associated uncertainty can be quantified.

1999 ASHRAE Applications Handbook (SI)

Basic Concepts. The concept of uncertainty can be better understood in terms of confidence limits. Confidence limits define the range of values that can be expected to include the true value with a stated probability (ASHRAE Guideline 2). Thus, a statement that the 95% confidence limits are 5.1 to 8.2 implies that the true value is contained in the interval bounded by 5.1 and 8.2 in 19 out of 20 predictions or, more loosely, that we are 95% confident that the true value lies between 5.1 and 8.2. For a given set of n observations with normal (Gaussian) error distribution, the total variance about the mean predicted value $\bar{X}$ provides a direct indication of the confidence limits. Thus, the “true” mean value $\bar{X}$ of the random variable is bounded as follows:

$$\bar{X} \pm t_{\alpha/2, n-1} \sqrt{\sigma^2/n}$$

where

- $\alpha$ = level of significance
- $\bar{X}$ = mean predicted value of random variable X
- $t_{\alpha/2, n-1}$ = t-statistic with probability of 1 - $\alpha/2$ and n - 1 degrees of freedom (tabulated in most statistical textbooks)
- n = number of observations, with Gaussian error distribution
- $\sigma^2$ = estimated measurement variance

The terms accuracy and precision are often used to distinguish between bias errors and random errors. A set of measurements with small bias errors is said to have high accuracy, while a set of measurements with small random errors is said to have high precision. In repeated measurements of a given sample via the same technique (single-sample data), each measurement has the same bias. Bias errors include (1) those that are known and can be calibrated out, (2) those that are negligible and are ignored, and (3) those that are estimated and are included in the uncertainty analysis. It is usually difficult to estimate bias limits, and this effect is often overlooked by most practitioners. However, a proper error analysis should include bias error, which is usually written as a plus-minus error. ASME Standard PTC 19.1 has a more complete discussion.

Because bias errors $b_m$ and random errors $\epsilon_m$ are usually uncorrelated, measurement variance $\sigma^2$ can be expressed as

$$\sigma^2_{\text{meas}}(b_m, \epsilon_m) = \sigma^2(b_m) + \sigma^2(\epsilon_m)$$

For further information on uncertainty, see Chapter 14 of the 1997 ASHRAE Handbook—Fundamentals.

Primary Measurement Uncertainty. Sensor and measuring equipment manufacturers usually specify measurement variances; frequent recalibration minimizes bias errors. As indicated by Equation (1), increasing the number of measurements n reduces the uncertainty bounds.

Uncertainty in Derived Quantities. Once a specific algorithm or equation for obtaining final data from physical measurements has been established, standard techniques can be used that incorporate primary measurement uncertainties into the final data product. For the random errors, the well-known Kline and McClintock (1953) error propagation method, based on a first-order Taylor series expansion, is widely used to determine measurement uncertainties in the derived variables in single-sample experiments. Bias errors are difficult to account for; the usual practice is to calibrate them out and exclude them from the uncertainty analysis.

Uncertainty in Statistical Regression Models. Statistical regression models developed from measured data are usually used for predictive purposes. Measurement errors are much smaller than model errors, which arise because the regression model is imperfect; that is, it is unable to explain the entire variation in the regressor variable (Box 1978). Measurement error is inherently contained in the identified model, so the total prediction variance is simply given by the model prediction uncertainty.
Building Energy Monitoring

Determination of prediction errors due to regression models is subject to different types of problems. The various sources of error can be classified into three categories (Reddy et al. 1998):

1. Model misspecification errors are due to the fact that the functional form of the regression model is usually an approximation of the true driving function of the response variable.
2. Model prediction errors arise due to the fact that a model is never perfect.
3. Model extrapolation errors arise when a model is used for prediction outside the region covered by the data from which the model was developed. Models developed from short data sets, which do not satisfy the represent the actual behavior of the system, are subject to this error. This error cannot be quantified in statistical terms alone, but certain experimental conditions are likely to lead to accurate predictive models. This falls under the purview of experimental design (Box 1978).

Sources 1 and 3 are likely to introduce both bias and random error in the predictions. If ordinary least-squares regression is used for parameter estimation, and if the model is subsequently used for prediction, error due to source 2 will be purely random. Thus, models identified from short data sets and used to predict seasonal or annual energy use are affected by error sources 1 and 3.

The least-squares method of calculating linear regression coefficients is incapable of producing unbiased estimators of the slope and intercept if there are errors associated with the measurement of the predictor variable. The uncertainty analysis methodology developed for in situ equipment testing uses standard linear regression practices to find the functional relationship and then estimates the increased uncertainty in the regression prediction due to random and bias errors in both variable measurements (Phelan et al. 1996).

Experimental Design. Errors can also be estimated based on historical experience (e.g., using results from previous similar projects). Alternatively, a pilot study can be launched to obtain an estimate of potential errors in a proposed analysis. Some estimate of potential error must be available to determine whether the project goals and objectives are reasonable.

Estimating data uncertainty is one part of the iterative procedure associated with proper experimental design. If the final data product uncertainty determined using the preceding evaluation procedure is unacceptable, the uncertainty can be reduced in one or more of the following ways:

- Reducing overall measurement uncertainty (improving sensor precision)
- Increasing the duration of the monitoring period to average out stochastic variations
- Increasing the number of buildings tested

On the other hand, if simulations indicate that the expected bias in the final data products is unacceptable, the bias may be reduced by one or more of the following steps:

- Adding sensors to get an unbiased measurement of the quantity
- Using more detailed models and analysis procedures
- Increasing data acquisition frequency, in combination with a more detailed model, to eliminate biases due to sensor or system nonlinearities

Accuracy Versus Cost. The need for accuracy must be carefully balanced against measurement and analysis costs. Accuracy loss can stem from instrumentation or measurement error, normalization or model error, sampling or statistical error, and errors of assumptions. Each of these sources of error can be controlled to varying degrees. However, it is generally true that more accurate methods follow the law of diminishing returns, in which further reductions in error come at progressively greater expense.

Because of this trade-off, the optimal measurement solution is usually found by an iterative approach, where incremental improvements in accuracy are assessed relative to the increase in measurement cost. Such optimization requires that a value be placed on increasing levels of accuracy. One method of evaluating the uncertainty of a proposed method is to calculate results using the highest and lowest values in the confidence interval. The difference between these values can be translated into a monetary amount that is at risk. The question that must be answered is whether further measurement investment is warranted to reduce this risk.

Part Eight: Specify Verification and Quality Assurance Procedures

Establishing and using data quality assurance (QA) procedures can be very important to the success of a field monitoring project. The amount and importance of the data to be collected help determine the extent and formality of the QA procedures. For most projects, the entire data path, from sensor installation to procedures that generate results for the final report, should be considered for verification tests. In addition, the data flow path should be checked routinely for failure of sensors or test equipment, as well as unexpected or unauthorized modifications to equipment.

Quality assurance often requires complex data handling. Building energy monitoring projects collect data from sensors and manipulate that data into results. Data handling in a project with only a few sensors and required readings can consist of a relatively simple data flow on paper. Computers, which are generally used in one or more stages of the process, require a different level of process documentation because much of what occurs has no direct paper trail.

Computers facilitate the collection of large data sets and increase project complexity. To achieve maximum automation, computers require the development of specific software. Often, separate computers are involved in each step, so passing information from one computer to another must be automated in large projects. To move the data as smoothly as possible, an automated data pipeline should be developed. This pipeline minimizes the time delay from data collection to results production and maximizes the cost-effectiveness of the entire project.

An automated data verification procedure should be used when possible. Frequent data acquisition (preferably automated) with a quality control review of summarized and plotted data is essential to ensure that reliable data are collected. Verification procedures should be performed at frequent intervals (daily or weekly), depending on the importance of missing data. This minimizes data loss due to equipment failure and/or changes at a building site. It also allows the processed information to be applied quickly.

The following QA actions should take place:

- Calibrate hardware and establish a good control procedure for collection of data. Use NIST-traceable calibration methods.
- Verify data, check for reasonableness, and prepare a summary report to assure the quality of the data after it is collected.
- Perform initial analysis of the data. Significant findings may lead to changes in procedures for checking data quality.
- Thoroughly document and control procedures applied to remedy problems. These procedures may entail changes in hardware or collected data (such as data reconstruction), which can have a fundamental impact on the results reported.
- Maintain an archive of the raw data obtained from the site to ensure project integrity.

Three aspects of a monitoring project that require quality assurance are shown in Table 10. Hardware, engineering data, and characteristics data. Three QA reviews are necessary for each of these aspects: (1) initial QA confirms that the project starts correctly; (2) ongoing QA confirms that the information collected by the project continues to satisfy requirements; and (3) periodic QA involves additional checks, established at an the beginning of the...

Part Nine: Specify Recording and Data Exchange Formats

This step involves specifying the formats in which the data will be supplied to the end user or other data analysts. Both raw and processed (adjusted for missing data or anomalous readings) data formats should be specified. In addition, if any supplemental analyses are planned, the medium and format to be used (magnetic tape, disk, spreadsheet, ASCII) should be specified. These requirements can be determined by analyzing the software data format specifications. Common formats for raw data are comma-delimited and blank-delimited ASCII, which do not require data conversion.

Data documentation is essential for all monitoring projects, especially when several organizations are involved. Data usability is improved by specifying and adhering to data recording and exchange formats. Most data transfer problems are related to inadequate documentation. Other problems include hardware or software incompatibility, errors in the tape or disk, errors or inconsistencies in the data, and transmittal of the wrong data set. The following precautions can prevent some of these problems:

- Provide documentation to accompany the data transfer. Table 11. Because these guidelines apply to general data, models, programs, and other types of information, the items listed in Table 11 may not all apply to every case.
- Provide documentation of transfer media, including the computer operating system, software used to create the files, media format (ASCII, EBCDIC, binary), and tape or disk characteristics (tracks, density, record length, block size).
- Provide procedures to check the accuracy and completeness of the data transfer, including statistics or frequency counts for variables and hard copy versions of the file. Test input data and corresponding output results for models on other programs.
- Keep all raw data, including erroneous records.
- Convert and correct data; save routines for later use.
- Limit equipment access to authorized individuals.
- Check incoming data soon after they are collected, using simple time-series and x-y inspection plots.
- Automate as many routines as possible to avoid operator error.

COMPUTERIZED energy management and control systems provide an excellent means of reducing the utility costs associated with maintaining environmental conditions in commercial buildings. These systems can incorporate advanced control strategies that respond to changing weather and building conditions and minimize operating costs.

HVAC systems are typically controlled using a two-level control structure. Lower level local-loop control of a single set point is provided by an actuator. For example, the supply air temperature from a cooling coil is controlled by adjusting the opening of a valve that provides chilled water to the coil. The upper control level, supervisory control, specifies the set points and other modes of operation that are time dependent.

The performance of large, commercial HVAC systems can be improved through better local-loop and supervisory control. Proper tuning of local-loop controllers can enhance comfort, reduce energy use, and increase component life. Set points and operating modes for cooling plant equipment can be adjusted by the supervisor to maximize the overall operating efficiency. Dynamic control strategies for ice or chilled water storage systems can significantly reduce on-peak electrical energy and demand costs to minimize total utility costs. Similarly, thermal storage inherent within a building’s structure can be dynamically controlled to minimize utility costs. In general, strategies that take advantage of thermal storage work best when forecasts of future energy requirements are available.

This chapter focuses on the opportunities and control strategies associated with using computerized control for centralized cooling systems. The chapter is divided into three major sections. The first section defines the systems and control variables considered and presents background on the impacts and opportunities associated with adjusting control variables. The second section presents a number of supervisory control strategies that can be implemented by computerized control systems and is intended for practitioners. Finally, the third section presents basic methods for optimization of systems both with and without significant thermal energy storage and is intended for researchers and developers of advanced control strategies.

BACKGROUND
SYSTEMS, DEFINITIONS, AND CONTROL VARIABLES

Figure 1 shows a schematic of a typical central cooling system for which control strategies are presented in this chapter. For the most part, the strategies assume that the equipment is electrically driven and that heat is rejected to the environment by cooling towers. However, some strategies apply to any type of system (e.g., return from night setup). For describing different systems and controls, it is useful to divide the system into the subsystems depicted in Figure 1: air distribution, chilled water loop, chiller plant, condenser water loop.

Subsystems

Air Distribution Systems. An air distribution system includes terminal units (VAV boxes, etc.), air-handling units, ducts, and controls. An air-handling unit (AHU) includes a cooling coil, dampers, fan, and controls (in addition to equipment for heating and humidification). A single air handler may serve several zones and several air handlers may be used in a building. For each AHU, ventilation air is mixed with return air from the zones and fed to the cooling coil. Typically, an economizer control is incorporated that selects between minimum and maximum ventilation air depending upon the condition of the outside air.

The air is cooled and dehumidified through the cooling coil. A local-loop controller adjusts the flow of water through the coil using a two- or three-way valve in order to maintain a specified set point temperature for the air leaving the cooling coil. This supervisory control variable is termed the supply air temperature (the air temperature supplied to the zones may be different due to fan heating or local reheat). A supply fan and return fan (not shown in Figure 1) provide the necessary airflow to and from the zones.

Two different types of zone controls are considered in this chapter: constant air volume (CAV) and variable air volume (VAV). CAV systems have fixed-speed fans and provide no feedback control of airflow to the zones. For this system, zone temperature is controlled...
to a set point using a feedback controller that regulates the amount of local reheating applied to the air entering each zone. With a VAV system, a feedback controller regulates the airflow to each zone in order to maintain zone temperature set points. The zone airflows are regulated using dampers located in VAV boxes in each zone. VAV systems also incorporate feedback control of the primary airflow through modulation fans. Typically, the inputs to a fan outlet damper, inlet vanes, blade pitch, or variable speed motor are adjusted in order to maintain a duct static pressure set point within the supply duct as described in Chapter 45.

Zone temperature set points are typically fixed values within the comfort zone during the occupied time and zone humidity is allowed to “float” within a range dictated by the system design and choice of the supply air set point temperature. Night setback is often used to raise the zone temperature set points during unoccupied times and reduce the heating requirements.

**Chilled Water Loop.** The chilled water loop consists of pumps, pipes, valves, and controls. Two different types of systems are considered in this chapter—primary and primary/secondary chilled water pumping. With a primary chilled water pumping system, a single piping loop is used and water that flows through the chiller evaporator also flows through the cooling coils. Often, fixed-speed chilled water pumps are used with their control dedicated to chiller control. Dedicated control means that each pump is cycled on and off with a chiller that it serves. Systems with fixed-speed pumps and two-way cooling coil valves often incorporate a chilled water bypass valve to maintain relatively constant chiller flow rates and reduce system pressure drop and pumping costs at low loads. The valve is typically controlled to maintain a fixed pressure difference between the main supply and return lines. This set point is termed the chilled water loop differential pressure. Sometimes, primary chilled water systems use one or more variable-speed pumps to further reduce pumping costs at low loads. In this case, the chilled water bypass is not used and the pumps are controlled directly to maintain a chilled water loop differential pressure set point.

**Primary/Secondary Chilled Water Systems.** These systems are designed specifically for variable-speed pumping. In the primary loop, fixed-speed pumps provide a relatively constant flow of water to the chillers. This design ensures good chiller performance and reduces the risk of freezing on evaporator tubes. The secondary loop incorporates one or more variable-speed pumps that are controlled to maintain a chilled water loop differential pressure set point. The primary and secondary loops may be separated by a heat exchanger. However, it is more common to use direct coupling with a common pipe.

**Chiller Plant.** One or more chillers that are typically arranged in parallel with dedicated pumps provide the primary source of cooling for the system. Individual feedback controllers adjust the cooling capacity of each chiller in order to maintain a specified chilled water supply temperature. Additional chiller control variables include the number of chillers operating and the relative loading for each chiller. For a given total cooling requirement, individual chiller cooling loads can be controlled by utilizing different chilled water supply set points for constant individual flow or by adjusting individual flows for identical set points.

Thermal storage can also be used in combination with chillers to provide cooling during occupied periods. During the night, when commercial buildings are unoccupied, the primary cooling equipment is used to cool the thermal storage medium for use the next day. During occupied times, the combination of the primary cooling system and storage must meet the building cooling requirements. The use of thermal storage can significantly reduce the costs of providing cooling in commercial buildings by reducing on-peak demand and energy costs. The term “charging” is often used to describe the cooling of storage, while “discharging” describes the use of storage to provide cooling. Control of thermal storage is defined by the manner in which the storage medium is charged and discharged over time. This control problem differs from the control of other system variables in that operating costs depend upon a time history of charging and discharging over several hours.

**Condenser Water Loop.** The condenser water loop consists of cooling towers, pumps, piping, and controls. Cooling towers reject heat to the environment through heat transfer and possibly evaporation (for wet towers) to the ambient air. Typically, large towers incorporate multiple cells sharing a common sump with individual fans having two or more speed settings. Often, a feedback controller adjusts the tower fan speeds in order to maintain a set point for the water temperature leaving the cooling tower, termed the condenser water supply temperature. Typically, condenser water pumps are dedicated to individual chillers (i.e., each pump is cycled on and off with a chiller that it serves).

**Control and Performance Measures**

The control of a VAV cooling system changes in response to increasing building cooling requirements in the following manner. With no changes in control, the zone temperature rises as energy gains to the zone air increase. However, the zone controller responds to higher temperatures by increasing local airflow by opening a damper. Opening of dampers reduces the static pressure in the primary supply duct, which causes the fan controller to create additional airflow. In the absence of any additional control changes, the supply air temperature of the cooling coils increases due to the greater airflow. However, feedback controllers for the supply air temperature respond to the higher temperatures and increase the water flow by opening the cooling coil valves. This increases the chilled water flow and heat transfer to the chilled water (i.e., the cooling load).

For fixed-speed chilled-water pumps, the differential pressure controller closes the chilled-water bypass valve and keeps the overall flow relatively constant. For variable-speed pumping, the differential pressure controller increases the pump speed. The return water temperature and/or flow rate to the chillers increases, which leads to an increase in the chilled water supply temperature. The chiller controller then responds by increasing the chiller cooling capacity in order to maintain the chilled water supply set point (and match the cooling coil loads). The increased energy removed by the chiller increases the heat rejected to the condenser water loop, which increases the temperature of water leaving the condenser. The increased water temperature entering the cooling tower increases the water temperature leaving the tower. However, the tower controller responds to the higher condenser water supply temperature and increases the tower airflow. At some load, the current set of operating chillers is not sufficient to meet the load (i.e., maintain the chilled water supply set points) and an additional chiller is brought online.

For this scenario, several local-loop controllers respond to the load change in order to maintain specified set points. The values of the set points and the modes of operation (e.g., economizer) are established by a supervisory controller. At any given time, the cooling needs can be met with several different combinations of modes of operation and set points. This chapter furnishes several methods for determining supervisory control variables that provide good overall performance.

For all-electric cooling without thermal storage, minimizing power at each point in time is equivalent to minimizing energy costs. Therefore, the “best” performance occurs when supervisory control variables are chosen to maximize the coefficient of performance (COP) at all times while meeting the building load requirements. The COP is defined as the ratio of the system power consumption to the total chiller cooling load. In addition to the control variables, the COP depends primarily on the cooling load and the ambient wet-bulb and dry-bulb temperatures. Often, the cooling load is expressed in a dimensionless form as a part-load ratio, PLR, which is the cooling load divided by the design cooling capacity.
For systems with thermal storage, performance depends on the time history of charging and discharging. In this case, the “best” performance occurs for controls that minimize operating costs that are integrated over the billing period. In addition, safety features that minimize the risk of prematurely depleting the storage capacity are important.

OPTIMIZING CONTROLS FOR COOLING WITHOUT STORAGE

Local-Loop Control Effects

Proportional-integral (PI) controllers are generally well suited to the control of linear or near-linear processes that occur in HVAC applications. However, the ability of a local-loop controller to maintain a set point depends on the type and quality of the control hardware, the nature of the process being controlled, and the tuning of the controller. Tuning of PI controllers is discussed in the section on Commissioning in Chapter 37, Fundamentals of Control, of the 1997 ASHRAE Handbook—Fundamentals. Improper tuning can influence energy consumption and diminish the benefits of optimizing set point choices. Furthermore, there may be interactions between control loops, particularly where a single controller is used to control multiple processes in sequence, such as an air handling system with the heating coil, cooling coil, and return/outside air dampers being modulated by a single controller.

Achieving a desired control response may require considering more than a single process. Reasonably good and poor set point control are shown in Figure 2 for pneumatic control on two air handlers serving an office building (Bushby and Kelly 1988). The control in Figure 2A performs best, maintaining the supply air temperature in a tight temperature band of about 1 K and following the prescribed reset schedule closely for outdoor temperatures ranging from 2 to 13°C. At temperatures below 2°C, the actual maintained set point continues its linear trend instead of maintaining the constant set point supply temperature normally implemented on this particular system.

Of particular interest is the response of the air handler shown in Figure 2B that indicates a similar pattern, except that the data have a much greater spread due to interaction between the outdoor air dampers and the steam preheat valve in the temperature range between -5 and 10°C. In fact, the outdoor air dampers and preheat valve have a tendency to swing open and closed in alternating fashion in a very short time. Figure 3 shows the position of the steam preheat valve and outdoor dampers for about 20 min (Bushby and Kelly 1988). The solid line indicates the position of the outdoor air dampers, and the dashed line represents the position of the steam preheat valve.

Both the steam preheat valve and the outdoor air dampers swing open and closed in a cyclic fashion in less than 2 min. The two cycles are roughly 180° out of phase. The effect of the valve and damper cycling on the mixed and supply air temperatures is shown in Figure 4. Both temperatures oscillate in conjunction with the steam valve and the dampers. The maximum peak-to-peak mixed air temperature swing approaches 15 K, while the maximum supply air temperature swing is smaller, approaching 2.5 K. Such control system performance wastes energy by unnecessary use of preheating and has a negative impact on comfort conditions. In addition, it causes needless wear and tear on valves, dampers, and actuators.
This problem may be correctable by proper tuning of the controls or resizing of the system components.

Supervisory Control Choices and Impacts

Figure 1 depicts multiple chillers, cooling towers, and pumps providing chilled water to a number of air-handling units in order to cool air that is supplied to building zones. At any given time, cooling needs may be met with different modes of operation and set points. However, one set of control set points and modes results in minimum power consumption. This optimal control point results from trade-offs between the energy consumption of different components. For instance, increasing the number of cooling tower cells (or fan speeds) increases fan power but reduces chiller power because the temperature of the water supplied to the chiller’s condenser is decreased. Similarly, increasing the condenser water flow by adding pumps (or increasing pump speed) decreases the chiller power but increases pump power.

Similar trade-offs exist for the chilled water loop variables of systems with variable-speed chilled water pumps and air-handler fans. For instance, increasing the chilled water set point reduces chiller power but increases pump power because greater flow is needed to meet the load. Increasing the supply air set point increases fan power, but decreases pump power.

Figure 3 illustrates the sensitivity of the total power consumption to condenser water-loop controls (from Braun et al. 1989a) for a single chiller load, ambient wet-bulb temperature, and chilled water supply temperature. Contours of constant power consumption are plotted versus cooling tower fan and condenser water pump speed for a system with variable-speed fans and pumps. Near the optimum, power consumption is not sensitive to either of these control variables, but increases significantly away from the optimum. The rate of increase in power consumption is particularly large at low condenser pump speeds. A minimum pump speed is necessary to overcome the static pressure associated with the height of the water discharge in the cooling tower above the sump. As the pump speed approaches this value, the condenser flow approaches zero and the chiller power increases dramatically. A pump speed that is too high is generally better than a pump speed that is too low. The broad area near the optimum indicates that the optimal setting does not need to be accurately determined. However, the optimal settings would change significantly with chiller load.

Figure 6 illustrates the sensitivity of power consumption to chilled-water and supply-air set-point temperatures for a system with variable-speed chilled water pumps and air-handler fans (from Braun et al. 1989a). Within about 2 K of the optimum values, the power consumption is within 1% of the minimum. Outside of this range, the sensitivity to the set points increases significantly. The penalty associated with operation away from the optimum is greater in the direction of smaller differences between the supply air and chilled water set points. As this temperature difference is reduced, the required flow of chilled water to this coil increases and the chilled water pumping power is greater. For a given chilled water or supply air temperature, the temperature difference is limited by the heat transfer characteristics of the coil. As this limit is approached, the required water flow and pumping power would become infinite if the pump speed were not constrained. It is generally better to have too large rather than too small a temperature difference between the supply air and chilled water set points.
For constant chilled-water flow, the trade-offs in energy use with chilled-water set point are very different than for variable-flow systems. Increasing the chilled-water set point reduces chiller power consumption, but has little effect on chilled-water pumping energy. Therefore, the benefits of chilled-water temperature reset are more significant than for variable-flow systems (although variable-flow systems use less energy). For constant chilled-water flow, the minimum cost strategy is to raise the chilled water set point to the highest value that will keep all discharge air temperatures at their set points and keep zone humidities within acceptable bounds.

For constant-volume air-handling systems (CAV), the trade-offs in energy use with supply air set point are also very different than for variable air volume systems. Increasing the supply-air set point for cooling reduces both the cooling load and reheat required, but does not change fan energy. Again, the benefits of supply air temperature reset for CAV systems are more significant than for VAV systems (although VAV systems use less energy). In general, the set point for a CAV system should be set at the highest value that will keep all zone temperatures at their set points and all humidities within acceptable bounds.

In addition to the set points used by local-loop controllers, a number of operational modes can impact performance. For instance, significant energy savings are possible when a system is properly switched over to an economizer cycle. At the onset of economizer operation, return dampers are closed, outside dampers are opened, and the maximum possible outside air is supplied to cooling coils. Two different types of switchover are typically used: (1) dry-bulb and (2) enthalpy. With a dry-bulb economizer, the switchover occurs when the ambient dry-bulb temperature is less than a specified value, typically between 13 and 18°C. With an enthalpy economizer, the switchover happens when the outdoor enthalpy (or wet-bulb temperature) is less than the enthalpy (or wet-bulb temperature) of the return air. Although the enthalpy economizer yields lower overall energy consumption, it requires wet-bulb temperature or dry-bulb and relative humidity measurements.

Another important operation mode is the sequencing of chillers and pumps. Sequencing defines the order and conditions associated with bringing equipment online or offline. Optimal sequencing depends on the individual design and part-load performance characteristics of the equipment. For instance, more efficient chillers should generally be brought online before less efficient ones. Furthermore, the conditions where chillers and pumps should be brought online depend upon their performance characteristics at part-load conditions.

Figure 7 shows the optimal system performance (i.e., optimal set-point choices) for different combinations of chillers and fixed-speed pumps in parallel as a function of load relative to the design load for a given ambient wet-bulb temperature. For this system (from Braun et al. 1989a), each component (chillers, chilled water pumps, and condenser water pumps) in each parallel set are identical and sized to meet half of the design requirements. The best performance occurs at about 25% of the design load with one chiller and pump operating. As the load increases, the system COP decreases due to decreasing chiller COP and a nonlinear increase in the power consumption of cooling tower and air handler fans. A second chiller should be brought online at the point where the overall COP of the system is the same with or without the chiller. For this system, this optimal switch point occurs at about 38% of the total design load or about 75% of the individual chiller’s capacity. The optimal switch point for bringing a second condenser and chilled water pump online occurs at a much higher relative chilled load (0.62) than the switch point for adding or removing a chiller (0.38). However, pumps are typically sequenced with chillers (i.e., they’re brought on-line together). In this case, Figure 7 shows that the optimal switch point for bringing a second chiller online (with pumps) is about 50% of the overall design load or at the design capacity of the individual chiller. This is generally the case for sequencing of chillers with dedicated pumps.

In most cases, zone humidities are allowed to float between upper and lower limits dictated by comfort (see Chapter 8, Thermal Comfort, of the 1997 ASHRAE Handbook—Fundamentals). However, variable air volume systems can control the zone humidity and temperature simultaneously. For a zone being cooled, the equipment operating costs are minimized when the zone temperature is at the upper bound of the comfort region. However, operating simultaneously at the upper limit of humidity does not minimize operating costs. Figure 8 shows a comparison of system COP and zone humidity with fixed and free-floating zone humidity as a function of the relative load (from Braun et al. 1989a). Over the range of loads, allowing the humidity to float within the comfort zone produces a lower cost and a lower zone humidity than setting the humidity at the highest acceptable value. The largest differences occur at the highest loads. Operation with the zone at the upper humidity bound results in lower latent loads than with a free-floating humidity, but this humidity control constraint requires a higher supply air temperature that, in turn, results in greater air-handler
power consumption. For minimum energy costs, the humidity should be allowed to float freely unless it falls outside the bounds of human comfort.

Effects of Load and Ambient Conditions on Optimal Supervisory Control

When the ratio of the individual zone loads to the total load does not change significantly with time, the optimal control variables are functions of the total sensible and latent gains to the zones and of the ambient dry- and wet-bulb temperatures. For systems with wet cooling towers and climates where moisture is removed from conditioned air, the effect of the ambient dry-bulb temperature alone is small because air enthalpy depends primarily on wet-bulb temperature, and the performance of wet-surface heat exchangers is driven primarily by the enthalpy difference. Typically, zone latent gains are on the order of 15 to 25% of the total zone gains and the effect of changes in latent gains have a relatively small effect on performance for a given total load. Consequently, in many cases optimal supervisory control variables depend primarily on ambient wet-bulb temperature and total chilled water load. However, the load distributions between zones may also be important if they change significantly over time.

As a general rule, optimal chilled-water and supply-air temperatures decrease with increasing load for a fixed ambient wet-bulb temperature and increase with increasing ambient wet-bulb temperature for a fixed load. Furthermore, optimal cooling tower airflow and condenser water flow rates increase with increasing load and ambient wet-bulb temperature.

Performance Comparisons for Supervisory Control Strategies

Optimization of plant operation is most important when loads vary and when operation is far from design conditions for a significant period. A variety of strategies are used for chilled water systems at off-design conditions. Commonly, the chilled water and supply air set-point temperatures are changed only according to the ambient dry-bulb temperature. In some systems, cooling tower airflow and condenser water flow are not varied in response to changes in the load and ambient wet-bulb temperature. In other systems these flow rates are controlled to maintain constant temperature differences between the cooling tower outlet and the ambient wet-bulb temperature (approach) and between the cooling tower inlet and outlet (range), regardless of the load and wet-bulb temperature. Although these strategies seem reasonable, they do not generally minimize operating costs.

Figure 9 shows a comparison of the COPs for optimal control and three alternative strategies as a function of load for a fixed ambient wet-bulb temperature. This system (from Braun et al. 1989a) incorporated the use of variable-speed pumps and fans. The three strategies are:

1. Fixed chilled water and supply air temperature set points (4.5 and 11°C, respectively), with optimal condenser loop control
2. Fixed tower approach and range (3 and 6.5 K, respectively), with optimal chilled water loop control
3. Fixed set points, approach, and range

Since the fixed values were chosen to be optimal at design conditions, the differences in performance for all strategies are minimal at high loads. However, at part-load conditions, Figure 9 shows that the savings associated with the use of optimal control become significant. Optimal control of the chilled water loop results in greater savings than that for the condenser loop for part-load ratios less than about 50%. The overall savings over a cooling season depend on the time variation of the load. If the cooling load is relatively constant and near the design load, fixed values of temperature set points, approach, and range could be chosen to give near-optimal performance. However, for typical building loads with significant daily and seasonal variations, the penalty for using a fixed set point control strategy is in the range of 5 to 20% of the cooling system energy.

Even greater energy savings are possible with economizer control and discharge air temperature reset with constant volume systems. Kao (1985) investigated the effect of different economizer and supply air reset strategies on both heating and cooling energy use for CAV, VAV, and dual-duct air handling systems for four different buildings. The results were generated using the building energy program BLAST (Hittle 1979) and typical meteorological year (TMY) hourly weather data for six cities in the United States—Lake Charles, LA; Madison, WI; Nashville, TN; Santa Maria, CA; Seattle, WA; and Washington, D.C. For the CAV and dual-duct systems, two different supply air reset strategies were considered: (1) reset based on outdoor air temperature or (2) space demand. In all cases, the air-handlers were operational only during occupied periods in the cooling season, and the conditioned zones used temperature set back at night during the heating season.

Figure 9 and Figure 10 (Kao 1985) show the yearly cooling and heating energy in a large office building. Cases 1 through 6 simulate a CAV, terminal reheat system for the entire building. Adding a dry-bulb economy cycle (Case 2) allows supply air temperature to be maintained by using cooler outside air, consequently saving a large amount of cooling energy but increasing the amount of heating. Changing to an enthalpy economizer (Case 3) results in more cooling savings and greater heating. The increase in heating energy for both economizer cycles results mainly from lowering the supply air temperature by the proportional controls during the period that the economizer cycles were in operation. Both the absolute amount and the percentage of cooling savings are greater in low cooling degree-day areas than in high degree-day areas.

Changing to an enthalpy economizer (Case 3) results in more cooling savings and greater heating. The increase in heating energy for both economizer cycles results mainly from lowering the supply air temperature by the proportional controls during the period that the economizer cycles were in operation. Both the absolute amount and the percentage of cooling savings are greater in low cooling degree-day areas than in high degree-day areas.
in sequence with the zone dampers. The dampers allow supply air to be reduced to 20% of design air volume. The interior zones have only damper controls. The base VAV system (Case 7), which has no special strategy, has cooling energy consumption comparable to the best reheat case—Case 6, which uses an enthalpy economy cycle and supply air temperature reset by zone demand. When an enthalpy economy cycle is added to the VAV system, 15% (Lake Charles) to 59% (Seattle) of cooling energy is saved. Contrary to results obtained with the reheat system, adding an enthalpy cycle to the VAV system (Case 8) does not significantly increase the heating energy requirement in most cities. The exceptions were Santa Maria (20% increase) and Lake Charles (7% increase).

Case 9 simulates a base dual-duct system for the perimeter zones and a simple VAV system for interior zones. Case 10 is the result of adding an enthalpy economy cycle to the entire building, with both the hot and the cold air of the dual-duct system reset by sensing the space temperature. It is difficult to pinpoint the effects of the individual strategies and systems for these two cases. The overall results show that much cooling and heating energy is saved as compared to the base VAV and dual-duct systems (Case 9). The perimeter zones are also simulated with a four-pipe fan-coil system having both the cold and hot water available year-round (Case 11). A fixed amount of outside air is introduced directly to the fan-coil units during operating hours. The interior system remains a VAV system with an economy cycle. The energy consumption for both heating and cooling is similar to that in Case 8.

Kao (1985) also analyzed the cooling and heating energy consumption of the combined classroom and office areas of a school building. Reheat, dual-duct, variable air volume, and cooling-type unit ventilator systems were simulated for these areas. Roughly the same relative pattern as for the large office building was observed for the cooling consumption of the first three systems. The cooling results of the various VAV system strategies were close together, the best being the one applying the enthalpy economy cycle and resetting the supply air temperature by zone sensing. The unit ventilator system performed slightly poorer on cooling than do the VAV systems. The school building was unlike the large office building discussed previously, in that applying economy cycles to the reheat systems of the school building did not significantly increase the heating energy. For the retail store, the best strategies and systems were the VAV system with supply air temperature reset by the outside air temperature and the packaged DX system, both with enthalpy economy cycles. A VAV system with enthalpy economy cycle and supply air temperature reset by zone demand sensing was the best choice for the small office building.
different control strategies and air-handling systems. For example, when the enthalpy economy cycle is used on the VAV system of the large office building, it consumes only 25% of the cooling energy and less than one-third of the heating energy consumed by a reheat system using a fixed amount of outside air year-round.

Variable Versus Fixed-Speed Equipment

The use of variable-speed motors for chillers, fans, and pumps can significantly reduce energy costs but can also complicate the problem of determining optimal control. The overall savings associated with the use of variable-speed equipment over a cooling season depends on the time variation of the load. Typically, the use of variable-speed drives results in operating costs that are 20 to 50% lower than for equipment with fixed-speed drives.

Figure 12 gives the overall optimal system performance for a cooling plant with either variable speed or variable vane control of a centrifugal chiller. At part-load conditions, the system COP associated with the use of a variable-speed chiller is improved as much as 25%. However, the power requirements are similar at conditions associated with peak loads, because at full load the vanes are wide open and the speed under variable-speed control and fixed-speed operation is the same. The results of Figure 12 are from a single case study of a large chilled water facility (Braun et al. 1989a)that was constructed in the mid 1970s and where the existing chiller was retrofitted with a variable-speed drive. Differences in performance between variable- and fixed-speed chillers may be smaller for current equipment.

The most common design for cooling towers places multiple tower cells in parallel with a common sump. Each tower cell has a fan with one, two, or possibly three operating speeds. Although multiple cells with multiple fan settings offer wide flexibility in control, the use of variable-speed tower fans can provide additional improvements in overall system performance. Figure 13 shows an example comparison of optimal performance for one-speed, two-speed, and variable-speed fans for four cell cooling towers.

Fixed-speed pumps that are sized to give proper flow to a chiller at design conditions are oversized for part-load conditions. As a result, the system will have higher operating costs than with a variable-speed pump of the same design capacity. Multiple pumps with different capacities have increased flexibility in control and the use of a smaller fixed-speed pump for low loads can reduce overall power consumption. The optimal performance for variable-speed and fixed-speed pumps applied to both the condenser and chilled water flow loops is shown in Figure 14 (Braun et al. 1989a). Large fixed-speed pumps were sized for design conditions, while the small pumps were sized to have one-half the flow capacity of the large pumps. Below about 60% of full-load conditions, a variable-speed pump showed a significant improvement over the use of a single, large fixed-speed pump. With the addition of a small fixed-speed pump, the improvements with the variable-speed pump were significant at about 40% of the maximum load.

The fan energy consumed by VAV systems is strongly influenced by the device used to vary the airflow. Brothers and Warren (1986) compared the fan energy consumption for three typical

Supervisory Control Strategies and Optimization

Flow modulation devices: (1) dampers on the outlet side of the fan, (2) inlet vanes on the fan, and (3) variable-speed control of the fan motor. The investigation used the DOE 2.1 program to simulate the annual energy consumption of a 1000 m² commercial building with a VAV system that used these three flow-control methods. Both centrifugal and vaneaxial fans were considered, even though dampers are not usually used with vaneaxial fans as they may overload the fan motor. The VAV system used an enthalpy economy cycle and provided cooling only during working hours, 7 A.M. to 5 P.M. five days a week. The analysis was performed for five cities: Fresno, CA; Forth Worth, TX; Miami, FL; Phoenix, AZ; and Washington, D.C.

Values for the annual energy consumption are presented in Table 2. In all locations, the centrifugal fan used less energy than the vaneaxial fan. Vaneaxial fans have higher efficiencies at the full-load design point, but centrifugal fans have better off-design characteristics that lead to lower annual energy consumption. For a centrifugal fan, inlet vane control saves about 20% of the energy (over the five locations) compared to damper control. Variable speed control savings, compared to inlet vane control, range from 42% for Miami to 65% for Washington, D.C., with an average savings of 57% over the five locations.

COOLING TOWER FAN CONTROL

Figure 14 shows a schematic of the condenser loop for a typical chilled-water unit consisting of centrifugal chillers, cooling towers, and condenser water pumps. Typically, the condenser water pump control is dedicated to the chiller control in order to provide relatively constant flow for individual chillers. However, the cooling tower cells may be independently controlled so as to maximize the system efficiency.

Typically, cooling tower fans are controlled using a feedback controller that attempts to maintain a temperature set point for the water supplied to the chiller condensers. Often, the condenser water supply temperature set point is held constant. However, a better strategy is to maintain a constant temperature difference between the condenser water supply and the ambient wet bulb (constant approach). Additional savings are possible through optimal control.

With a single feedback controller, the controller output signal must be converted to a specific fan sequence that depends on the number of operating cells and the individual fan speeds. Typically, with the discrete control associated with one- or two-speed tower fans, the set point cannot be realized, resulting in the potential for oscillating tower fan control. Fan cycling can be reduced through the use of deadbands, “sluggish” control parameters, and/or lower limits for on and off periods.

Braun and Diderrich (1990) demonstrated that feedback control for cooling tower fans could be eliminated through the use of an open-loop supervisory control strategy. This strategy requires only the measurement of the chiller loading to specify the control and is inherently stable. The tower fan control is separated into two parts: tower sequencing and optimal airflow. For a given total tower airflow, general rules for optimal tower sequencing are used to specify the number of operating cells and fan speeds that give the minimum power consumption for both the chillers and tower fans. The optimal tower airflow is estimated with an open-loop control equation that uses design information for the cooling tower and chiller. This computational procedure is presented in this section and the control strategy is summarized in a set of steps and sample calculations.

**Near-Optimal Tower Fan Sequencing**

For variable-speed fans, the minimum power consumption results when all cooling tower cells are operated under all
conditions. Tower airflow varies almost linearly with fan speed, while the fan power consumption varies approximately with the cube of the speed. Thus, for the same total airflow, operating more cells in parallel allows for lower individual fan speeds and lower overall fan power consumption. An additional benefit associated with full-cell operation is lower water pressure drops across the spray nozzles, which results in lower pumping power requirements. However, at very low pressure drops, inadequate spray distribution may adversely affect the thermal performance of the cooling tower.

Most cooling towers use multiple-speed, rather than continuously adjustable variable-speed fans. In this case, it is not optimal to operate all tower cells under all conditions. The optimal number of cells operating and individual fan speeds depend on the system characteristics and ambient conditions. However, simple relationships exist for the best sequencing of cooling tower fans as capacity is added or removed. When additional tower capacity is required, Braun et al. (1989a) showed that in almost all practical cases, the speed of the tower fan operating at the lowest speed (including fans that are off) should be increased first. The rules for bringing cell fans on line are as follows:

**Sequencing Rules**
- **All Variable-Speed Fans**: Operate all cells with fans at equal speeds.
- **Multi-Speed Fans**: Increment lowest speed fans first when adding tower capacity. Reverse for removing capacity.
- **Variable/Multi-Speed Fans**: Operate all cells with variable-speed fans at equal speeds. Increment lowest speed fans first when adding tower capacity with multi-speed fans. Add multi-speed fan capacity when variable-speed fan speeds match the fan speed associated with the next multi-speed fan increment to be added.

Similarly, for removing tower capacity, the highest fan speeds are the first to be reduced and sequences defined above are reversed.

These guidelines were derived from evaluating the incremental power changes associated with fan sequencing. For two-speed fans, the incremental power increase associated with adding a low-speed fan is less than that for increasing one to high speed if the low speed is less than 79% of the high fan speed. In addition, if the low speed is greater than 50% of the high speed, then the incremental increase in airflow is greater (and therefore better thermal performance) for adding the low-speed fan. Most commonly, the low speed of a two-speed cooling tower fan is between one-half and three-quarters of full speed. In this case, tower cells should be brought online at low speed before any operating cells are set to high speed. Similarly, the fan speeds should be reduced to low speed before any cells are brought offline.

For three-speed fans, low speed is typically greater than or equal to one-third of full speed and the difference between the high and intermediate speeds is equal to the difference between the intermediate and low speeds. In this situation, the best sequencing strategy is to increment the lowest fan speeds first when adding tower capacity and decrement the highest fan speeds when removing capacity. Typical three-speed combinations that satisfy these criteria are (1) one-third, two-thirds, and full speed or (2) one-half, three-quarters, and full speed.

Another issue related to control of multiple cooling tower cells having multiple-speed fans concerns the distribution of water flow to the individual cells. Typically, the water flow is divided equally among the operating cells. Even though the overall thermal performance of the cooling tower is best when the flow is divided such that the ratio of water-to-airflow rates is identical for all cooling tower cells, equal water flow distribution results in near-optimal performance.

Near-Optimal Tower Airflow

Figure 16 illustrates the trade-off between the chiller and cooling tower fan power associated with increasing tower airflow for variable-speed fans. As the airflow increases, the fan power increases with a cubic relationship. At the same time, there is a reduction in the temperature of the water supplied to the condenser of the chiller resulting in lower chiller power consumption. The minimum total power occurs at a point where the rate of increase in fan power with airflow is equal to the rate of decrease in chiller power. Near the optimum, the total power consumption is not very sensitive to the control. This “flat” optimum indicates extreme accuracy is not needed to determine the optimum control. In general, it is better to have too high rather than too low a fan speed.

Braun et al. (1989a) showed that the tower control that minimizes the instantaneous power consumption of a cooling plant varies as a near linear function of the load over a wide range of conditions. Although the optimal control depends upon the ambient wet-bulb temperature, this dependence is small compared to the load effect. Figure 17 shows an example of how the optimal tower control varies for a specific plant. The tower airflow as a fraction of the design capacity is plotted as a function of load relative to design load for two different wet-bulb temperatures. For a 10 K change in wet-bulb temperature, the optimal control varies only about 5% of the tower capacity. This difference in control results in less than a 1% difference in the plant power consumption. Figure 17 also shows that linear functions work well in correlating the optimal control over a wide range of loads for the two wet-bulb temperatures. Given the insensitivity to wet-bulb temperature and the fact that the load is highly correlated with wet bulb, then a single linear relationship is adequate in correlating the optimal tower control in terms of load.

Figure 18 depicts the general form to determine tower airflow as a function of load. The (unconstrained) relative tower airflow is computed as a linear function of the part-load ratio as

\[
G_{\text{twr}} = 1 - \beta_{\text{twr}}(\text{PLR}_{\text{twrcap}} - \text{PLR}) \text{ for } 1.0 < \text{PLR} < 0.25
\]

where
- \(G_{\text{twr}}\) = tower airflow divided by maximum airflow with all cells operating at high speed
- \(\text{PLR}\) = chilled water load divided by design total chiller plant cooling capacity (part-load ratio)
- \(\text{PLR}_{\text{twrcap}}\) = part-load ratio (value of PLR) at which tower operates at its capacity (\(G_{\text{twr}} = 1\))
- \(\beta_{\text{twr}}\) = slope of relative tower airflow \((G_{\text{twr}})\) versus part-load ratio (PLR) function

**Near-Optimal Tower Airflow**

**Figure 16 Trade-offs Between Chiller Power and Fan Power with Tower Airflow**
The linear relationship between airflow and load is only valid for loads greater than about 25% of the design load. For many installations, chillers do not operate at these small loads. However, for those situations for which chiller operation is necessary below 25% of full load, the tower airflow should be ramped to zero as the load goes to zero according to

$$G_{twr} = 4PLR[1 - \beta_{twr}(PLR_{twr, \text{cap}} - 0.25)] \text{ for } PLR < 0.25$$  \hfill (2)

The results of either Equation (1) or (2) must be constrained between 0 and 1. This fraction of tower capacity is then converted to a tower control using the sequencing rules of the previous section.

The variables of the open-loop linear control Equation (1) that yield near-optimal control depend on the characteristics of the system. Detailed measurements may be taken over a range of conditions and this information can be used to accurately estimate these variables. However, this requires measuring component power consumption along with considerable time and expertise and may not be cost effective, unless performed by on-site plant personnel. Alternatively, simple estimates of these parameters may be obtained using design data.

**Open-Loop Parameter Estimates Using Design Data.** Good estimates of the parameters of Equation (1) may be determined analytically using design information as summarized in Table 3.

These estimates were derived by Braun and Diderrich (1990) by applying optimization theory to a simplified mathematical model of the chiller and cooling tower, assuming that the tower fans are sequenced in an near-optimal manner. In general, these estimates are conservative in that they should provide greater rather than less than the optimal tower airflow. The results given in Table 3 for variable-speed fans should also provide adequate estimates for three-speed fans.

The design factors that affect the parameter estimates given in Table 3 are (1) the ratio of chiller power to cooling tower fan power at design conditions $P_{ch, \text{des}}/P_{twr, \text{des}}$, (2) the sensitivity of the chiller power to changes in condenser water return temperature at design conditions $S_{cwr, \text{des}}$, and (3) the sum of the tower approach and range at design conditions $(a_{twr, \text{des}} + r_{twr, \text{des}})$. The chiller power consumption at design conditions is the total power consumption of all plant chillers operating at their design cooling capacity. Likewise, the design tower fan power is the total power associated with all tower cells operating at high speed. As the ratio of chiller power to tower fan power increases, it becomes more beneficial to operate the tower at higher airflows. This would be reflected in a decrease in the part-load ratio at which the tower reaches its capacity, $PLR_{twr, \text{cap}}$. If the tower airflow were free (i.e., zero fan power), then $PLR_{twr, \text{cap}}$ goes to zero, and the best strategy would be to operate the towers at full capacity independent of the load. A typical value for the ratio of the chiller power to the cooling tower fan power at design conditions is 10.

The chiller sensitivity factor $S_{cwr, \text{des}}$ is the incremental increase in chiller power for each degree increase in condenser water temperature as a fraction of the power

$$S_{cwr, \text{des}} = \frac{\text{Change in chiller power}}{\text{Change in cond. water return temp.} \times \text{Chiller power}}$$  \hfill (3)

If the chiller power increases by 2% for a 0.5 K increase in condenser water temperature, $S_{cwr, \text{des}}$ is equal to 0.04 $\text{K}^{-1}$. A large sensitivity factor means that the chiller power is very sensitive to the cooling tower control favoring operation at higher airflow rates (low $PLR_{twr, \text{cap}}$). The sensitivity factor should be evaluated at design conditions using chiller performance data. Typically, the sensitivity factor is between 0.02 $\text{K}^{-1}$ and 0.06 $\text{K}^{-1}$. For multiple chillers with different performance characteristics, the sensitivity factor at design conditions is estimated as

$$S_{cwr, \text{des}} = \frac{\sum_{i=1}^{N_{ch}} S_{cwr, \text{des}, i} P_{ch, \text{des}, i}}{\sum_{i=1}^{N_{ch}} P_{ch, \text{des}, i}}$$  \hfill (4)
where $S_{c wr,des}$ is the sensitivity factor and $P_{ch,des,i}$ is the power consumption for the $i$th chiller at the design conditions and $N_{ch}$ is the total number of chillers.

The design approach to wet bulb $a_{c wr,des}$ is the temperature difference between the condenser water supply and the ambient wet bulb for the tower operating at its air and water flow capacity at the plant design conditions. The design range $t_{c wr,des}$ is the temperature difference across the tower at these same conditions (condenser water return minus supply temperature). The sum of $a_{c wr,des}$ and $r_{c wr,des}$ is the temperature difference between the tower inlet and the ambient wet buld and represents a measure of the tower’s capability to reject heat to ambient relative to the system requirements. A small temperature difference (tower approach plus range) results from a high tower heat transfer effectiveness or high water flow rate and yields lower condenser water temperatures with lower chiller power consumption. Typical values for the design approach and range are 4 K and 6 K.

The part-load ratio associated with the tower operating at full capacity $PLR_{twr, cap}$ may be greater than or less than one. Values less than unity imply that from an “energy point of view” the tower is not sized for optimal operation at design load conditions and that the tower should operate at its capacity for a range of loads less than the design load. Values of $PLR_{twr, cap}$ greater than one imply that the tower is oversized for the design load and that the tower should never operate at its capacity.

For multiple chillers with very different performance characteristics, different open-loop parameters may be used for any combination of operating chillers. The sensitivity factors and chiller design power used to determine the open-loop control parameters in Table 3 should be estimated for each combination of operating chillers and the part-load ratio used in Equation (1) should be determined using the design capacity for the operating chillers (not all chillers). In this case, the part-load ratio associated with the tower operating at full load condition must be maintained for a sufficient time for the power consumption to approach steady-state and to hold the chilled-water supply temperature constant. The control setting that produces the minimum total power consumption is deemed optimal. This set of experiments is performed for a number of chilled-water cooling conditions (1) or (2). The fractional tower airflow as determined by Equation (1) or Equation (2) must be bounded between 0 and 1 according to the physical constraints of the equipment. Additional constraints on the temperature of the supply water to the chiller condensers are necessary to avoid potential chiller maintenance problems. Many (older) chillers have a low limit on the condenser-water supply temperature that is necessary to avoid lubrication migration from the compressor. A high-temperature limit is also necessary to avoid excessively high pressures in the condenser that can lead to compressor surge. If the condenser water temperature falls below the low limit, then it is necessary to override the open-loop tower control and reduce the tower airflow to go above this limit. Similarly, if the high limit is exceeded, then the tower airflow should be increased as required.

**Open-Loop Parameter Estimates Using Plant Measurements.** Energy consumption can be reduced slightly by determining the open-loop control parameters from plant measurements. However, this results in additional complexity associated with implementation. One method for estimating the open-loop control parameters of Equation (1) from plant measurements involves performing a set of one-time trial-and-error experiments. At a given set of conditions (i.e., cooling load and ambient conditions), the optimal tower control is estimated by varying the fan settings and monitoring the total chiller and fan power consumption. Each tower control setting and load condition must be maintained for a sufficient time for the power consumption to approach steady-state and to the chilled-water supply temperature constant. The control setting that produces the minimum total power consumption is desired. This set of experiments is performed for a number of chilled-water cooling loads and the best fit straight line through the resulting data points is used to estimate the parameters of Equation (1). As initial control settings for each load, Equation (1) may be used with estimates from design data as summarized in the previous section.

Another method for estimating the variables of Equation (1) uses an empirical model for total power consumption that is fit to plant measurements. The control that minimizes the power consumption associated with the model is then determined analytically. The section on Control Optimization Methods describes a general method for determining linear control relations in this manner using a quadratic model. For cooling tower fan control, chiller and fan power consumption are correlated with load and tower airflow for a constant chilled water supply temperature using a quadratic function according to:

$$P = a_0 + a_1 PLR + a_2 PLR^2 + a_3 t_{c wr}$$

$$+ a_4 t_{c wr}^2 + a_5 PLR \cdot G_{twr}$$  \hspace{1cm} (5)

where $a_0 = a_2$ are empirical constants that are determined through linear regression applied to measurements. For the quadratic function of Equation (5), the tower airflow that results in minimum power is a linear function of the PLR. The parameters of the open-loop control Equation (1) are then

$$PLR_{twr, cap} = \left( \frac{a_3 + 2a_4}{a_5} \right)$$

$$\beta_{twr} = \left( \frac{a_3}{2a_4} \right)$$  \hspace{1cm} (6) \hspace{1cm} (7)

For multiple chillers with very different performance characteristics, different open-loop parameters could be determined for any combination of operating chillers. In this case, separate correlations for near-optimal airflow or power consumption would need to be determined for each chiller combination.

**Overrides for Equipment Constraints.** The fractional tower airflow as determined by Equation (1) or Equation (2) must be bounded between 0 and 1 according to the physical constraints of the equipment. Additional constraints on the temperature of the supply water to the chiller condensers are necessary to avoid potential chiller maintenance problems. Many (older) chillers have a low limit on the condenser-water supply temperature that is necessary to avoid lubrication migration from the compressor. A high-temperature limit is also necessary to avoid excessively high pressures in the condenser that can lead to compressor surge. If the condenser water temperature falls below the low limit, then it is necessary to override the open-loop tower control and reduce the tower airflow to go above this limit. Similarly, if the high limit is exceeded, then the tower airflow should be increased as required.

**Summary and Implementation.** Prior to commissioning, the parameters of the open-loop control Equation (1) must be specified. These parameters are estimated using Table 3. After the system is in operation, these parameters may be fined-tuned with measurements as outlined in the previous section. If multiple chillers have significantly different performance characteristics, it may be advantageous to determine different parameters for Equation (1) depending on the combination of operating chillers.

The relative tower airflow must be converted to a specific set of tower fan settings using the sequencing rules defined previously. This involves defining a relationship (i.e., table) for fan settings as a function of tower airflow. The table is constructed by defining the best fan settings for each possible increment of airflow. The conversion process between the continuous output of Equations (1) or (2) and the fan control involves choosing the set of discrete fan settings from the table that produces a tower airflow closest to the desired flow. However, in general, it is better to have greater rather than less than the optimal airflow. A good general rule is to choose the set of discrete fan controls that results in a relative airflow that is closest to, but not more than 10% less than the output of Equations (1) or (2).

With the parameters of Equation (1) specified, the following procedure is applied at each decision interval (e.g., 15 min or less) in order to determine the tower control.

1. If the temperature of the supply water to the chiller condenser is less than the low limit, then reduce the tower airflow by one increment according to the near-optimal sequencing rules and exit the algorithm. Otherwise go to Step 2.
2. If the temperature of the supply water to the chiller condenser is greater than the high limit, then increase the tower airflow by one
Supervisory Control Strategies and Optimization

increment according to the near-optimal sequencing rules and exit the algorithm. Otherwise go to Step 3.
3. Determine the chilled water load relative to the design load.
4. If the chilled water load has changed by a significant amount (e.g., 10%) since the last control change, then go to Step 5. Otherwise exit the algorithm.
5. If the part-load ratio is greater than 0.25, then compute the near-optimal tower airflow as a fraction of the tower capacity, G
\text{twr}
, with Equation (1). Otherwise, determine G
\text{twr}
 with Equation (2).
6. Limit G
\text{twr}
 to keep the change from the previous decision interval less than a minimum value (e.g., less than 0.1 change).
7. Restrict the value of G
\text{twr}
 between 0 and 1.
8. Convert the value of G
\text{twr}
 to a specific set of control functions for each of the tower cell fans according to the near-optimal sequencing rules.

Implementation of this procedure requires some estimate of the chilled water load, along with a measurement of the condenser water supply temperature. However, the accuracy of the load estimate is not extremely critical. In general, near-optimal control determined with load estimates that are accurate to within 5 to 10% results in total power consumption that is within 1% of the minimum. The best method for determining the chilled-water load would be from the product of the measured chilled-water flow rate and the temperature difference between the chilled-water return and supply. For systems that use constant flow pumping to the chillers, the flow rates may be estimated from design data for the pumps and system pressure drop characteristics.

Example 1. Consider an example plant consisting of four 2000 kW chillers with four cooling tower cells, each having two-speed fans. Each chiller consumes approximately 340 kW at the design capacity, while each tower fan uses 42 kW at high speed. At design conditions, the chiller power increases approximately 12.2 kW for a 1 K increase in condenser water temperature, giving a sensitivity factor of 12.2/340 or 0.036 K. The tower design approach and range from manufacturer’s data are 4 and 6 K.

Solution

The first step in applying the open-loop control algorithm to this problem is the determination of the parameters of Equation (1) from the design data. From Table 3, the part-load ratio at which operation of the tower is at its capacity is estimated for the two-speed fans as

\[
\text{PLR}_{\text{twr, cap}} = \frac{1}{\frac{1}{2} \left( \frac{0.036}{K} \right) \left( \frac{4 \times 340}{4 \times 42} \right) (4 + 6)} = 0.83
\]

while the slope of the fractional airflow versus part-load ratio is estimated to be

\[
\beta_{\text{twr}} = \frac{2}{3 \times 0.83} = 0.80
\]

Given these parameters and the part-load ratio, the fractional tower airflow is estimated as

IF (PLR > 0.25) THEN
\[ G_{\text{twr}} = 1 - \beta_{\text{twr}} \times (\text{PLR}_{\text{twr, cap}} - \text{PLR}) \]
ELSE
\[ G_{\text{twr}} = 4 \times \text{PLR} \times (1 - \beta_{\text{twr}} \times (\text{PLR}_{\text{twr, cap}} - 0.25)) \]
\[ G_{\text{twr}} = \text{MIN}(1, \text{MAX}(0, G_{\text{twr}})) \]

In order to convert G
\text{twr}
 into a specific tower control, the tower sequencing must be defined. The following table gives this information in a form that specifies the relationship between G
\text{twr}
, and tower control for this example.

For a specific chilled water load, the fan control should be the sequence of tower fan settings from the table that results in a value of G
\text{twr}
 that is closest to, but not more than 10% less than the output of Equation (1) or (2).

Note that this example assumes that proper water flow can be maintained over all cooling tower cells.

### Cooling Tower Fan Sequencing for Example 1

| Sequence No. | G
\text{twr}
 | Cell #1 | Cell #2 | Cell #3 | Cell #4 |
|-------------|--------|--------|--------|--------|--------|
| 1           | 0.125  | Low    | Off    | Off    | Off    |
| 2           | 0.250  | Low    | Low    | Off    | Off    |
| 3           | 0.375  | Low    | Low    | Low    | Off    |
| 4           | 0.500  | Low    | Low    | Low    | Low    |
| 5           | 0.625  | High   | Low    | Low    | Low    |
| 6           | 0.750  | High   | High   | Low    | Low    |
| 7           | 0.875  | High   | High   | High   | Low    |
| 8           | 1.000  | High   | High   | High   | High   |

**CHILLED WATER RESET WITH FIXED-SPEED PUMPING**

Figure 19 shows a common configuration using fixed-speed chilled water pumps with two-way valves at the cooling coils. A two-way bypass valve controlled to maintain a fixed pressure difference between the main supply and return lines is used in order to ensure relatively constant flow through chiller evaporators and reduce pressure drop and pumping costs at low loads. However, additional pump and chiller power savings can be realized by adjusting the chilled water supply temperature in order to keep some cooling coil valves open and thereby minimize the bypass flow.

Ideally, the chilled water temperature should be adjusted in order to maintain all discharge air temperatures with a minimal number of cooling coil control valves in a saturated (fully-open) condition. The procedure described in this section is designed to accomplish this goal in a reliable and stable manner that reacts quickly to changing conditions.

**Pump Sequencing**

Individual chilled water pumps are commonly physically dedicated to individual chillers. In this case, the sequencing of chilled water pumps is defined by the sequencing of chillers. In some installations the chiller pumps are not dedicated to chillers. Instead they are arranged in parallel, sharing common headers. In this case, the order for bringing pumps online and offline and the conditions for adding or removing chilled water pump capacity must be specified. For pumps of different capacities, the logical order for bringing pumps online is from small to large. For pumps of similar capacity, the most efficient pumps should be brought online first and taken offline last.
Optimal Chilled Water Temperature

One method for determining the optimal chilled water temperature is to monitor the water control valve positions of "representative" air handlers and to adjust the set temperature incrementally at fixed decision intervals until a single control valve is fully open. The "representative" air handlers should be chosen to include load diversity at all times and ensure reliable data. One difficulty of this control approach is that the valve position data is often unreliable. The valve could be stuck open or the saturation indicator could be faulty. This problem can be overcome by also monitoring the discharge air temperatures. The discharge air temperatures allow for a consistency check on the valve position data. If a valve is unsaturated, this implies that the coil has sufficient capacity to maintain the discharge air temperature near the set point. Conversely, if a valve remains saturated at 100% open, the discharge air temperature should ultimately increase above the set point. These considerations lead to the following simple rules for increasing or decreasing the chilled water set point in response to valve position and discharge air temperature data.

1. If all water valves are unsaturated or the discharge air temperatures associated with all valves that are saturated are lower than the set point, increase the chilled water temperature.
2. If more than one valve is saturated at 100% open and their corresponding discharge air temperatures are greater than their set point, decrease the chilled water temperature.

In implementing these rules, a fixed increment for increasing or decreasing the chilled water temperature must be chosen. A small increment results in more stable control, but also results in a slow response to sudden changes in load or supply air temperature set points. Using a first-order approximation, the chilled water temperature can be reset in response to sudden changes in load and supply air temperature set point according to

\[ t_{chws} = t_{as} - \frac{PLR}{PLR_o} (t_{as_o} - t_{chws_o}) \]  
(8)

where

- \( t_{chws} \) = new chilled water set point temperature
- \( t_{as} \) = current supply air set point temperature
- \( PLR \) = current part-load ratio (chiller load divided by total design load for all chillers)
- \( t_{chws_o} \) = chilled water set point associated with last control decision
- \( t_{as_o} \) = supply air set point associated with last control decision
- \( PLR_o \) = part-load ratio associated with last control decision

Equation (8) assumes that the chilled water temperature associated with the last control decision was optimal. As a result, it only applies to anticipating the effects of significant changes in the load and supply-air set-point temperature on the optimal chilled-water set point. The “bump-and-wait” strategy acts to fine-tune the chilled water supply temperature when the load and supply air set point are stable. For a variable-air-volume system, the supply air set points are most often constant and identical for all air-handling units. However, for a constant-air-volume system, these set points may vary with different air handlers. In this case, the supply air set point to use in Equation (8) should be an average value for the “representative” air handlers.

Equation (8) indicates that the optimal chilled water supply temperature increases with increasing supply air temperature and decreasing load. This is because these changes cause the cooling coil valves to close and the optimal control involves keeping at least one valve open. Increasing supply air temperature causes the cooling coil valves to close somewhat due to a larger average temperature difference for heat transfer between the water and air. A lower load requires smaller air-to-water temperature differences, which also leads to control valves closing.

Overrides for Equipment and Comfort Constraints

For a given chiller load, the chilled water temperature has both upper and lower limits. The lower limit is necessary to avoid ice formation on the evaporator tubes of the chiller. This limit depends primarily on the load in relation to the size of the evaporator or, in other words, the temperature difference between the chilled water and refrigerant. At small temperature differences (large area or small load), the evaporator can tolerate a lower chilled water temperature in order to avoid freezing than at large temperature differences. The lower limit on the chilled water set point should be evaluated at the design load, since the overall system performance is improved by increasing chilled water temperature above this limit for loads less than design. This lower limit can range from 3 and 7°C.

An upper limit on the chilled water temperature arises from comfort constraints associated with the zones and the possibility of microbial growth associated with high humidities. For the available flows, the chilled water temperature should be low enough to provide discharge air at a temperature and humidity sufficient to maintain all zones in the comfort region and avoid microbial growth. This upper limit varies with both load and entering air conditions and is accounted for by monitoring the zone conditions to ensure that they are in the comfort zone. If zone temperatures or humidities are not within reasonable bounds then the discharge air temperature set point should be lowered.

Summary and Implementation

At each decision interval (e.g., 5 min), the following algorithm would be applied for determining the optimal chilled water set point temperature.

1. Determine the time-averaged total chilled water load for the previous decision interval.
2. If the chilled water load or supply air set point temperature have changed by a significant amount (e.g., 10%) since the last control change, then estimate a new optimal chilled water set point with Equation (8) and go to Step 6. Otherwise, go to Step 3.
3. Determine the time-averaged position of (or controller output for) the cooling coil water valves and corresponding discharge air temperatures for “representative” air handlers.
4. If more than one valve is saturated at 100% open and their corresponding supply air temperatures are greater than set point (e.g., 0.5 K), then decrease the chilled water temperature by a fixed amount (e.g., 0.25 K) and go to Step 6. Otherwise, go to Step 5.
5. If all water valves are unsaturated or the supply air temperatures associated with all valves that are saturated are lower than the set point, then raise the chilled water set temperature by a fixed amount (e.g., 0.25 K). Otherwise, exit the algorithm with the chilled water set point unchanged.
6. Limit the chilled water set point temperature between the upper and lower limits dictated by comfort, humidity, and equipment safety.

Implementation of this algorithm requires some estimate of the chilled water load, along with a measurement of the discharge air temperatures and control valve positions. However, an accurate estimate of the load is not important.

CHILLED WATER RESET WITH VARIABLE-SPEED PUMPING

Figure 20 shows a common configuration for systems utilizing variable-speed chilled water pumps with primary/secondary water loops. The primary pumps are fixed speed and are generally sequenced with chillers to provide a relatively constant flow of water through the chiller evaporators. The secondary chilled water pumps are variable speed and are typically controlled to maintain a...
specified set point for pressure difference between supply and return flows for the cooling coils.

Although variable-speed pumps are usually used with primary/secondary chilled water loops, they may also be applied to systems with a single chilled water loop. In either case, variable-speed pumps offer the potential for a significant operating cost saving when both chilled water and pressure differential set points are optimized in response to changing loads. This section presents an algorithm for determining near-optimal values of these control variables.

Optimal Differential Pressure Set Points

In practically all variable-speed chilled water pumping applications, the pump speed is controlled to maintain a constant pressure differential between the main chilled water supply and return lines. However, this approach is not optimal. In order to maintain a constant pressure differential with changing flow, the control valves for the air-handling units must close as the load (i.e., flow) is reduced, resulting in an increase in the flow resistance. The best strategy for a given chilled water set point would be to reset the differential pressure set point in order to maintain all discharge air temperatures with at least one control valve in a saturated (fully-open) condition. This results in a relatively constant flow resistance and greater pump savings at low loads. With variable differential pressure set points, the optimization of the chilled water loop is described in terms of finding the chilled water temperature that minimizes the sum of the chiller and pumping power with the pump control dependent upon the set point and the load.

Near-Optimal Chilled Water Set Point

The optimal chilled water supply temperature at a given load results from a trade-off between chiller and pumping power as illustrated in Figure 21. As the chilled water temperature increases, the chiller power is reduced due to a reduction in the lift requirements of the chiller. For a higher set temperature, more chilled water flow is necessary to meet the load requirements and the pumping power requirements increase. The minimum total power occurs at a point where the rate of increase in pumping power with chilled water temperature is equal to the rate of decrease in chiller power. This optimal set point moves to lower values as the load increases.

Braun et al. (1989a) demonstrated that the optimal chilled water set point varies as a near linear function of both load and wet-bulb temperature over a wide range of conditions. Figure 22 shows an example of how the optimal set point varies for a specific plant. The set point is plotted as a function of load relative to design load for two different wet-bulb temperatures. In general, the optimal chilled water temperature decreases with load because the pump power becomes a larger fraction of the total power. A lower set-point limit is set in order to avoid conditions that could form ice on evaporator tubes or too high a chiller “lift”, while an upper limit is established to ensure adequate cooling coil dehumidification. For a given load, the chilled water set point increases with wet-bulb temperature because the energy transfer across each cooling coil is proportional to the difference between its entering air wet-bulb temperature and the entering water temperature (the chilled water set point). For a constant load this temperature difference is constant and the chilled water supply temperature increases linearly with entering air wet-bulb temperature.

The results of Figure 22 were obtained for a system where both the chilled water supply and supply air set points to the zones were optimized. For this case, the supply air temperatures varied between 13°C at high loads and 16°C at low loads. More typically, the supply air temperatures are constant at 13°C. In this case, the variation in chilled water supply temperature would be smaller than that shown in Figure 22.

Figure 23 depicts the general form for an algorithm to determine chilled water supply set points as a function of load and the average
Table 4 are: (1) the ratio of the chiller power to chilled water pump power at design conditions $P_{ch,des}/P_{chwp,des}$ (2) the sensitivity of the chiller power to changes in chilled water temperature at design conditions $S_{chws,des,i}$ and (3) the difference between the design entering air wet-bulb temperature and the chilled water supply temperature, $(t_{mx,wb,des} - t_{chws,des})$.

The chiller power consumption at design conditions is the total power consumption of all plant chillers operating at their design cooling capacity. Likewise, the design pump power is the total power associated with all secondary chilled water supply pumps operating at high speed. As the ratio of chiller power to pump power increases, then it becomes more beneficial to operate the chillers at higher chilled water temperatures and the pumps at higher flows. This is reflected in an increase in $PLR_{chws,cap}$. If the chiller power were free, then $PLR_{chws,cap}$ goes to zero, and the best strategy would be to operate the chillers at the minimum possible set point, resulting in low chilled water flow rates. Typical values for the ratio of the chiller power to the pump power at design conditions are between 10 and 20, depending primarily on whether primary/secondary pumping is used or not.

The chiller sensitivity factor $S_{chws,des,i}$ is the incremental increase in chiller power for each degree decrease in chilled water temperature as a fraction of the power or:

$$S_{chws,des} = \frac{\text{Increase in chiller power}}{\text{Decrease in chilled water temp.} \times \text{Chiller power}}$$

If the chiller power increases by 2% for a 0.5 K decrease in chilled water temperature, then $S_{chws,des}$ is equal to 0.4 K$^{-1}$. A large sensitivity factor means that the chiller power is very sensitive to the set point control favoring operation at higher set point temperatures and flows (higher $PLR_{chws,cap}$). The sensitivity factor should be evaluated at design conditions using chiller performance data. Typically, the sensitivity factor is between 0.02 K$^{-1}$ and 0.06 K$^{-1}$. For multiple chillers with different performance characteristics, the sensitivity factor at design conditions is estimated as:

$$S_{chws,des} = \frac{\sum_{i=1}^{N_{ch}} S_{chws,des,i} P_{ch,des,i}}{\sum_{i=1}^{N_{ch}} P_{ch,des,i}}$$

where $S_{chws,des,i}$ is the sensitivity factor and $P_{ch,des,i}$ is the power consumption for the $i$th chiller at the design conditions and $N_{ch}$ is the total number of chillers.

The design difference between the coil inlet air wet-bulb temperature and the entering water temperature should be evaluated for a typical air handler operating at its design load and flows. A small temperature difference results from a high coil heat transfer effectiveness or high water flow rate, allowing higher chilled water temperatures with lower chiller power consumption. This is evident from equation (9) where chilled water set point decreases linearly with $(t_{mx,wb,des} - t_{chws,des})$ for a given $\Gamma$, while $\Gamma$ is inversely related to the square root of $(t_{mx,wb,des} - t_{chws,des})$. Typically, this temperature difference is about 10 K.
Example 2. Consider an example plant with primary/secondary chilled water pumping. There are four 2000 kW chillers, each with its own dedicated primary pump. Each chiller consumes approximately 340 kW at the design capacity. At design conditions, the chiller power increases approximately 12.2 kW for a 1 K decrease in chilled water temperature, giving a sensitivity factor of 2.2/340 = 0.036 K⁻¹. The design chilled water set point is 5°C, while the coil entering wet-bulb temperature is 16°C at design conditions. The secondary loop uses three identical 45 kW chilled water pumps: one with a variable-speed and two with fixed-speed motors.

Solution:
The first step in applying the open-loop control algorithm to this problem is the determination of the parameters of Equation (10) from the design data. From Table 4, the part-load ratio at which the chilled water temperature reaches a minimum (with the design entering wet-bulb temperature to the coils) is:

\[
\text{PLR}_{\text{chws, cap}} = \frac{1}{4} \left( \frac{4 \times 340}{3 \times 45} \right) (0.036/\text{K}) (11) = 1.15
\]

while the slope of the set point versus part-load ratio is estimated to be:

\[
\beta_{\text{chws}} = \frac{0.5}{1.15} = 0.43
\]

Given these parameters and the part-load ratio, the unconstrained chilled water set point temperature from Equations (9) and (10) is then

\[
\text{t}_\text{chw} = \text{t}_{\text{sub}} - \left[ 1 - 0.43(1.15 - \text{PLR}) \right] 11
\]

Pump Sequencing
Variable-speed pumps are sometimes used in combination with fixed-speed or other variable-speed pumps. The problem of pump sequencing involves determining both the order and point that pumps should be brought online and offline.

Pumps should be brought online in an order that allows a continuous variation in flow rate and maximized operating efficiency of the pumps at each switch point for the specific pressure loss characteristic. For a combination of fixed-speed and variable-speed pumps, at least one variable-speed pump should be brought online prior to any fixed-speed pumps. For single-loop systems (i.e., no secondary-loop) with variable-speed pumps, the pressure drop characteristics change when chillers are added or removed and the optimal sequencing of pumps depends on the sequencing of chillers.

An additional pump should be brought online whenever the current set of pumps are operating at full capacity and can no longer satisfy the differential pressure point. This situation can be detected by monitoring the differential pressure or the controller output signal. Insufficient pump capacity leads to extended periods with differential pressures that are less than the set point and a controller output that is saturated at 100%. A pump may be taken offline, whenever the remaining pumps have sufficient capacity to maintain the differential pressure set point. This condition can be determined by comparing the current (time-averaged) controller output with the controller output (time-averaged) at the point just after the last pump was brought online. The pump can be brought offline when the current output is less than the switch point value by a specified deadband (e.g., 5%).

Overrides for Equipment and Comfort Constraints
The chilled water temperature is bounded by upper and lower limits dictated by comfort, humidity, and equipment safety concerns. However, within these bounds, the chilled water temperature may not always be low enough to maintain supply air set point temperatures for the cooling coils. This situation might occur at high loads when the chilled water flow is at a maximum and is detectable by monitoring the coil discharge air temperatures. Limits on the pressure differential set point might also be imposed in order to ensure adequate controllability of the cooling coil control valves.

Summary and Implementation
Prior to commissioning, the parameters of the open-loop control for chilled water set point [Equation (10)] need to be estimated using the results of Table 4. After the system is in operation, these parameters may be fine-tuned with measurements as outlined in the section on Control Optimization Methods. With the parameters specified, the control algorithm is separated into two reset strategies: chilled water temperature and pressure differential.

Chilled Water Temperature Reset. The chilled water supply temperature set point is reset at fixed decision intervals (e.g., 15 min) using the following procedure:

1. Determine the time-averaged position of (or controller output for) the cooling coil water valves and corresponding discharge air temperatures for “representative” air handlers over the previous decision interval.
2. If more than one valve is saturated at 100% open and their corresponding discharge air temperatures are greater than set point (e.g., 0.5 K), then decrease the chilled water temperature by a fixed amount (e.g., 0.25 K) and go to Step 5. Otherwise, go to Step 3.
3. Determine the total chilled water flow and load.
4. Estimate an optimal chilled water set point with Equations (9) and (10). Increase or decrease the actual set point in the direction of the near-optimal value by a fixed amount (e.g., 0.5 K).
5. Limit the new set point between upper and lower constraints dictated by comfort and equipment safety.

Pump Sequencing. Secondary pumps should be brought online or offline at fixed decision intervals (e.g., 15 min) with the following logic:

1. Evaluate the time-averaged pump controller output over the previous decision interval.
2. If the pump controller is saturated at 100%, then bring the next pump online. Otherwise, go to Step 3.
3. If the pump control output is significantly less (e.g., 5%) than the value associated with the first time interval after the last pump was brought online, then bring that pump offline.

Differential Pressure Reset. The set point for differential pressure between supply and return lines should be reset at smaller time intervals than the supply water temperature reset and pump sequencing strategies (e.g., 5 min) using the following procedure:

1. Check the water valve positions (or controller output) for “representative” air handlers and determine the time-averaged value over the last decision interval.
2. If more than one valve has been saturated at 100% open, then increase the differential pressure set point by a fixed value (e.g., 5% of the design value) and go to Step 4. Otherwise, go to Step 3.
3. If none of the valves have been saturated, then decrease the differential pressure set point by a fixed value (e.g., 5% of the design value).
4. Limit the differential pressure set point between upper and lower constraints.

SEQUENCING AND LOADING OF MULTIPLE CHILLERS
Multiple chillers are normally configured in a parallel manner and typically controlled to give identical chilled water supply temperatures. In most cases, controlling for identical set temperatures is the best and simplest strategy. With this approach, the relative loadings on operating chillers is controlled by the relative chilled water flow rates. Typically, the distribution of flow rates to heat exchangers for both chilled and condenser water are dictated by chiller pressure drop characteristics and may be adjusted through flow balancing, but are not controlled using a feedback controller. In
addition to the distribution of chilled and condenser water flow rates, the chiller sequencing affects energy consumption. Chiller sequencing defines the order that and conditions where chillers are brought online and offline. Simple guidelines may be established for each of these controls that are near optimal.

Near-Optimal Condenser Water Flow Distribution

In general, the condenser water flow to each chiller should be set to give identical leaving condenser water temperatures. This condition approximately corresponds to relative condenser flow rates equal to the relative loads on the chillers, even if the chillers are loaded unevenly. Figure 24 shows results for four sets of two chillers operated in parallel. The curves represent data from chillers at three different installations: (1) a 19.3 MW variable-speed chiller at the Dallas-Fort Worth Airport, Texas (Braun et al. 1989a); (2) a 1.9 MW fixed-speed chiller at an office building in Atlanta (Hackner et al. 1984, 1985); and (3) a 4.4 MW fixed-speed chiller at a large office building in Charlotte, North Carolina (Lau et al. 1985). The capacities of the chillers in the two office buildings were scaled up for comparison with the Dallas-Ft. Worth airport chiller.

The overall chiller coefficient of performance (COP) is plotted versus the difference between the condenser water return temperatures for equal chiller loading. For identical chillers, and with either variable-speed or fixed-speed motors, the temperature difference between the chillers is almost zero. For situations where chillers do not have identical performance, equal leaving condenser water temperatures result in chiller performance that is close to the optimum. Even for the variable- and fixed-speed chiller combinations that have very different performance characteristics, the penalty associated with the use of identical condenser leaving water temperatures is small. In order to achieve equal condenser leaving water temperatures, it is necessary to properly balance the condenser water flow rates at design operating conditions.

Optimal Chiller Load Distribution

Assuming identical chilled water return and chiller supply temperatures, the relative chilled water load for each parallel chiller (load divided by total load) that is operating could be controlled by its relative chilled water flow rate (flow divided by total flow). In order to change the relative loadings in response to operating conditions, the individual flow rates must be controlled. However, this is typically not done and it is probably sufficient to establish the load distributions based upon design information and then balance the flow rates to achieve these load distributions. Alternatively, the individual chiller loads can be precisely controlled through variations of individual chiller supply water set points.

Chillers with Similar Performance Characteristics. Braun et al. (1989a) showed that for chillers with identical design COPs and part-load characteristics, a minimum or maximum power consumption occurs when each chiller is loaded according to the ratio of its capacity to the sum total capacity of all operating chillers. This is equivalent to each chiller operating at equal part-load ratios (load divided by cooling capacity at design conditions). For the rth chiller, the optimal chiller loading is then

$$Q_{ch,i}^* = \frac{Q_{load}}{\sum_{i=1}^{N} Q_{ch,des,i}}$$

where $Q_{load}$ is the total chiller load, $Q_{ch,des,i}$ is the cooling capacity of the rth chiller at design conditions, and N is the number of chillers operating.

The loading determined with Equation (13) could result in either minimum or maximum power consumption. However, this solution gives a minimum when the chillers are operating at loads greater than the point at which the maximum COP occurs (i.e., chiller COP increases with increased loading). Typically, the maximum COP occurs at loads that are less than the nominal design capacity. Figure 25 shows the effect of the relative loading on chiller COP for different sets of identical chillers loaded at approximately 70% of their total capacities. Three of the chiller sets have maximum COPs when evenly loaded (matching the criterion of Equation [13]) while the fourth (Dallas-Ft. Worth fixed-speed) obtains a minimum at that point. The part-load characteristic of the Dallas-Ft. Worth fixed-speed chiller is unusual in that the maximum overall COP occurs at its maximum capacity. This chiller was retrofit with a different refrigerant and drive motor, which derated its capacity from 30.6 to 19.3 MW. As a result, the evaporators and condensers are oversized for its current capacity. Overall, the penalty associated with equally loading the Dallas-Ft. Worth fixed-speed chillers is small as compared with optimal loading and this strategy is probably appropriate. However, a slight reduction in energy consumption is possible if one of the two chillers operates at full capacity. The loading criterion of Equation (13) also works well for many combinations of chillers with different performance characteristics.
In order to achieve specified relative chiller loadings with equal chilled water set points, the chilled water flow rates must be properly balanced. The relative loadings of Equation (13) only depend on design information and the flow balancing can be achieved through proper design and commissioning.

**Chillers with Different Performance Characteristics.** For the general case of chillers with significantly different part-load characteristics, a point of minimum or maximum overall power occurs where the partial derivatives of the individual chiller’s power consumption with respect to their loads are equal, or:

\[
\frac{\partial P_{ch,i}}{\partial Q_{ch,i}} = \frac{\partial P_{ch,j}}{\partial Q_{ch,j}} \quad \text{for all } i \text{ and } j
\]

and subject to the constraint that

\[
\sum_{i=1}^{N} Q_{ch,i} = Q_{load}
\]

where \(Q_{ch,i}\) is the cooling load for the \(i\)th chiller and \(Q_{load}\) is the total cooling load.

In general, the power consumption of a chiller can be correlated as a quadratic function of cooling load and difference between the leaving condenser water and chilled water supply temperatures according to:

\[
P_{ch,i} = a_{0,i} + a_{1,i}(t_{cwr,i} - t_{chws,i}) + a_{2,i}(t_{cwr,i} - t_{chws,i})^2 + a_{3,i}Q_{ch,i} + a_{4,i}Q_{ch,i}^2 + a_{5,i}(t_{cwr,i} - t_{chws,i})Q_{ch,i}
\]

where, for the \(i\)th chiller, \(t_{cwr,i}\) is the leaving condenser water temperature and \(t_{chws,i}\) is the chilled water supply temperature. The coefficients of Equation (16) \((a_{0,i} \text{ to } a_{5,i})\) could be determined for each chiller through regression applied to measured or manufacturers’ data.

If each chiller has identical leaving condenser and chilled water supply temperatures, the criterion of Equation (14) applied to the correlation of Equation (16) leads to:

\[
a_{3,i} + 2a_{4,i}Q_{ch,i} + a_{5,i}(t_{cwr,i} - t_{chws,i})^2 = a_{3,j} + 2a_{4,j}Q_{ch,j} + a_{5,j}(t_{cwr,j} - t_{chws,j})^2 \quad \text{for } i \neq j
\]

where \(Q_{ch,i}\) is the optimal load for the \(i\)th chiller. Equations (17) and (15) represent a system of \(N\) linear equations in terms of \(N\) chiller loads that can be solved to give minimum (or possibly maximum) power consumption. For a given combination of chillers, the solution depends on the operating temperatures and total load. However, the individual chiller loads must be constrained to be less than the maximum chiller capacity at these conditions. If an individual chiller load determined from these equations is greater than its cooling capacity, then this chiller should be fully loaded and Equations (17) and (15) should be resolved for the remaining chillers [Equation (17) should only include unconstrained chillers].

In order to control individual chiller loads with identical chilled water supply temperatures, individual chilled water flow rates need to be controlled with two-way valves, which is not typical. However, the distribution of chiller loads could be changed for a fixed flow distribution by using different chilled water set point temperatures. For a given flow and load distribution, the individual chiller set point for parallel chillers is determined according to:

\[
t_{chws,i} = t_{chwr} - \frac{Q_{ch,i}}{f_{P,i}}(t_{chwr} - t_{chws})
\]

where \(f_{P,i}\) is the flow for the \(i\)th chiller divided by the total flow, \(t_{chws}\) is the chilled water supply temperature set point for the combination of chillers determined using the previously defined reset strategies, and \(t_{chwr}\) is the temperature of the water returned to the chillers from the building.

Substituting Equation (18) into Equation (16) and then applying the criterion of Equation (14) leads to the following:

\[
A_i + B_i Q_{ch,i} = A_j + B_j Q_{ch,j} \quad \text{for } i \neq j
\]

where

\[
A_i = a_{3,i} + [a_{4,i} + 2a_{5,i}(t_{cwr,i} - t_{chwr})]t_{chwr} - t_{chws}f_{P,i}Q_{load} + a_{5,i}(t_{cwr,i} - t_{chws})
\]

\[
B_i = 2a_{4,i} + a_{5,i}(t_{chwr} - t_{chws}) + a_{5,i}(t_{chwr} - t_{chws})^2
\]

The optimal chiller loads are determined by solving the linear system of equations represented by Equations (19) and (15). The individual chiller set points are then evaluated with Equation (18). If any set points are less than the minimum set point or greater than the maximum set point, then the set point should be constrained and Equations (19) and (15) should be resolved for the remaining chillers [Equation (19) should only include unconstrained chillers].

**Example 3.** The optimal loading for two chillers will be determined using the three methods outlined in this section. Table 5 gives the design cooling capacities and coefficients of the curve-fit of Equation (16) for the two chillers. The chillers are operating with a total cooling load of 5064 kW, condenser water return temperature of 29°C, an overall chilled water supply temperature set point of 7°C, and a chilled water return temperature of 13°C. Figure 26 shows the COPs for the two chillers as a function load relative to their design loads for the given operating temperatures determined using Equation (25). Chiller 1 is more efficient at higher part-ratios and less efficient at lower part-load ratios as compared with Chiller 2.

**Solution:**

The first case that will be considered is the chillers operating at equal part-load ratios. The ratio of the cooling load to the cooling

![Fig. 26 Chiller COP for Two Chillers](image-url)
capacity of the operating chillers is 5064/(4396 + 1934). From Equation (13), the individual chiller loads are:

\[ \dot{Q}_{ch,1}^* = 0.8(4396 \text{ kW}) = 3517 \text{ kW} \]

\[ \dot{Q}_{ch,2}^* = 0.8(1934 \text{ kW}) = 1547 \text{ kW} \]

The power for each chiller is computed for the specified operating conditions with Equation (16) and the coefficients of Table 5. For the case of equal part-load ratios, the total chiller power consumption is

\[ P_{ch} = P_{ch,1} + P_{ch,2} = 649.7 \text{ kW} + 292.2 \text{ kW} = 941.9 \text{ kW} \]

A second solution is determined for optimal chiller loads for the case of equal chilled water temperature set points and controllable flow for each chiller. In this case, algebraic manipulation of Equations (15) and (17) produces the following results for the individual chiller loads:

\[ \dot{Q}_{ch,1}^* = \frac{(a_{2,2} - a_{1,2}) + 2a_{4,2}Q_{load} + (a_{5,2} - a_{5,1})(t_{cw} - t_{ch})}{2(a_{4,1} + a_{4,2})} = 4277 \text{ kW} \]

\[ \dot{Q}_{ch,2}^* = Q_{load} - \dot{Q}_{ch,1}^* = 787 \text{ kW} \]

The resulting power consumption is then:

\[ P_{ch} = P_{ch,1} + P_{ch,2} = 688.6 \text{ kW} + 222.2 \text{ kW} = 910.8 \text{ kW} \]

Optimal loading of the chillers reduces the overall chiller power consumption by about 4% through heavier loading of Chiller 1 and lighter loading of Chiller 2 (see Example 3).

Finally, optimal chiller loading is determined for the case where the individual loadings are controlled by using different chilled water temperature set points (individual flow is not controllable). In order to apply Equations (18) and (19) the relative chilled water flow rate for each chiller must be known. For this example, the relative flow for the 6th chiller is assumed to be equal to the ratio of its design capacity to the design capacity for the operating chillers, so that:

\[ f_1 = \frac{Q_{ch,des,1}}{Q_{ch,des,1} + Q_{ch,des,2}} = \frac{4396}{4396 + 1934} = 0.694 \]

\[ f_2 = \frac{Q_{ch,des,2}}{Q_{ch,des,1} + Q_{ch,des,2}} = \frac{1934}{4396 + 1934} = 0.306 \]

Then, solution of Equations (15) and (19) leads to the following results for the individual chiller loads:

\[ \dot{Q}_{ch,1}^* = \frac{(a_{2,1} - a_{1,1}) + f_1(Q_{load} - Q_{ch,2})}{B_1 + B_2} = 4034 \text{ kW} \]

\[ \dot{Q}_{ch,2}^* = Q_{load} - \dot{Q}_{ch,1}^* = 1030 \text{ kW} \]

These loads lead to a total chiller power consumption of:

\[ P_{ch} = P_{ch,1} + P_{ch,2} = 705.8 \text{ kW} + 216.4 \text{ kW} = 922.2 \text{ kW} \]

The individual chilled water set points are determined from Equation (18) and are 6.1°C and 9°C for Chillers 1 and 2, respectively. The power consumption has increased slightly from the case of identical chiller set points and variable flow.

Note that either changing flows or chilled water setpoints complicates the overall system control as compared with loading the chillers with fixed part-load ratios and leads to relatively small savings.

**Order for Bringing Chillers Online and Offline**

For chillers with similar efficiencies, the order in which chillers are brought online and offline may be dictated by their cooling capacities and the desire to provide even runtimes. However, whenever beneficial and possible, chillers should be brought online in an order that minimizes the incremental increase in energy consumption. At a given condition, the power consumption of any chiller can be evaluated using the correlation given by Equation (16), where the coefficients are determined using manufacturers’ data or in-situ measurements. Then, the overall power consumption for all operating chillers is

\[ P_{ch} = \sum_{i=1}^{N} P_{ch,i} \]

When an additional chiller \((N + 1)\) is required (see next section), the best chiller to bring on line should result in the smallest increase (or largest decrease) in overall chiller power consumption as estimated with Equations (20) and (16) with chiller loading determined as outlined in the previous section. Although these estimates could be performed online, it is probably adequate to determine the order for bringing chillers online (and offline) using design operating temperatures and assuming that the current \((N)\) chillers are operating at their design loads.

For chillers with similar design cooling capacities, a simpler approach can be used for determining the order for bringing chillers online and offline. In this case, the chiller with the highest peak COP can be brought online first, followed by the second most efficient chiller, etc. and then brought offline in reverse order. The maximum COP for each chiller can be evaluated using manufacturers’ design and part-load data or from curve-fits to in-situ performance.

The chiller load associated with maximum COP for each chiller can be determined by applying a first-order condition for a maximum, using Equation (16) and the definition of COP. For this functional form, the maximum (or possibly minimum) COP occurs for

\[ \dot{Q}_{ch,i}^* = \frac{a_{1,i} + a_{1,i}(t_{cw} - t_{ch}) + a_{2,i}(t_{cw} - t_{ch})^2}{a_{4,i}} \]

The load determined from Equation (21) yields a maximum COP whenever it is real and bounded between upper and lower limits. Otherwise, it can be assumed that the maximum COP occurs at full load conditions. Typically, the maximum COP occurs between about 40% and 80% of design load and increases as the temperature difference between the condenser leaving water and chilled water supply decreases. Equation (21) could be applied online to determine the rank ordering of chillers to bring online as a function of operating temperatures. However, it is often sufficient to use Equation (21) at the design temperature difference and establish a chiller sequencing order at the design or commissioning stage.

**Example 4.** The loads for maximum COP will be determined for two different chillers at a chilled water set point of 7°C and a condenser water return temperature of 27°C. Table 6 gives the design cooling capacities and coefficients of the curve-fit of Equation (16) for the two chillers. Figure 27 shows the COPs of the two chillers determined from the correlations as a function of relative load (PLR) and temperature difference \((t_{cw} - t_{ch})\). These chillers have identical performance at design
conditions, but very different part-load characteristics due to different methods used for capacity control.

Solution:
The loading associated with the maximum COP for each chiller is determined using Equation (21) and the coefficients of Table 6. The power for each chiller is then determined using Equation (16) and the COP follows directly. Results of the calculations are given in Table 7. The maximum COP for chiller A is about 20% greater than that for the chiller B at the specified operating temperatures and should be brought on-line first.

Load Conditions for Bringing Chillers Online or Offline

In general, chillers should be brought online at conditions where the total power (including pumps and tower or condenser fans) of operating with the additional chiller would be less than without it. Conversely, a chiller should be taken offline when the total power of operating with that chiller would be less than with it. In practice, the switch point for bringing a chiller online should be greater than that for bringing that same chiller offline (e.g., 10%), in order to ensure a stable control. The optimal sequencing of chillers depends primarily upon their part-load characteristics and the manner with which the chiller pumps are controlled.

Dedicated Pumps. Where individual condenser and chilled water pumps are dedicated to the chiller, Hackner et al. (1985) and Braun et al. (1989a) showed that a chiller should be brought online when the operating chillers reach their capacity. This conclusion is the result of considering both the chiller and pumping power in determining optimal control. If the pumping power is ignored, the optimal chiller sequencing occurs when the chiller efficiency is maximized at each load. Because the maximum efficiency often occurs at part-load conditions, the optimal point for adding or removing chillers may occur when chillers are operating at less than their capacity. However, the additional pumping power required with bringing additional pumps online with the chiller offset any reductions in overall chiller power consumption associated with part-load operation.

When pumps are dedicated to chillers, situations may arise where the chillers are operating at less than their capacity and yet the chilled water flow to the cooling coils is insufficient to meet the building load. This generally results from an inadequate design or improper maintenance. Under these circumstances, either some zone conditions need to float to reduce the chilled water setpoint (if possible), or an additional chiller needs to be brought online. Monitoring the zone air handler conditions is one method used to detect this situation. If (1) the chilled water set point is at its lower limit and more than one valve is saturated at 100% open and (3) their corresponding discharge air temperatures are significantly greater (e.g., 1 K) than set point, then the chilled water flow is probably insufficient and an additional chiller/pump combination could be brought online. One advantage of this approach is that it is consistent with the reset strategies for both fixed and variable-speed chilled water systems.

Chillers can be brought on or offline with the following logic:

1. Evaluate the time-averaged values of the chilled water supply temperature and overall cooling load over a fixed time interval (e.g., 5 min).
2. If the chilled water supply temperature is significantly greater than the set point (e.g., 0.5 K), then bring the next chiller online. Otherwise, go to Step 3.
3. Determine the time-averaged position of the cooling coil water valves and corresponding discharge air temperatures for “representative” air handlers.
4. If the chilled water supply set point is at its lower limit and more than one valve is saturated at 100% open and their corresponding discharge air temperatures are significantly greater than set point (e.g., 0.5 K), then bring another chiller/pump combination online. Otherwise, go to Step 5.
5. If the cooling load is significantly less (e.g., 10%) than the value associated with the first time interval after the last chiller was brought online, then bring that chiller offline.

Fig. 27 Chiller A and B Performance Characteristics for Maximum COP Example 4
Non-Dedicated Pumps. For systems that do not have dedicated chiller pumps (e.g., variable-speed primary systems), the optimal load conditions for bringing chillers online or offline do not generally occur at the full capacity of the chillers. In determining the optimal chiller switch points, ideally both the chiller and pumping power should be considered because the pressure drop characteristics and pumping change when a chiller is brought online or offline. However, simple estimates of the optimal switch points may be determined by considering only the chiller power.

A chiller should be brought online whenever it would reduce the overall chiller power or if the current chillers can no longer meet the load (see previous section). A chiller should be added if the power consumption associated with \((N + 1)\) chillers is significantly less (e.g., 5%) than the current \(N\) chillers, with both conditions evaluated using Equation (20) with correlations of the form given in Equation (16) and sequencing and loading determined as outlined in previous sections. Conversely, a chiller should be removed if the power consumption associated with \((N - 1)\) chillers is significantly less (e.g., 5%) than the current \(N\) chillers. The decision to add or remove chillers is readily determined using the current load and operating temperatures.

STRATEGIES FOR AIR-HANDLING UNITS (AHUS)

Air Handler Sequencing and Economizer Cooling

Traditional air-handler sequencing strategies use a single PI controller in order to control heating, cooling with outdoor air, mechanical cooling with 100% outside air, and mechanical cooling with minimum outside air. Sequencing between these different modes is accomplished by splitting up the controller output into different regions of operation as shown in Figure 28.

Figure 28 depicts the relationship between the control signal to the valves and dampers and the feedback controller output. The controller adjusts its output in order to maintain the supply air temperature set point. If the output is between 100% and 200%, mechanical cooling is used to cool the air. When the outdoor conditions are suitable, the outdoor air dampers switch from their minimum position (minimum ventilation air) to fully open. For a dry-bulb economizer, this switch point occurs when ambient air is less than a specified value. This switch point should be less than the switch point to return to minimum outside air in order to ensure stable control. The economizer switch over temperature may be significantly lower than the return air temperature (e.g., 5 K lower) in humid climates where latent ventilation loads are significant. However, in dry climates, the switch over temperature may be close to the return temperature (e.g., 24°C). An enthalpy (or wet-bulb) economizer compares the outside and return air enthalpies (or wet-bulb temperatures) in order to initiate or terminate economizer operation. In general, enthalpy economizers yield lower energy costs than dry-bulb economizers, but require a humidity measurement. Humidity sensors require regular maintenance in order to ensure accurate readings. When the controller output is between 0% and 100% (see Figure 28), the cooling coil valve is fully closed and cooling is provided through the use of ambient air only. In this case, the controller output modulates the position of the outside air dampers to maintain the set point. If the controller output signal is between \(-100\%\) and 0%, the heating coil is used to maintain set point and the outside air dampers are set at their minimum position.

A single feedback controller is difficult to tune to perform well for all four modes of operation associated with an AHU. An alternative to the traditional sequencing strategy is to use three separate feedback controllers as described by Seem et al. (1998). This approach can improve temperature control, reduce actuator usage, and reduce energy costs. Figure 29 shows a state transition diagram for implementing a sequencing strategy that incorporates separate feedback controllers.

In State 1, a feedback controller adjusts the heating valve to maintain the supply air set point temperature with minimum outside air. The transition to State 2 occurs after the control signal has been saturated at the no-heating position for a period equal to a specified state transition delay (e.g., 3 min). In State 2, a second feedback controller adjusts the outdoor and return air dampers to achieve set point with heating and cooling valves closed. Transition back to State 1 only occurs after the damper control signal is saturated at its minimum value for the state transition delay, whereas transition to State 3 is associated with saturation at the maximum damper position for the state transition delay. In State 3, the damper remains fully open and a third feedback controller is used to adjust the flow of cooling water in order to maintain the supply air temperature at set point. Transition back to State 2 occurs if the controller output is saturated at its minimum value for the state transition delay. For a dry-bulb economizer, transition to State 4 occurs when the ambient dry-bulb temperature is greater than the switch over temperature by a deadband (e.g., 1 K). The feedback controller continues to modulate the cooling coil valve to achieve set point. Transition back to State 3 occurs when the ambient dry-bulb is less than the switch over temperature (e.g., 18°C). For an enthalpy economizer, the ambient enthalpy is compared with return air enthalpy in order to initiate transitions between States 3 and 4.

Figure 28 AHU Sequencing Strategy with Single Feedback Controller

Figure 29 AHU Sequencing Strategy with Multiple Feedback Controllers
Supply Air Temperature Reset for Constant Air Volume (CAV)

The benefits of resetting supply air temperature set points for CAV systems are very significant. Increasing the supply air set point for cooling reduces both the cooling load and reheat required, but does not change fan energy. In general, the set point for a CAV system could be set at the highest value that will keep all zone temperatures at their set points and all humidities within acceptable limits. A simple reset strategy based upon this concept follows.

At each the decision interval (e.g., 5 min), the following logic can be applied:

1. Check the controller outputs for “representative” zone reheat units and determine time-averaged values over the last decision interval.
2. If any controller output is less than a threshold value (e.g., 5%), then decrease the supply air set point by a fixed value (e.g., 0.3 K) and go to Step 4. Otherwise, go to Step 3.
3. If all zone humidities are acceptable and all controller outputs are greater than a threshold value (e.g., 10%), then increase the discharge air set point by a fixed value (e.g., 0.3 K) and go to Step 4. Otherwise, do not change the set point.
4. Limit the set point between upper and lower limits based on comfort considerations.

Static Pressure Reset for Variable Air Volume (VAV)

Flow may be modulated in a VAV system by using dampers on the outlet side of the fan, inlet vanes on the fan, vane-axial fans with controllable pitch fan blades, or variable-speed control of the fan motor. Typically, the inputs to any of these controlled devices are modulated in order to maintain a duct static pressure set point as described in Chapter 45. In a single duct VAV system, the duct static pressure set point is typically selected by the designer to be a fixed value. The sensor is located at a point in the duct work such that the established set point will ensure proper operation of the zone VAV boxes under varying load (supply airflow) conditions. A shortcoming of this approach is that static pressure is controlled based on a single sensor intended to represent the pressure available to all VAV boxes. Either a poor location or malfunction of this sensor will cause operating problems.

For a fixed static pressure set point, all of the VAV boxes tend to close as the zone loads and flow requirements decrease. Therefore, the flow resistance increases with decreasing load. Significant fan energy savings are possible if the static pressure set point is reset so that at least one of the VAV boxes remains open. With this approach, the flow resistance remains relatively constant. Englander and Norford (1992), Hartman (1993), and Warren and Norford (1993) proposed several different strategies based on this concept. Englander and Norford used simulations to show that either static pressure or fan speed can be controlled directly using a flow error signal from one or more zones and simple rules. Their technique forms the basis of the following reset strategy.

At each the decision interval (e.g., 5 minutes), the following logic can be applied:

1. Check the controller outputs for “representative” zone reheat boxes and determine time-averaged values over the last decision interval.
2. If any of the controller outputs is greater than a threshold value (e.g., 98%), then increase the static pressure set point by a fixed value (e.g., 5% of the design range) and go to Step 4. Otherwise, go to Step 3.
3. If all of the controller outputs are less than a threshold value (e.g., 90%), then decrease the static pressure set point by a fixed value (e.g., 5% of the design range) and go to Step 4. Otherwise, do not change the set point.
4. Limit the set point between upper and lower limits based on upper and lower flow limits and the duct design.

STRATEGIES FOR BUILDING ZONE TEMPERATURE SET POINTS

Typically, zone temperatures in commercial buildings are maintained at constant set points in the comfort zone during occupied periods. However, during unoccupied times, the set points are set up for cooling and set back for heating in order to reduce energy use. Optimal start algorithms determine times for turning equipment on so that the building zones reach the desired conditions when the building becomes occupied. The goal of these algorithms is to minimize the precool (or preheat) time. In some situations, the thermal mass of a building represents a storage medium that may be used to reduce peak cooling requirements. This section presents some simple strategies for these purposes.

Recovery from Night Setback or Setup

For buildings that are not continuously occupied, a significant savings in operating costs may be realized by raising the building set point temperature for cooling and by lowering the set point for heating during unoccupied times. Bloomfield and Fisk (1977) showed energy savings of 12% for a high-mass building and 34% for a low-mass building.

An optimal controller for return from night setback or setup returns zone temperatures to the comfort range precisely when the building becomes occupied. Seem et al. (1989) compared seven different algorithms for minimum return time. Each method requires the estimation of parameters from measurements of the actual return times from night setback or setup.

Seem et al. (1989) showed that the optimal return time for cooling was not strongly influenced by the outdoor temperature. The following quadratic function of the initial zone temperature was found to be adequate for estimating the return time:

$$\tau = a_0 + a_1 t_{z,i} + a_2 t_{z,i}^2$$ \hspace{1cm} (22)

where $\tau$ is an estimate of optimal return time, $t_{z,i}$ is initial zone temperature at the beginning of the return period, and $a_0$, $a_1$, and $a_2$ are empirical parameters. The parameters of Equation (22) may be estimated by applying linear least squares techniques to the difference between the actual return time and the estimates. These parameters may be continuously corrected using recursive updating schemes as outlined by Ljung and Söderström (1983).

For heating, Seem et al. found that ambient temperature has a significant effect on the return time and that the following relationship works well in correlating return times.

$$\tau = a_0 + (1-w)(a_1 t_{z,i} + a_2 t_{z,i}^2) + w a_3 t_a$$ \hspace{1cm} (23)

where $t_a$ is the ambient temperature, $a_0$, $a_1$, $a_2$, and $a_3$ are empirical parameters, and $w$ is a weighting function given by

$$w = 1000 (t_{z,i} - t_{occ}) / (t_{occ} - t_{unocc})$$ \hspace{1cm} (24)

where $t_{occ}$ and $t_{unocc}$ are the zone set points for unoccupied and occupied periods. Within the context of Equation (23), this function weights the outdoor temperature more heavily when the initial zone temperature is close to the set point temperature during the unoccupied time. Again, the parameters of Equation (23) may be estimated by applying linear least squares techniques to the difference between the actual return time and the estimates.

Ideally, separate equations should be used for zones that have significantly different return times. Equipment operation is initiated for the zone with the earliest return time. In a building with a central cooling system, the equipment should be operated above some
minimum load limit. With this constraint, some zones need to be returned to their set point earlier than the optimum time.

Optimal start algorithms often use a measure of the building mass temperature rather than the space temperature to determine return time. Although use of space temperature results in lower energy costs (i.e., shorter return time), the mass temperature may result in better comfort conditions at the time of occupancy.

Emergency Strategy to Limit Peak Cooling Requirements

Keeney and Braun (1997) developed a simple control strategy that makes use of building thermal mass in order to reduce peak cooling requirements in the event of a loss of a chiller. This emergency strategy is used only on days where the cooling capacity is not sufficient to keep the building in the comfort range using night setup control. It involves precooling the building during unoccupied times and allowing the temperature to float through the comfort zone during occupancy.

The precooling control strategy is depicted in Figure 30 along with conventional night setup control. Precooling is controlled at a constant temperature set point designated as \( t_{pre} \). The warm-up period is used to reset the zone air temperature set point so that the cooling system turns off without calling for heating. During this time, the zone air warms due to lighting and equipment loads. The occupied set point \( (t_{occ}) \) is set at the low end of the comfort region so that the building mass charge is held as long as cooling capacity is available. This set point is maintained until the limit on cooling capacity is reached. After this point, the temperatures in the zones float up and the building thermal mass provides additional cooling. If the precooling and occupied set points have been chosen properly and the cooling capacity is sufficient, the zone conditions will remain in comfortable throughout the occupied period. The peak cooling requirement can be reduced by as much as 25% using this strategy as compared with night setup control. Thus, the loss of one of four identical chillers could be tolerated. This strategy could also be used for spaces such as auditoriums that have a high occupancy density for a short period.

The length of time and temperature for precooling and the occupied temperature set point chosen for this strategy strongly influences the capacity reduction and could impact occupant comfort. A reasonable strategy is to precool at 20°C beginning at midnight, allow a 30 minute warmup period prior to occupancy, and then adjust the occupied set point to 21°C. The zone temperature will then rise above this set point when the chillers are operating at capacity.

Case Study. The control strategy was tested in a 130,000 m² office building located near Chicago. The facility has two identical buildings with very similar internal gains and solar radiation loads that are connected by a large separately cooled entrance area. During tests, the east building used the existing building control strategy while the west building used the precooling strategy.

Four 3200 kW vapor compression chillers normally provide chilled water to the air handling units. The loss of one chiller results in a 25% reduction of the total capacity. This condition was simulated by limiting the vane position of the two chiller units that cool the west building to 75%. The capacity limitation was imposed directly at the chiller control panels. Set points were provided to local zone controllers from a modern energy management and control system. Chiller cooling loads and zone thermal comfort conditions were monitored throughout the tests.

Consistent with simulation predictions, the precooling control strategy successfully limited the peak load to 75% of the cooling capacity for the west building, while the east building operated at 100% of capacity. Figure 31 shows the total chiller coil load for the east and west buildings for a week of testing in the middle of August 1995. The cooling coil load profile on Monday is the most dramatic example of the load shifting during this test period. The peak cooling load for this facility often occurs on Monday morning. The cooling load was achieved on Monday during a period in which a heat emergency had been declared in the city. The severe ambient conditions were compounded by a power outage that caused a loss of the west side chiller units for approximately 20 minutes. Under these demanding conditions, the precooling strategy maintained occupant comfort while successfully limiting cooling demand of the west side of the building to less than 75% of that for the east side.

The east side cooling requirement was at or below the 75% chiller capacity target for Tuesday through Friday so the emergency precooling strategy was not necessary. For these off-design days, the emergency strategy is not effective in reducing the on-peak cooling requirements because discharge of the mass is not initiated when the capacity is below the target. The thermal mass remains charged so that peak reduction would occur if the target value on the off design days was reset to a lower value.

Precooling of the top floor of the facility had already been implemented into the conventional control strategy used for the east building. This was necessary to maintain comfort conditions with full cooling capacity on hot days. As a result, even greater peak reduction would have been recorded if the precool strategy had been compared with conventional night setup control. The total electrical use was greater for the precooled west building, however the strategy was designed as an emergency strategy and does not attempt to minimize costs.

This emergency strategy should only be applied on days when the available cooling capacity is not sufficient to maintain comfort conditions.
conditions when using night setup control. Otherwise, the costs associated with providing cooling could increase significantly.

**CONTROL OF COOL THERMAL STORAGE**

As described in [Chapter 33](#), thermal storage can significantly reduce the costs of providing cooling in commercial buildings by shifting a portion of the daytime cooling requirements to the night-time hours. The savings result from reductions in both demand and energy charges. This section emphasizes ice storage applications, although much of it is relevant to chilled water storage as well. [Figure 32](#) shows a schematic of a typical ice storage system. The system consists of one or more chillers, cooling tower cells, condenser water pumps, chilled water/glycol distribution pumps, ice storage tanks, and valves for controlling charging and discharging modes of operation. Ice is made at night and used during the day to provide a portion of a building’s cooling requirements. The partial storage terminology comes about because the storage is not sized to handle the full on-peak load requirement on the design day. Typically, in a load-leveling scheme, the storage and chiller capacity are sized such that chiller operates at full capacity during the on-peak period on the design day.

Typical modes of operation for the system shown in [Figure 32](#) are as follows:

1. **Storage Charging Mode.** Typically, the storage only charges (i.e., ice is made) when the building is unoccupied and off-peak electric rates are in effect. In this mode, the load bypass valve (V-2) is fully closed to the building cooling coils, the storage control valve (V-1) is fully open to the ice-storage tank (the total chilled water/glycol flow is through the tank), and the chiller produces low temperatures (e.g., −7°C) sufficient to make ice.

2. **Storage Discharging Mode.** The storage only discharges (i.e., the ice melts) when the building is occupied. In this mode, valve V-2 is open to the building cooling coils and valve V-1 modulates the mixture of flows from the storage tank and chiller in order to maintain a constant supply temperature to the building cooling coils (e.g., 3°C). Individual valves at the cooling coils modulate their chilled water/glycol flow to maintain supply air temperatures to the zones.

3. **Direct Chiller Mode.** The chiller may operate to meet the load directly without the use of storage during the occupied mode (typically when off-peak electric rates are in effect). In this mode, valve V-1 is fully closed with respect to the storage tank.

For a typical partial-storage system, the storage meets only a portion of the on-peak cooling loads on the design day and the chiller operates at capacity during the on-peak period. As a result, the peak power is limited by the capacity of the chiller. For off-design days, many different control strategies would meet the building’s cooling requirements. However, each method has a different operating cost.

The best control strategy for a given day is a complex function of such factors as utility rates, load profile, chiller characteristics, storage characteristics, and weather. For a utility rate structure that includes both time-of-use energy and demand charges, the optimal strategy depends on variables that extend over a month. Consider the following typical discrete cost function associated with electrical use in a building:

$$ J = \sum_{k=1}^{N} \left[ E_k P_k \Delta t \right] + \max_{1 \leq k \leq N} \left[ D_k P_k \right] $$

where $J$ is the utility cost associated with the billing period (e.g., one month); $\Delta t$ is the stage time interval (typically equal to the time over which demand charges are levied, e.g., 0.25 h); $N$ is the number of time stages in a billing period, and for each stage $k$, $P_k$ is the average building electrical power (kW); $E_k$ is the energy cost rate or cost per unit of electrical energy ($$/kWh); and $D_k$ is the demand charge rate or cost per peak power rate over the billing period ($$/kW).

The first term in [Equation (25)](##) represents the total cost of energy use for a building over a billing period, which is usually a month. Typically, the energy cost rate varies according to time of use with high rates during the daytime on weekdays and low costs at night and on weekends. The second term in [Equation (25)](##) is the building demand cost and is the product of the peak power consumption that occurs during the billing period and the demand cost rate for that stage. The demand cost rate can also vary with time of day with higher rates occurring during on-peak periods. In order to determine a control strategy for charging and discharging storage that minimizes utility costs for a given system, it would be necessary to perform a minimization of [Equation (25)](##) over the entire billing period because of the influence of the demand charge. An even more complicated cost optimization would result if the utility rate included ratchet clauses whereby the demand charge is the maximum of the monthly peak demand cost and some fraction of the previous monthly peak demand cost during the cooling season. In either case, it is not worthwhile to perform an optimization over periods longer than those for which reliable forecasts of cooling requirements or ambient conditions could be performed (e.g., 1 day). It is therefore important to have simple control strategies for charging and discharging storage over a daily cycle.

The following control strategies for limiting cases of the cost function of [Equation (25)](##) provide further insight.

1. **Chiller-priority Control.**
   - In a limiting case where the demand cost rate is zero and the energy cost rate does not vary with time, the minimization of [Equation (25)](##) is equivalent to minimizing the total electrical energy use. In general, the cooling plant efficiency is much lower when it makes ice than when it cools the building. Thus, the optimal strategy for minimum energy use would minimize the use of storage. Although this may seem like a simple example, the most common control strategy in use today for partial ice storage attempts to minimize the use of storage and is called **chiller-priority control**.

   2. **Storage-priority Control.** In a situation where the demand cost rate is zero but energy costs are higher during on-peak than off-peak periods, the minimization of [Equation (25)](##) involves trade-offs between energy use and energy cost rates. For a relatively small difference between on-peak and off-peak rates of less than about 30%, the energy penalties for ice making typically outweigh the effect of the reduced rates and chiller-priority control is optimal for many cases. However, with differentials higher than about 30% between on-peak and off-peak energy rates or with chillers having smaller charging-mode energy penalties, the optimal strategy might maximize the use of storage. A control strategy that attempts to maximize the load-shifting potential of storage is typically termed **storage-priority control**. With storage-priority control, the chiller operates during the off-peak period to fully charge storage (i.e., make
ice). During the on-peak period, storage is used to cool the building in a manner that minimizes the use of the chiller(s). Partial storage systems that use storage-priority control strategies require forecasts for building cooling requirements in order to avoid the premature depletion of storage.

3. If energy were free and only on-peak demand costs are considered, the optimal control strategy would tend to minimize the use of storage and would control the discharge of storage in a manner that would always minimize the peak building power. A storage-priority, demand-minimization control strategy for partial-storage systems would require both cooling load and non-cooling electrical use forecasts.

A number of control strategies based on the three limiting cases described above have been proposed for ice storage (Rawlings 1985, Tambllyn 1985, Speithmann 1989, Grummun and Butkus 1989, Braun 1992, Drees and Braun 1996). Braun (1992) evaluated the performance of chiller-priority and storage-priority control strategies as compared with optimal control. The storage-priority strategy was termed load-limiting control because it attempts to minimize the peak cooling load during the on-peak period. The load-limiting strategy provided near-optimal control in terms of demand costs in all cases and worked well with respect to energy costs when time-of-day energy charges were available. However, the scope of the study was limited.

Krauti et al. (1996) evaluated chiller-priority and storage-priority control strategies as compared with optimal control for a wide range of systems, utility rate structures, and operating conditions. Similar to Braun (1992), they concluded that load-limiting, storage-priority control provides near-optimal performance when there is a significant differential cost between on-peak and off-peak energy and demand charges. However, optimal control provides superior performance in the absence of time-of-day incentives. In general, the monthly utility costs associated with chiller-priority control are significantly higher than optimal and storage-priority control. However, without time-of-use energy charges, chiller-priority control did provide good performance for individual days when the daily peak power was less than the monthly peak.

Drees and Braun (1996) developed a simple rule-based control strategy that combines elements of storage-priority and chiller-priority strategies in a way that results in near-optimal performance under all conditions. The strategy uses rules obtained from both daily and monthly optimization results for several simulated systems.

The choice of control strategy results from a trade-off between performance (i.e., operating cost) and ease of implementation (i.e., initial cost). Chiller-priority control has the lowest implementation cost, but generally leads to the highest operating cost. Storage-priority strategies provide superior performance, but require the use of a forecaster and a measurement of state of charge for storage. The rest of this section presents details of chiller-priority, load-limiting, and a rule-based control. Each of these strategies shares the same procedures for charging storage, but differ in the manner in which storage is discharged. In general, the control strategies presented are appropriate for utility rate structures that include time-of-use energy and demand charges, but would not be appropriate in conjunction with real-time pricing. Additional information on control strategies for cool storage can be found in Chapter 33, Thermal Storage.

Charging Strategies

Ice making should be initiated when the building is both unoccupied and off-peak electrical rates are in effect. During the ice-making period, the chiller should operate at full capacity. Cooling plants for ice storage generally operate most efficiently at full load due to the auxiliaries and the characteristics of ice-making chillers. With feedback control of the chilled water/glycol supply temperature, full capacity control is accomplished by establishing a low enough set point to ensure this condition (e.g., 7°C).

Internal Melt Storage Tanks. The chiller should operate until the tank reaches its maximum state of charge or the charging period (e.g., off-peak, unoccupied period) ends. This strategy ensures that sufficient ice will be available for the next day without the need for a forecaster. Typically, only a small heat transfer penalty is associated with restoring a partially discharged, internal melt storage tank to a full charge. For this type of storage device, the charging cycle always starts with a high transfer effectiveness because water surrounds the tubes regardless of the amount of ice melted. The heat transfer effectiveness drops gradually until the new ice formations intersect with old formations, at which point the tank is fully recharged.

External Melt Storage Tanks. These tanks have a more significant heat transfer penalty associated with recharging after a partial discharge because ice forms on the outside of existing formations during charging. In this case, it is desirable from an efficiency standpoint to fully discharge the tank each day and only recharge as necessary to meet the next day’s cooling requirements. To ensure that adequate ice is available, the maximum possible storage capacity needed for the next day must be forecast. The storage requirements for the next day depend on the discharge strategy used and the building load. In general, the state of charge for storage necessary to meet the next day’s load can be estimated according to

\[
X_{\text{chg}} = \frac{Q_{\text{load}, k} - Q_{\text{ch}, k}}{C_s} \tag{26}
\]

where \(X_{\text{chg}}\) is the relative state of charge at the end of the charging period, \(C_s\) is the maximum change in internal energy of the storage tank that can occur during a normal discharge cycle, and \(Q_{\text{load}, k}\) and \(Q_{\text{ch}, k}\) are forecasts of the building load and chiller cooling requirement for the \(k\)th stage (e.g., hour) of the occupied period. The relative state of charge is defined in terms of two reference states: the fully discharged and fully charged conditions that correspond to values of zero and one. These conditions are defined for a given storage based on its particular operating strategy (Elleson 1996, ASHRAE 1997). The fully charged condition is that existing when the control stops the charge cycle as part of its normal sequence. Similarly, the fully discharged condition is the point where no more usable cooling is recovered from the tank. Typically, zero state of charge corresponds to a tank of water at a uniform temperature of 0°C and a complete charge is associated with a tank having maximum ice build at 0°C. (The fully discharged and fully charged conditions are arbitrarily selected reference states.) In abnormal circumstances, a storage tank can be discharged or charged beyond these conditions, resulting in relative states of charge below zero or above one.

Hourly forecasts of the next day’s cooling requirement can be determined using the algorithm described in following section on Forecasting Diurnal Energy Requirements. However, long-term forecasts are highly uncertain and a safety factor based on previous forecast errors is appropriate (e.g., uncertainty of two or three times the standard deviation of the errors of previous forecasts). Estimates of the hourly chiller requirements should be determined using the intended discharge strategy (described in the next section) and the building load forecasts.

Discharging Strategies

Three discharge strategies are presented for use with utility structures having on-peak and off-peak energy and demand charges: (1) chiller-priority control, (2) storage-priority, load-limiting control, and (3) a rule-based strategy that uses both chiller-priority and load-limiting strategies.

Chiller-Priority Discharge. During the storage discharge mode, the chiller operates at full cooling capacity (or less if sufficient to
Supervisory Control Strategies and Optimization

meet the load) and storage matches the difference between the building requirement and chiller capacity. For the example system illustrated in Figure 32, the chiller supply temperature set point $t_{chsw}$ is set equal to the desired supply temperature for the coils $t_{ccoh}$. If the capacity of the chiller is sufficient to maintain this set point at any time, then storage is not used and the system operates in the direct chiller mode. Otherwise, the storage control valve modulates the flow through storage to maintain the supply set point, providing a cooling rate that matches the difference between the building load and the maximum cooling capacity of the chillers.

This strategy is easy to implement and does not require a load forecaster. It works well for design conditions, but can result in relatively high demand and energy costs for off-design conditions because the chiller operates at full capacity during the on-peak period.

**Load-Limiting, Storage Priority Control.** Several storage-priority control approaches ensure that storage is not depleted prematurely. Braun (1992) presented a storage-priority control strategy, termed load-limiting control, which tends to minimize the peak cooling plant power demand. The operation of equipment for load-limiting control during different parts of the occupied period can be described as follows:

1. **Off-Peak, Occupied Period.** During this period, the goal is to minimize the use of storage and the chiller-priority described in the previous section should be applied.

2. **On-Peak, Occupied Period.** During this period, the goal is to operate the chillers at a constant load while discharging the ice storage such that the ice is completely melted when the off-peak period begins. This requires the use of a building cooling load forecaster. At each decision interval (e.g., 15 min), the following steps are applied.
   - (a) Forecast the total integrated building cooling requirement until the end of the discharging period.
   - (b) Estimate the state of charge of the ice-storage tank from measurements.
   - (c) At any time, the chiller loading for load-limiting control is determined as:
     \[
     \dot{Q}_{LLC} = \max \left( \frac{\dot{Q}_{load,occ} - (X - X_{min})C_s}{\Delta t_{on}}, \dot{Q}_{ch, min} \right) \tag{27}
     \]
     where $\dot{Q}_{load,occ}$ is a forecast of the integrated building load for the rest of the on-peak period, $X$ is the current state of charge defined as the fraction of the maximum storage capacity, $X_{min}$ is a minimum allowable state of charge, $C_s$ is the maximum possible energy that could be added to storage during discharge, and $\dot{Q}_{ch, min}$ is the minimum allowable chiller cooling capacity. If the chiller does not need to be operated during the remainder of the occupied, on-peak period, the minimum allowable cooling capacity could be set to zero. Otherwise, the cooling capacity should be set to the minimum at which the chiller can safely operate.
   - (d) Determine the chiller set point temperature necessary to achieve the desired loading as
     \[
     t_{chsw} = t_{chwr} - \frac{\dot{Q}_{LLC}}{C_{chw}} \tag{28}
     \]
     where $t_{chwr}$ is the temperature of water/glycol returned to the chiller and $C_{chw}$ is the capacitance rate (mass flow times specific heat) of the flow stream.

Hourly forecasts of cooling loads can be determined using the algorithm described in the section on Forecasting Diurnal Energy Requirements. The hourly forecasts are then integrated to give a forecast of the total cooling requirement. To ensure sufficient cooling capacity, a worst-case forecast of cooling requirements could be estimated as the sum of the best forecast and two or three times the standard deviation of the errors of previous forecasts.

**Rule-Based Controller.** Drees and Braun (1996) presented a rule-based controller that combines elements of chiller-priority and storage-priority strategies, along with a demand-limiting algorithm to achieve near-optimal control. The demand-limiting algorithm requires a measurement of the total building electrical use. A simpler strategy is described here that doesn’t require this measurement and yields equivalent performance whenever the peak demand for the billing period is coincident with the peak cooling load.

**Figure 33** shows a flowchart for the discharge strategy that is applied during each decision interval (e.g., 15 min) during the occupied period. Block 1 determines whether the use of storage should be maximized or minimized. Block 2 is used if the use of storage lowers daily energy costs and storage is sufficient to meet the remainder of the load for the occupied period without operating the chillers. Otherwise, the goal of the strategy in Block 3 is to minimize the use of storage while keeping the peak load below a limit. This strategy tends to keep the chiller(s) heavily loaded (and therefore operating efficiently) until they are no longer needed. The logic in each block is as follows.

1. **Block 1: Discharge Strategy Selection.** The discharge of storage will not reduce the energy cost whenever the cost of replenishing the ice is greater than the cost of providing direct cooling by the chiller(s). This situation is always the case during the off-peak, occupied period since the electricity rates are the same as those associated with the charging period and chillers are less efficient in ice making mode than when providing direct cooling. Furthermore, during the on-peak, occupied period the use of storage generally reduces energy costs whenever the following criterion holds.

\[
ECR > \frac{COP_d}{COP_c} \tag{29}
\]

where ECR is the ratio of on-peak to off-peak energy charges and $COP_d$ and $COP_c$ are the coefficients of performance for the cooling plant (including chiller, pumps, and cooling tower fans) during discharging and charging of the tank. The COPs should be evaluated at the worst-case charging and discharging conditions associated with the design day. Typically, this ratio is between about 1.2 and 1.8 for systems with cooling towers. However, this ratio can be lower for systems with air-cooled condensers in dry climates due to cool nighttime temperatures.

If the criterion of Equation (29) is satisfied, the control will switch from chiller-priority to storage-priority strategy whenever the storage capacity is greater than the remaining integrated load. Therefore, the storage-priority control is enabled whenever

\[
(X - X_{min})C_s \geq \dot{Q}_{load,occ} \tag{30}
\]

**Figure 33** Flowchart for Rule-Based Controller Discharge Strategy
Hourly forecasts of cooling loads can be determined using the algorithm described in the section on Forecasting Diurnal Energy Requirements and then integrated to give a forecast of the total cooling requirement. To ensure that adequate ice is available, worst-case hourly forecasts could be determined by adding the expected value of the hourly forecasts and the forecast errors associated with a specified confidence interval (e.g., 2 standard deviations for a 95% confidence interval). The worst-case hourly forecasts would then be integrated to give a worst-case integrated forecast.

2. Block 2: Maximum Use of Storage. In this mode, the chillers are turned off and storage is used to meet the entire load throughout the remainder of the occupied period. However, a chiller may need to be turned on if the storage discharge rate is not sufficient to meet the building load (i.e., the coil supply temperature set point cannot be maintained).

3. Block 3: Minimize Use of Storage with Peak Load Limiting. At any time, a target chiller load is determined as

\[ Q_{ch} = \min \{Q_{ch, peak}, Q_{LCC}, Q_{load}\} \]  

(31)

where \( Q_{ch, peak} \) is the peak chiller cooling requirement that has occurred during the on-peak period for the current billing period, \( Q_{LCC} \) is the chiller load associated with load-limiting control and determined with \( Q_{peak} \) and \( Q_{load} \) is the current building load. The chiller set point temperature necessary to achieve the desired loading is determined as:

\[ t_{chws} = \max \left\{ t_{chw} - \frac{Q_{ch}}{C_{chw}}, t_{cool} \right\} \]  

(32)

On the first day of each billing period, \( Q_{peak} \) is set to zero. For this first day, application of Equation (31) leads to the load-limiting control strategy described in the previous section. On subsequent days, load-limiting control is used only if the current peak limit would lead to premature depletion of storage. Whenever the current load is less than \( Q_{ch, peak} \) and \( Q_{LCC} \), Equations (31) and (32) lead to chiller-priority control.

**FORECASTING DIURNAL ENERGY REQUIREMENTS**

As discussed previously, forecasts of cooling requirements and electrical use in buildings are often necessary for the control of thermal storage to shift electrical use from on-peak to off-peak periods. In addition, forecasts can help plant operators anticipate major changes in operating modes such as bringing additional chillers online.

In most methods, future predictions are estimated as a function of time-varying input variables that affect the cooling requirements and electrical use. Examples of inputs that affect building energy use include: (1) ambient dry-bulb temperature, (2) ambient wet-bulb temperature, (3) solar radiation, (4) building occupancy, and (5) wind speed. Methods that include time-varying measured input variables are often termed deterministic methods.

Not all inputs that affect cooling requirements and electric use are easily measured. For instance, building occupancy is difficult to determine and solar radiation measurements are expensive. In addition, the accuracy of forecast models that use deterministic inputs depends on the accuracy of future predictions of the inputs. As a result, most inputs that affect building energy use are typically not used.

Much of the time-dependent variation in cooling loads and electrical use for a building can be captured with time as a deterministic input. For instance, building occupancy follows a regular schedule that depends on time of the day and time of the year. In addition, variations in ambient conditions follow a regular daily and seasonal pattern. Many of the forecasting methods use time in place of unmeasured deterministic inputs in a functional form that captures the average time dependence of the variation in energy use.

The use of a deterministic model has a limited accuracy for forecasts due to both unmeasured and unpredictable (random) input variables. Short-term forecasts can be improved significantly by adding previous values of deterministic inputs and previous output measurements (cooling requirements or electrical use) as inputs to the forecasting model. The time history of these inputs provides valuable information about recent trends in the time variation of the forecasted variable and the unmeasured input variables that affect it. Most forecasting methods use variables that reflect past history to predict the future.

Any forecasting method requires that a functional form is defined and the parameters of the model are learned based on measured data. Either offline or online methods can be used to estimate parameters. Offline methods involve estimating parameters from a batch of data that has been collected. Typically, the parameters are determined by minimizing the sum of squares of the forecast errors. The parameters of the process are assumed to be constant over time in the offline methods. Online methods allow the parameters of the forecasting model to vary slowly with time. Again, the sum of squares of the forecast errors is minimized, but this is accomplished in a sequential or recursive manner. Often, a forgetting factor is used in order to give additional weight to the recent data. The ability to track time-varying systems can be important when forecasting cooling requirements or electric use in buildings because of the influence of seasonal variations in weather.

Forrester and Wepfer (1984) presented a forecasting algorithm that uses current and previous ambient temperatures and previous loads to predict future requirements. Trends on an hourly time scale are accounted for with measured inputs for a few hours preceding the current time. Day-to-day trends are considered by the use of the load that occurred 24 h earlier as an input. One of the major limitations of this model is its inability to accurately predict loads when an occupied day (e.g., Monday) follows an unoccupied day (e.g., Sunday) or when an unoccupied day follows an occupied day (e.g., Saturday). The cooling load for a particular hour of the day on a Monday depends very little on the requirement 24 h earlier on Sunday. Forrestor and Wepfer (1984) described a number of methods for eliminating this 24 h indicator. MacArthur et al. (1989) also presented a load profile prediction algorithm that uses a 24 h regressor.

Armstrong et al. (1989) presented a very simple method for forecasting either cooling or electrical requirements that does not use the 24 h regressor. Then Seem and Braun (1991) further developed and validated the method. The “average” time-of-day and time-of-week trends are modeled using a lookup table with time of day and type of day (e.g., occupied versus unoccupied) as the deterministic input variables. Entries in the table are updated using an exponentially-weighted, moving-average model. Short-term trends are modeled using previous hourly measurements of cooling requirements in an autoregressive (AR) model. Model parameters adapt to slow changes in the system characteristics. The combination of updating the table and modifying model parameters works well in adapting the forecasting algorithm to changes in season and occupancy schedule.

Kreider and Wang (1991) used artificial neural networks (ANNs) to predict energy consumption of various HVAC equipment in a commercial building. Data inputs to the ANN included (1) previous hour’s electrical power consumption, (2) building occupancy, (3) wind speed, (4) ambient relative humidity, (5) ambient dry-bulb temperature, (6) previous hour’s ambient dry-bulb temperature, (7) two hours’ previous ambient temperature, (8) sine and cosine of the hour number to roughly represent the diurnal change of temperature and solar insolation. The primary purpose in developing these models was to detect changes in equipment and system performance for monitoring purposes. However, the authors suggested that an ANN-based predictor might be
value. Seem and Braun recommend using a value of 0.30 for \( \lambda \) approaches the average of all data for that hour and day type. When

\[
\text{Given the hour of the day and the day type, the deterministic part of the forecast is simply a lookup table for the forecasted variable in terms of hour of the day and the type of day. Seem and Braun recommend the use of three distinct day types: unoccupied days, occupied days following unoccupied days, and occupied days following occupied days. The three day types account for differences between the building response associated with return from night setup and return from weekend setup. The building operator or control engineer must specify the number of day types and a calendar of day types.}

\[
\text{The deterministic part of the forecast is simply a lookup table for the forecasted variable in terms of hour of the day and type of day. Seem and Braun recommend the use of three distinct day types: unoccupied days, occupied days following unoccupied days, and occupied days following occupied days. The three day types account for differences between the building response associated with return from night setup and return from weekend setup. The building operator or control engineer must specify the number of day types and a calendar of day types.}
\]

\[
\text{Given the hour of the day and the day type, the deterministic part of the forecast is simply the value stored in that location in the table. Table entries are updated when a new measurement becomes available for that hour and day type. Updates are accomplished through the use of an exponentially-weighted, moving-average (EWMA) model as}
\]

\[
\hat{D}(h,d) = \hat{D}(h,d)_{old} + \lambda [E(n) - \hat{D}(h,d)_{old}] \tag{34}
\]

\[
\text{where}
\]

\[
E(n) = \text{measured value of cooling load or electrical use for current hour } n
\]

\[
\lambda = \text{exponential smoothing constant, } 0 < \lambda < 1
\]

\[
\hat{D}(h,d)_{old} = \text{previous table entry for } \hat{D}(h,d)
\]

\[
\text{As } \lambda \text{ increases, the more recent observations have more influence on the average. As } \lambda \text{ approaches zero, the table entry approaches the average of all data for that hour and day type. When } \lambda \text{ equals one, the table entry is updated with the most recent measured value. Seem and Braun recommend using a value of 0.30 for } \lambda \text{ in conjunction with three day types and 0.18 with two day types.}
\]

\[
\text{The stochastic portion of the forecast is estimated with a third-order autoregressive model, AR(3), of the forecasting errors associated with the deterministic model. With this model, an estimate of the next hour’s error in the deterministic model forecast is given by the following equation:}
\]

\[
\hat{X}(n + 1) = \phi_1 X(n) + \phi_2 X(n - 1) + \phi_3 X(n - 2) \tag{35}
\]

\[
\text{where}
\]

\[
x(n) = \text{difference between measurement and deterministic forecast of cooling load or electrical use at any hour } n
\]

\[
\phi_1, \phi_2, \phi_3 = \text{parameters of AR(3) model that must be learned}
\]

\[
\text{The error in the deterministic forecast at any hour is simply}
\]

\[
X(n) = E(n) - D(h,d) \tag{36}
\]

\[
\text{For forecasting more than one hour ahead, conditional expectation is used to estimate the deterministic model forecast errors using the AR(3) model as follows:}
\]

\[
\hat{X}(n + 2) = \phi_1 \hat{X}(n + 1) + \phi_2 \hat{X}(n) + \phi_3 X(n - 1)
\]

\[
\hat{X}(n + 3) = \phi_1 \hat{X}(n + 2) + \phi_2 \hat{X}(n + 1) + \phi_3 X(n)
\]

\[
\vdots
\]

\[
\hat{X}(n + k) = \phi_1 \hat{X}(n + k + 1) + \phi_2 \hat{X}(n + k) + \phi_3 X(n - 1)
\]

\[
\text{for } k > 3 \tag{37}
\]

\[
\text{Online estimation of the AR(3) model parameters is accomplished by minimizing the following time-dependent cost function.}
\]

\[
J(\phi) = \sum_{k=1}^{n} \alpha^{|k-n|} [X(n) - \hat{X}(n)]^2 \tag{38}
\]

\[
\text{where the constant } \alpha \text{ is called the forgetting factor and has a value between 0 and 1. With this formulation, the residual for the current time step has a weight of one and the residual for } k \text{ time steps back has a weight of } \alpha^k. \text{ By choosing a value of } \alpha \text{ that is positive and less than one, recent data has greater influence on the parameter estimates. In this manner, the model can track changes due to seasonal or other effects. Seem and Braun recommend using a forgetting factor of 0.99. Parameters of the AR(3) model should be updated at each hour when a new measurement becomes available.}
\]

\[
\text{Ljung and Söderström (1983) describe online estimation methods for determining coefficients of an AR model. The parameter estimates should be evaluated for stability. If an AR model is not stable, then the forecasts will grow without bound as the time of forecasts increases. Ljung and Söderström discuss methods for checking stability.}
\]

\[
\text{Seem and Braun compared forecasts of electrical usage with both simulated and measured data. Figure 34 shows the standard deviation of the 1 h through 24 h errors in electrical use forecasts for annual simulation results. Results are given for the deterministic model alone, deterministic plus AR(2), and deterministic plus AR(3). For the combined models, the standard deviation of the residuals increases as the forecast length increases. For short time steps (i.e., less than six hours), the combined deterministic and stochastic models provide much better forecasts than the purely deterministic model (i.e., lookup table).}
\]

\[
\text{Seem and Braun also investigated a method for adjusting the deterministic forecast based upon the use of Weather Service forecasts of maximum daily ambient temperature as an input. For short periods (i.e., less than 4 h), the forecasts for the temperature-dependent model were nearly identical to the forecasts for the temperature}
\]
independent model. For longer periods, the temperature-dependent model provided better forecasts than the temperature-independent model.

CONTROL OPTIMIZATION METHODS

STATIC OPTIMIZATION

Optimal supervisory control of cooling equipment involves determining the control that minimizes the total operating cost. For an all-electric system without significant storage, the optimization of cost leads to minimization of power at each instant in time. The optimal control does depend on time, through changing cooling requirements and ambient conditions. Static optimization techniques applied to a general simulation can be used to determine the optimal supervisory control variables. The simulation could be based on physical or empirical models. However, for control variable optimization, empirical and semi-empirical models are often used where variables are estimated from measurements. This section presents a framework for determining optimal control and a simplified approach for estimating control laws for cooling plants.

General Static Optimization Problem

Figure 35 depicts the general nature of the static optimization problem for a system of interconnected components. Each component in a system is represented as a separate set of mathematical relationships organized into a computer model. Its output variables and operating cost are functions of parameter, input, output, uncontrolled, and controlled variables. The structure of the complete set of equations to be solved for the entire system is dictated by the manner in which the components are interconnected.

The problem is formally stated as the minimization of the sum of the operating costs of each component $J_i$ with respect to all discrete and continuous controls or

Minimize $J(f, M, u) = \sum_{i=1}^{n} J_i(x_i, y_i, f_i, M_i, u_i)$ \hspace{1cm} (39)

with respect to $M$ and $u$, subject to equality constraints of the form

$g(f, M, u) = \begin{bmatrix} g_1(f_1, M_1, u_1, x_1, y_1) \\ g_2(f_2, M_2, u_2, x_2, y_2) \\ \vdots \\ g_n(f_n, M_n, u_n, x_n, y_n) \end{bmatrix} = 0 \hspace{1cm} (40)$

and inequality constraints of the form

$h(f, M, u) = \begin{bmatrix} h_1(f_1, M_1, u_1, x_1, y_1) \\ h_2(f_2, M_2, u_2, x_2, y_2) \\ \vdots \\ h_n(f_n, M_n, u_n, x_n, y_n) \end{bmatrix} \geq 0 \hspace{1cm} (41)$

where, for any component $i$,

$x_i =$ vector of input stream variables

$y_i =$ vector of output stream variables

$f_i =$ vector of uncontrolled variables

$M_i =$ vector of discrete control variables

$u_i =$ vector of continuous control variables

$J_i =$ operating cost

$g_i =$ vector of equality constraints

$h_i =$ vector of inequality constraints

Typical input and output stream variables for thermal systems are temperature and mass flow rate. The uncontrolled variables are measurable quantities that may not be controlled, but that affect the component outputs and/or costs, such as ambient dry-bulb and wet-bulb temperature.

Both equality and inequality constraints arise in the optimization of chilled water systems. One example of an equality constraint that arises when two or more chillers are in operation is that the sum of their loads must equal the total load. The simplest type of inequality constraint is a bound on a control variable. For example, lower and upper limits are necessary for the chilled water set temperature, in order to avoid freezing in the evaporator and to provide adequate dehumidification for the zones. Any equality constraint may be rewritten in the form of Equation (40) such that when it is satisfied, the constraint equation is equal to zero. Similarly, inequality constraints may be expressed as Equation (41) so that the constraint equation is greater than or equal to zero to avoid violation.
Braun (1988) and Braun et al. (1989b) presented a component-based non-linear optimization and simulation tool and used it to investigate optimal performance. Each component is represented as a separate subroutine with its own parameters, controls, inputs, and outputs. The optimization problem is solved in an efficient manner by using second-order representations for costs that arise from curve-fits or Taylor series approximations. Application of the component-based optimization led to many guidelines for control and a simplified system-based optimization methodology. In particular, the results showed that optimal set points could be correlated as a linear function of load and ambient wet-bulb temperature.

Cumali (1988, 1994) presented a method for real-time global optimization of HVAC systems including the central plant and associated piping and duct networks. The method uses a building load model for the zones based on a coupled weighting factor method similar to that used in DOE-2. Variable time steps are used to predict loads over a five to fifteen minute period. The models are based on thermodynamic, heat transfer, and fluid mechanics fundamentals and are calibrated to match the actual performance using data obtained from the building and plant. Pipe and duct networks are represented as incidence and circuit matrices, and both dynamic and static losses are included. The coupling of the fluid energy transfers with the zone loads is done via custom weighting factors calibrated for each zone. The resulting equations are grouped to represent feasible equipment allocations for each range of building loads, and solved using a non-linear solver. The objective function is the cost of delivering or removing energy to meet the loads, and is constrained by the comfort criteria for each zone. The objective function is minimized using the reduced gradient method, subject to constraints on comfort and equipment operation. The optimization starts with the feasible points as determined by a nonlinear equation solver for each combination of equipment allocation. The values of the set points that minimize the objective function are determined; the allocation with the least cost is the desired operation mode. The results obtained from this approach have been applied to high-rise office buildings in San Francisco with central plants, VAV, dual duct, and induction systems. Electrical demand reductions of 8 to 12% and energy savings of 18 to 23% were achieved.

Simplified System-Based Optimization Approach

The component-based optimization method presented by Braun et al. (1989b) was used to develop a simpler method for determining the optimal control. The method involves correlating overall cooling plant power consumption using a quadratic functional form. Minimization of this function leads to linear control laws for control variables in terms of the uncontrolled variables. The technique may be used to tune parameters of the cooling tower and chilled water reset strategies presented in the major section on Supervisory Control Strategies and Tools. It may also be used to define strategies for supply air temperature reset for VAV systems and flow control for variable-speed condenser water pumps.

In the vicinity of any optimal control point, the plant power consumption may be approximated as a quadratic function of the continuous control variables for each of the operating modes (i.e., discrete control mode). A quadratic function also correlates power consumption in terms of the uncontrolled variables (i.e., load, ambient temperature) over a wide range of conditions. This leads to the following general functional relationship between overall cooling plant power and the controlled and uncontrolled variables:

\[ J(f, M, u) = u^T A u + b^T u + F^T C f + d^T f + E^T u + g \]  (42)

where \( J \) is the total plant power, \( u \) is a vector of continuous and free control variables, \( f \) is a vector of uncontrolled variables, \( M \) is a vector of discrete control variables, and the superscript \( T \) designates the transpose vector. \( A, C, \) and \( E \) are coefficient matrices, \( b \) and \( d \) are coefficient vectors, and \( g \) is a scalar. The empirical coefficients of the above function depend on the operating modes so that these constants must be determined for each feasible combination of discrete control modes.

A solution for the optimal control vector that minimizes the power may be determined analytically by applying the first-order condition for a minimum. Equating the Jacobian of Equation (42) with respect to the control vector to zero and solving for the optimal control set points gives

\[ u^* = k + Kf \]  (43)

where

\[ k = -A^{-1}b/2 \]  (44)

\[ K = -A^{-1}E/2 \]  (45)

The cost associated with the unconstrained control of Equation (43) is:

\[ J^* = f^T \theta f + c^T f + \tau \]  (46)

where

\[ \theta = K^T A k + EK + c \]  (47)

\[ \sigma = 2K^T A k + Kb + Ek + d \]  (48)

\[ \tau = K^T A k + b^T k + g \]  (49)

The control defined by Equation (43) results in a minimum power consumption if \( A \) is positive definite. If this condition holds and if the system power consumption is adequately correlated with Equation (42), then Equation (43) dictates that the optimal continuous, free control variables vary as a nearly linear function of the uncontrolled variables. However, a different linear relationship applies to each feasible combination of discrete control modes. The minimum cost associated with each mode combination must be computed from Equation (46) and compared in order to identify the minimum.

Uncontrolled Variables. As discussed in the background section, optimal control variables primary depend on ambient wet-bulb temperature and total chilled water load. The load affects the heat transfer requirements for all heat exchangers, whereas the wet-bulb temperature impacts chilled and condenser water temperatures necessary to achieve a given heat transfer rate. As discussed in the section on Supervisory Control Strategies and Tools, cooling coil heat transfer depends on the coil entering wet-bulb temperature. However, this reduces to an ambient wet-bulb temperature dependence for a given ventilation mode (e.g., minimum outside air or economizer) and fixed zone conditions. Thus, separate cost functions are necessary for each ventilation mode with load and ambient wet-bulb as uncontrolled variables. Alternatively, for a specified ventilation strategy (e.g., the economizer strategy from the section on Supervisory Control Strategies and Tools), three uncontrolled variables could be used for all ventilation modes: load, ambient wet-bulb temperature, and average cooling coil inlet wet-bulb temperature.

Additional uncontrolled variables that could be important if varied over a wide range are the individual zone latent-to-sensible load ratios and the ratios of individual sensible zone loads to the total sensible loads for all zones. However, these variables are difficult to determine from measurements and are of secondary importance.

Free Control Variables. The number of independent or "free" control variables in the optimization can be reduced significantly by using the material developed in the section on Supervisory Control Strategies and Tools. For instance, the optimal static pressure set point for a VAV system should keep at least one VAV box fully open and should not be considered as a free optimization variable. Similarly, the supply air temperature for a CAV system should be set to minimize reheat. Additional near-optimal guidelines were presented for sequencing of cooling tower fans, sequencing of chillers,
loading of chillers, reset of pressure differential set point for variable-speed pumping, and chilled water reset with fixed-speed pumping. Furthermore, Braun et al. (1989a) showed that using identical supply air set points for multiple air handlers gives near optimal results for VAV systems.

For all variable-speed auxiliary equipment (i.e., pumps and fans), the free set point variables to use in Equation (42) could be reduced to the following: (1) supply air set temperature, (2) chilled water set temperature, (3) tower air flow relative to design capacity, and (4) condenser water flow relative to design capacity. All of the other continuous supervisory control variables are dependent upon these variables with the simplified strategies presented in the section on Supervisory Control Strategies and Tools.

Some of the dependent control variables may be discrete control variables. For instance, variable flow pumping may be implemented with multiple fixed and variable-speed pumps where the number of operating pumps is a discrete variable that will change when a variable-speed pump reaches its capacity. These discrete changes could lead to discrete changes in the costs due to changes in overall pump efficiency. However, this has a relatively small effect on the overall power consumption and may be neglected in fitting the overall cost function to changes in the control variables.

Some of the discrete control variables may also be independent variables. In general, different cost functions arise for all operating modes consisting of each possible combination of discrete control variables. With all variable-speed pumps and fans, the only significant discrete control variable is the number of operating chillers. Then, the optimization involves determining optimal values of only four continuous control variables for each of the feasible chiller modes. A chiller mode defines which of the available chillers are to be online. The chiller mode giving the minimum overall power consumption represents the optimum. For a chiller mode to be feasible, the specified chillers must operate safely within their capacity and surge limits. In practice, abrupt changes in the chiller modes should also be avoided. Large chillers should not be cycled on or off except when the savings associated with the change is significant.

Using fixed-speed equipment reduces the number of free continuous control variables. For instance supply air temperature would be removed as a control variable for CAV systems and chilled water temperature would not be included for fixed-speed chilled water pumping. However, for multiple chilled water pumps not dedicated to chillers, the number of operating pumps could become a free discrete control variable. Similarly, for multiple fixed-speed cooling tower fans and condenser water pumps, each of the discrete combinations could be considered as separate modes. However, for multiple cooling tower cells with multiple fan speeds, the number of possible combinations may be large. A simpler approach that works satisfactorily is to treat the relative flows as continuous control variables. For instance supply air temperature would be removed as a control variable for CAV systems and chilled water temperature, (2) chilled water reset with fixed-speed pumping. However, for multiple chilled water pumps not dedicated to chillers, the number of operating pumps could become a free discrete control variable. Similarly, for multiple fixed-speed cooling tower fans and condenser water pumps, each of the discrete combinations could be considered as separate modes. However, for multiple cooling tower cells with multiple fan speeds, the number of possible combinations may be large. A simpler approach that works satisfactorily is to treat the relative flows as continuous control variables. For instance supply air temperature would be removed as a control variable for CAV systems and chilled water temperature, (2) chilled water reset with fixed-speed pumping. However, for multiple chilled water pumps not dedicated to chillers, the number of operating pumps could become a free discrete control variable. Similarly, for multiple fixed-speed cooling tower fans and condenser water pumps, each of the discrete combinations could be considered as separate modes. However, for multiple cooling tower cells with multiple fan speeds, the number of possible combinations may be large. A simpler approach that works satisfactorily is to treat the relative flows as continuous control variables. cells with two-speed fans and the three condenser pumps were treated as continuous control variables. The optimal control determined by the near optimal Equation (43) also agreed well with that determined using a nonlinear optimization applied to a detailed simulation of the system.

In subsequent work, Braun et al. (1989b) considered complete system simulations (cooling plant and air handlers) to evaluate the performance of the quadratic, system-based approach. A number of different system characteristics were considered. Figures 17, 22, 36, and 53 show comparisons between the controls as determined with the component-based and system-based methods for a range of loads, for a relatively low and high ambient wet-bulb temperature (16°C and 27°C).

In Figures 22 and 36, optimal values of the chilled water and supply air temperatures are compared for a system with variable air and water flow. The near-optimal control equation provides a good fit to the optimization results for all conditions considered. The chilled water temperature was constrained between 3°C and 13°C, while the supply air set point was allowed to float freely. Figures 22 and 36 show that for the conditions where the chilled water temperature is constrained, the optimal supply air temperature is also nearly bounded at a value that depends upon the ambient wet bulb.

Optimal relative cooling tower air and condenser water flow rates are compared in Figures 17 and 57 for a system with variable-speed cooling tower fans and condenser water pumps. Although the optimal controls are not exactly linear functions of the load, the linear control equation provides an adequate fit. The differences in these controls result in insignificant differences in overall power consumption, because, as discussed in the background section, the optimum is extremely flat with respect to these variables. The non-linearity of the condenser loop controls is partly due to the constraints imposed upon the chilled water set temperature. However, this effect is not very significant. Figures 17 and 57 also suggest that the optimal condenser loop control is not very sensitive to the ambient wet-bulb temperature.

**DYNAMIC OPTIMIZATION**

Cool storage is often used in commercial cooling applications as a means of shifting cooling requirements from periods of on-peak or high electrical costs to off-peak periods. Cool storage may be implemented using ice, water, or the building structure. In any case, the optimal supervisory control for storage is a complex function of such factors as utility rates, load profile, chiller characteristics, storage characteristics, and weather. For a utility rate structure that includes both time-of-use energy and demand charges, the optimal strategy can depend on variables that extend over a monthly time scale. The overall problem of minimizing the utility cost over a billing period (e.g., a month) can be mathematically described as follows:

Minimize

\[
J = \sum_{k=1}^{N} \{ E_k P_k \Delta t \} + \max_{1 \leq k \leq N} \{ D_k P_k \} 
\]

with respect to the control variables \((u_1, u_2, \ldots, u_N)\) and subject to the following constraints for each stage \(k\):

\[
u_{\min,k} \leq u_k \leq u_{\max,k}
\]

\[
x_k = f(x_{k-1}, u_{k-1})
\]

\[
x_{\min,k} \leq x_k \leq x_{\max,k}
\]

\[
x_N = x_0
\]

where \(J\) is the utility cost associated with the billing period (e.g., a month); \(\Delta t\) is the stage time interval (typically equal to the time window over which demand charges are levied, e.g., 0.25 h); \(N\) is the number of time stages in a billing period, and for each stage \(k\), \(P\) is the average building electrical power (kW); \(E\) is the energy cost rate or cost per unit of electrical energy ($/kWh); \(D\) is the demand charge rate or cost per peak power rate over the billing period ($/kW); \(u\) is the control variable that regulates the rate of energy removal from or addition to storage over the stage; \(u_{\min,k}\) is the maximum value for \(u\); \(u_{\max,k}\) is the minimum value for \(u\); \(x\) is the state of storage at the end of the stage; \(x_{\max}\) is the maximum admissible state of storage; \(x_{\min}\) is the minimum admissible state of storage; and \(f\) is a state equation that relates the state of storage at stage \(k\) to the previous state and current control.

The first and second terms in Equation (50) are the total cost of energy use and building demand for the billing period. Both the energy and demand cost rates can vary with time, but typically have two values associated with on-peak and off-peak periods. An even more complex cost optimization results if the utility includes ratchet clauses in which the demand charge is the maximum of the monthly peak demand cost and some fraction of the previous monthly peak
demand cost during the cooling season. With real-time pricing, the demand charge, which is the second term in Equation (50), might not exist and the hourly energy rates would vary over time according to the generation costs.

For ice or chilled water storage systems, the control variable could be the rate at which energy is added or removed from storage. In this case, the constraint given by Equation (51) arises from limits that depend on the chiller and storage heat exchanger and can also depend upon the state of storage. For use of building thermal mass, the control variable could be the zone temperature(s) and the constraint of Equation (51) would be associated with comfort consideration or capacity constraints. Different comfort limits would probably apply for occupied and unoccupied periods.

The equality constraint of Equation (52) is termed the state equation. The state of storage at any stage \( k \) is a function of the previous state \( x_{k-1} \), the control \( u_k \), and other time-dependent factors (e.g., ambient temperature). For lumped storage systems (e.g., ice), the state of storage can be characterized with a single state variable. However, for a distributed storage (e.g., a building structure), multiple state equations may be necessary to properly characterize the dynamics. The state of storage is also constrained to be between states associated with full discharge and full charge [Equation (53)]. The constraint of Equation (54) forces a steady-periodic solution to the problem. This constraint becomes less important as the length of analysis increases.

In order to determine a control strategy for charging and discharging storage that minimizes utility cost, Equation (50) must be minimized over the entire billing period because of the influence of the demand charge. Alternatively, the optimization problem can be posed as a series of shorter-term (e.g., daily or weekly) optimizations with a constraint on the peak demand charge according to:

\[
J = \sum_{k=1}^{N} \left( E_k P_k \Delta t \right) + TDC 
\]

with respect to the control variables \( (u_1, u_2, ..., u_N) \) and a billing period demand cost target (TDC) and subject to the constraints of Equations (51) through (54) and the following equation:

\[
D_k P_k \leq TDC 
\]

The constraint expressed in Equation (56) arises from the form of the cost function chosen for Equation (55). At each stage, the demand cost must be less than or equal to the peak demand cost for the billing period. The peak or target demand cost TDC is an optimization variable that affects both energy and demand costs. The advantage of posing the optimization problem using Equation (55) rather than Equation (50) is that it simplifies the numerical solution.

Two types of solutions to the optimization problem are of interest: (1) minimum billing period operating cost and (2) minimum energy cost for a specified target demand cost (TDC) and short-term horizon (e.g., a day). The first problem is useful for benchmarking the best control and minimum cost through simulation, but would not be useful for online control because forecasts beyond a day are unreliable. Mathematical models of the building, equipment, and storage would be used to estimate load requirements, power, and state of storage. The second solution could be used for online control in conjunction with a system model and forecaster.

For minimum operating costs (first optimization problem), \( N + 1 \) variables must be determined to minimize the cost function of Equation (55) over the length of the billing period. For a given value of TDC, the minimization of Equation (55) with respect to the \( N \) charging (and discharging) control variables could be accomplished using dynamic programming (Bellman 1957) or some other direct search method. The primary advantages of dynamic programming are that it handles constraints on both state and control variables in a straightforward manner and may not always be triggered.

For shorter-term optimizations (second optimization problem), dynamic programming could still be used to minimize Equation (55) with respect to the \( N \) charging (and discharging) control variables for a specified TDC. However, an optimal value for TDC cannot be determined when demand charges are imposed. For ice storage, Drees and Braun (1996) found that a simple and near-optimal approach is to set TDC to zero at the beginning of each billing period. Therefore, the optimizer minimizes the demand cost for the first optimization period (e.g., a day) and then uses this demand as the target for the billing period unless it is exceeded. For online optimization, the optimization problem can be resolved at regular intervals (e.g., 1 h) during each day’s operation.

### Ice Storage Control Optimization

Several researchers have studied optimal supervisory control of ice storage systems. Braun (1992) solved daily optimization problems for two limiting cases: minimum energy (i.e., no demand charge) and minimum demand (no energy charge). Results of the optimizations for different days and utility rates were compared with simple chiller-priority and load-limiting control strategies (see the section on Supervisory Control Strategies and Tools). The ice-on-pipe system considered, load-limiting control was found to be near optimal for both energy and demand costs with on-peak to off-peak energy cost ratios greater than about 1.4.

Drees and Braun (1996) solved both daily and monthly optimization problems for a range of systems with internal-melt area-constrained ice storage tanks. The optimization results were used to develop rules that became part of a rule-based, near-optimal controller that is presented in the section on Supervisory Control Strategies and Tools. For a range of partial-storage systems, load profiles, and utility rate structures, the monthly electrical costs for the rule-based control strategy were, on average, within about 3% of the optimal costs.

Henze et al. (1997a) developed a simulation environment which determines the optimal control strategy to minimize the operating cost, including energy and demand charges, over the billing period. A modular cooling plant model was used that includes three compressor types (screw, reciprocating, and centrifugal), three ice storage media (internal melt, external melt, and ice harvester), a water-cooled condenser, central air handler, and all required fans and pumps. The simulation tool was used to compare the performance of chiller-priority, constant-proportion, storage-priority, and optimal control.

Henze et al. (1997b) presented a predictive optimal controller for use with real-time pricing (RTP) structures. For the RTP structure considered, the demand term of Equation (55) disappears and the optimization problem only involves a 24-h period. The controller calculates the optimal control trajectory at each time step (e.g., 30 min), executes the first step of that trajectory, and then repeats that process at the next time step. The controller requires a model of the plant and storage, along with a forecast of the future cooling loads.

In order to apply the optimization approach described in the previous section, models for storage, system power consumption, and building loads are needed. For online optimization, simple empirical models that can be trained using system measurements are appropriate. However, physically based models would be best for simulation studies.
The optimization studies that have been performed for ice storage assumed that the state of storage could be represented with a single state variable. Assuming negligible heat gains from the environment, the relative state of charge (i.e., fraction of the maximum available storage capacity) for any stage \( k \) is

\[
x_k = x_{k-1} + \frac{u_k \Delta t}{C_s}
\]  

where \( C_s \) is the maximum change in internal energy of the storage tank that can occur during a discharge cycle and \( u_k \) is the storage charging rate. The state of charge defined in this manner must be between zero and one.

The charging rate for storage depends on the storage heat exchanger area, secondary fluid flow rate and inlet temperature, and the thickness of ice. At any stage, the maximum charging rate can be expressed as

\[
u_{k, \text{max}} = \varepsilon_{c,k, \text{max}} \cdot \dot{m}_{f,k} \cdot c_f (t_s - t_f)
\]

where \( \varepsilon_{c,k, \text{max}} \) is a heat transfer effectiveness for charging at the current stage of storage if the secondary fluid flow rate were at its maximum value of \( \dot{m}_{f,k, \text{max}} \), \( c_f \) is the secondary fluid specific heat, \( t_f \) is the temperature of secondary fluid inlet to the tank, and \( t_s \) is the temperature at which the storage medium melts or freezes (e.g., 0°C).

The minimum charging rate is actually the negative of the maximum discharging rate and can be given by

\[
u_{k, \text{min}} = -\varepsilon_{d,k, \text{max}} \cdot \dot{m}_{f,k} \cdot c_f (t_s - t_f)
\]

where \( \varepsilon_{d,k, \text{max}} \) is the heat transfer effectiveness for discharging at the current state of storage if the secondary fluid flow rate were at its maximum value of \( \dot{m}_{f,k, \text{max}} \).

In general, the heat transfer effectiveness for charging and discharging at the design flow can be correlated as a function of the ambient wet-bulb temperature and the chiller supply temperature. For simulation studies, a building model would be used to estimate building cooling loads. For online optimization, a forecaster would provide estimates of future building cooling loads.

# Building Commissioning

## Advantages of Building Commissioning

- Enable owner to recognize system capabilities and limitations
- Reduce callbacks and assist in dealing with warranty claims
- Help ensure on-schedule occupancy
- Improve operation and maintenance programs
- Establish continuous monitoring of priorities and schedules
- Improve quality of turnover documents
- Establish coordination plans
- Improve quality of operator personnel training
- Document indoor air quality (IAQ) and comfort control
- Ease building turnover process
- Help ensure on-schedule occupancy
- Reduce callbacks and assist in dealing with warranty claims
- Enable owner to recognize system capabilities and limitations

Owners and design professionals may implement the commissioning process at any stage of a project. However, the commissioning process is most effective when started early.

## Commissioning Team

The size and makeup of the commissioning team depends on the size and complexity of the project and the owner’s desires to invest in quality assurance. The responsibility of each member of the commissioning team is documented in the commissioning plan.

All participants in the construction project have a commissioning responsibility. Participants include the commissioning authority, owner, design professionals, construction manager, general contractor, subcontractors, operation and maintenance manager, suppliers, and equipment manufacturers. The project building operation, production, and maintenance managers need to be brought into the commissioning process early, preferably during the predesign phase. Their knowledge of occupancy, special lighting, anticipated equipment loads, and other factors should influence the design and set performance objectives. Additionally, the early participation of both the TAB and HVAC controls’ contractors is also important because their experience can provide guidance on space requirements, balancing devices, probe and control locations, and accessibility to equipment.

## Commissioning Authority

The commissioning authority is a qualified professional, company, or agency that implements the overall commissioning process in cooperation with the commissioning team as specified in the contract documents. The commissioning authority has a significant role in the project and is responsible for:

- Setting and directing the commissioning work
- Providing coordination and guidance
- Performing the commissioning work
- Issuing the commissioning report

The preparation of this chapter is assigned to TC 9.9, Building Commissioning.
impact on the project and must be able to take responsibility for acting on or verifying the performance aspects of the project. However, the appointment of a commissioning authority does not alter other professional or contractual obligations. The owner should select a qualified commissioning authority who has proven experience and is registered as a professional in a recognized organization.

The commissioning authority should understand all building systems being commissioned. The authority should also be familiar with applicable design and building standards, use of test instruments and equipment for functional testing, and interaction of the various systems. Additional qualifications of the commissioning authority may be found in ASHRAE Guideline 1.

Responsibility. The primary responsibility of the commissioning authority is to inform the owner of the status, integration, and performance of all tested systems in the facility.

Information. The commissioning authority should function as a catalyst and initiator to disseminate information and assist the design and construction teams in verifying satisfactory completion of construction. The authority verifies system completeness, performance, and adequacy to meet intended performance standards. The authority may provide such services as design review, establishing commissioning specifications, construction observation, spot testing, verification, and functional performance testing. Turnover information services may include providing performance and operating information (i.e., operating and maintenance manuals, training) to the responsible parties.

Quality Assurance. The commissioning authority assists all parties in achieving a high level of installation quality and system performance. Through an effective turnover process, the personnel responsible for the facility should be able to maintain that high level of systems performance.

Observation of Tests. The commissioning authority should observe and coordinate testing as required to ensure the performance meets design intent and contract documents.

Documentation of Tests. The commissioning authority should document or witness the results of the performance testing. The authority should provide or approve test forms to be used by representative parties to ensure a consistent format and to specify the type of information to be recorded.

Resolution of Disputes. The commissioning authority should remain an objective party, present on the project, with specific project knowledge. Should disputes arise, the authority should be available to determine the scope and extent of the problem and educate the involved parties as to the nature and extent of the problem. The owner or their designate should preside over resolution of problems as specified in the contract documents.

Deficiencies. The commissioning authority should verify that deficiencies found during the commissioning process are corrected.

Acceptance. The commissioning authority should determine and advise the owner of the date of acceptance for each component and system. Acceptance may extend to representing the owner with warranty start data, substantial completion, certificate of occupancy, assembling or coordinating turnover documents, and scheduling training.

Turnover. The commissioning authority participates in the successful transfer of control of the facility from the construction team to the owner.

Cost Factors

No reliable data are available to determine the cost or cost-contributing factors of building commissioning. The number of cost-contributing factors depends on the size and complexity of the project and the willingness of the owners to invest in the appropriate commissioning process.

A wide range of professional services, comprehensive documentation, system testing, and operator training are available to be included in the scope of commissioning. One intent of commissioning is to fully recover its own capital investment over the life of the system through improved management and owner satisfaction.

Commissioning Objectives

The owner should expect the following results from commissioning:

• Improved operator knowledge as to how building systems should operate or be maintained
• Reduced ongoing training requirements
• Performance in accordance with the owner’s intent and the contract documents
• Well-structured turnover documents (i.e., manuals, as-builds, submittal data, final sequences of operation) that provide easy reference documents for equipment and system operation and maintenance.
• A method that allows operators to continuously update documents
• Reduced downtime due to better diagnosis of failures
• Improved ability to provide accurate information to occupants regarding maintenance of environmental conditions in the occupied space throughout the year
• Lower operating costs due to optimized performance and improved operational techniques
• Increased comfort and reduced complaints due to poor indoor environmental quality

Designers can expect the following advantages:

• All building systems perform in accordance with the owner’s requirements
• Reduced risk exposure because problems are identified earlier
• Improved knowledge for use in future designs and installations
• Benefit of supporting professional input, leading to the most cost-effective design and operation
• Reduced number of interference drawings during construction, due to improved communication and coordination

Contractors can expect the following benefits:

• Clear understanding of the owner’s goals, (i.e. program, design intent)
• Improved coordination through implementation of the commissioning plan
• Improved coordination between different trades and reduced likelihood of site interference drawings required throughout the project
• Well-documented successful system tests, which ease turnover and acceptance
• Reduced number of deficiencies at substantial completion
• Reduced number of callbacks
• Reduced number of calls for operation guidance because operations and maintenance personnel participate in training programs

Program and Predesign Commissioning Phase

Objectives. The objectives of the predesign commissioning phase are to

• Document requirements as specified in the owner’s program
• Select the commissioning authority
• Identify and assign responsibilities
• Document the initial design intent
• Begin development of the commissioning plan

This phase should begin as close to project inception as possible. The information gathered is used to develop the design of the system and establish a method to evaluate its performance.

Owner’s Program. This program outlines the owner’s overall vision for the facility and expectations as to how it will be used and operated. The owner’s program should contain known performance
Building Commissioning

41.3

goals and objectives along with budget constraints, schedules, and other limitations. Typically, the technical aspects of the owner’s program includes use of the facility, user needs, occupancy requirements, type of construction, system functions, as well as energy, air quality, power quality, and environmental performance criteria. The program should define the scope of the commissioning process and the preferred organizational structure. It should contain all requirements needed to develop the initial design intent document. This critical document forms the basis from which all other documentation is developed.

Team Selection. The commissioning authority and the design team should be selected at this time. The operations and maintenance (O&M) personnel should be identified and encouraged to lend their knowledge to ensure that important O&M issues are considered in design and during commissioning.

Commissioning Plan. This document or group of documents defines the commissioning process or schedule at the various stages of project development. It continually evolves and is updated as the design and construction of the building progresses.

As the design concepts evolve from the initial design intent document, a preliminary commissioning plan is developed that outlines the process required to commission the building systems. This plan should develop the extent of the commissioning process and communicate it to all project participants. It must include the scope of the process, the time required for completion, and an organizational chart indicating reporting relationships. The scope and potential cost as outlined in the preliminary commissioning plan then should be evaluated and approved.

The roles and responsibilities of each project participant with respect to commissioning are identified in the preliminary commissioning plan. This plan should recognize the owner, commissioning authority, design professional(s), operation and maintenance staff, contractors, vendors, and other specialists as appropriate. The team may be expanded or modified as the project progresses.

Systems Manual. Material for the systems manual should begin to be compiled. The manual provides the information needed to understand, operate, and maintain each system. In this phase, the manual will contain a statement that conveys the required functional operation in all normal and emergency modes of operation. The initial design intent document shall be included in the systems manual, which is updated through all phases of the project.

Design Commissioning Phase

Objectives. The design phase of the commissioning process begins with preparation of schematic design documents. This phase has the following objectives:

• Ensure that clear design intent documents are developed
• Develop or refine commissioning plan and specifications
• Prepare contract documents that clearly identify, describe, and fulfill the design intent
• Review and accept contract documents for compliance with design intent
• Coordinate all building systems with the HVAC equipment and systems

Documentation of Design Intent. Changes to the initial design intent occurring during the design phase should be documented, reviewed, and approved. The revised design intent document should become part of the contract documents and will be represented in the updated systems manual.

Design Intent Documents. The developing of clear design intent documents is a critical aspect of commissioning. The initial design intent document is a detailed explanation of the information developed in the owner’s program. This document should describe the facility’s functional needs, intended levels and quality of environmental control, environmental needs, and schedules.

When approved, the design intent document should be used as the starting point for the development of the contract documents and referred to in case of ambiguities or uncertainties about project design. Changes to the design intent occurring during the course of the project should be documented, reviewed, and approved. The design intent document may be included in the contract documents as a reference. The final design intent document becomes part of the systems manual.

Conceptual designs for HVAC systems and other building systems should be prepared to provide options to the owner that meet the owner’s program.

The design intent is updated and defines design assumptions, building energy performance, performance standards of the proposed systems, the most appropriate conceptual approach, space requirements, zoning, and other requirements that affect building use and aesthetics.

Basis of Design. The basis of design should respond to and be consistent with performance criteria specified in the owner’s program. The basis of design includes the requirements for each occupancy, activity, and/or physical area of the proposed facility. The basis should reference ASHRAE or other applicable standards, local building codes, and environmental quality objectives.

Because the design intent may be revised and changes may be accepted as design concepts, the basis of design should be reviewed with regard to these changes and updated as needed. The final versions of the design intent document and its reference to the basis of design should be included in the contract documents.

Commissioning Plan. During the design phase, the approved preliminary commissioning plan may expand the planned activities for all participants relative to the commissioning process. Updated information includes work roles and responsibilities, project organization chart, and scheduling of the process. The plan identifies which systems, system components, and functions will be tested on this project. This document also sets the scope for the testing specification.

Observations of the progress of construction are important for updating the commissioning plan, particularly with respect to the scheduling of activities. In addition to construction requirements, observations should be conducted to ensure compliance with manufacturers’ installation instructions.

Commissioning Specification. The building systems commissioning specification is part of the project specification. This specification is required to contractually implement the post-design phases of the process. The commissioning specification is a detailed description of the scope and objective of commissioning during the construction, acceptance, and post-acceptance phases of a project. It must specify the scope of work, roles, responsibilities, and requirements of each commissioning team member, and their lines of authority. This specification is needed by contractors so that they can include in their bid the support required by commissioning, which includes meetings, training, testing, etc.

The commissioning specification should detail testing requirements, acceptance phase procedures for verification, functional performance testing acceptance criteria, and any other required acceptance phase procedures. It should include a list of equipment and systems to be evaluated, along with checklist formats and sample test forms.

The scope of work in the specification should identify the required skills and qualifications of the commissioning team, including operation and maintenance personnel. It should include a section for each trade involved in the construction of the building, detailing their scope of work in the commissioning process. Management of turnover documents and training must be specified.

Contract Documents. These documents should clearly reveal, describe, and fulfill the requirements specified in the design intent documents.

Design Intent Compliance. The contract documents should be reviewed to ensure consistency and that they correctly represent the
current design intent document. Results are reported to the owner. The contract documents then should be accepted or rejected by the owner or the owner’s designee.

System Coordination. Part of the review of drawings includes verifying system coordination. All other specified building systems including other mechanical, electrical, fire-safety, and life-safety service requirements, should be coordinated with the HVAC equipment and systems.

Construction Commissioning Phase

Objectives. During the construction phase, all systems are installed, started, and operated. This phase includes the following objectives:

- Review submittals
- Finalize details of the commissioning plan
- Conduct periodic commissioning team meetings
- Maintain documentation of all tests, observations and issues, verify system installation
- Verify equipment/system start-up and operation
- Verify performance of temperature and building management controls
- Verify testing, adjusting, and balancing (TAB) work
- Coordinate as-built drawings
- Manage assembly, indexing, and turnover of all documents
- Coordinate O&M training

During installation, O&M personnel should observe and monitor the systems and testing. Through this procedure, they should develop a better understanding of the intended operation and performance and become familiar with the location of equipment and devices, including those that may be hidden when construction is complete.

Procedures. During the construction phase, the following activities are part of commissioning:

- Review submittals for performance parameters
- Detail the commissioning plan
- Create project-specific test procedures and checklists needed to supplement the specified tests
- Make necessary observations and inspections
- Manage documentation of all tests/observations including turnover documents
- Report progress and deficiencies to all parties involved
- Coordinate training of operations and maintenance personnel

The updated operation description should be included as part of the systems manual. This description should be updated and combined with equipment data, including performance data, for training of and subsequent use by the operations and maintenance staff.

Regularly scheduled meetings of the entire project team should be held to communicate issues to all concerned, resolve conflicts, report on the progress of the commissioning process, identify urgent work, and identify and resolve deficiencies. This site coordination is critical to ensure a quality commissioning process.

Testing and calibration of controls should begin concurrent with and be completed prior to the completion of the TAB work. Specified TAB work must be performed prior to acceptance procedures. Prior to functional performance testing, operational tests should be conducted on equipment, duct, pipe, and control systems to verify that pressures, flow rates, and control functions meet design requirements. The training program for operations and maintenance personnel should be coordinated with the appropriate participants.

Submittals. Submittals should be reviewed prior to systems installation. Submittals include shop drawings, equipment submittals, and testing and balancing procedures and forms. Submittals should also include test procedures, report forms, data sheets, and checklists that will be used in the functional performance testing.

1999 ASHRAE Applications Handbook (SI)

Equipment submittals should include full and part-load performance data covering the entire operating range for each piece of equipment. The equipment operations and maintenance information (including parts lists, installation instructions, and special tool needs) should be submitted in accordance with specification requirements and reviewed for completeness, clarity, and accessibility. Commissioning submittal review is intended to verify correct information on test documents. It does not supersede or supplant design commissioning review.

Commissioning Plan. The commissioning plan should be updated to define the on-site activities required for implementing the commissioning specifications. This plan must be project specific and reflect the actual equipment that will be installed. The commissioning plan should

- Define each party’s role in the inspections, verification, testing and training
- Detail the schedule of inspections during construction
- Develop the schedule for verification and functional performance tests
- Define the process for reporting and correcting any deficiencies identified
- Detail any training sessions for operations and maintenance personnel that are to take place during this phase

Documentation. All commissioning activities that occur during the construction phase should be documented. The equipment and control sequence documentation developed during the design phase should be updated to match the equipment supplied on the project.

Acceptance Commissioning Phase

Objectives. During the acceptance phase, verification, functional performance tests, and other acceptance procedures take place. The objectives of the acceptance commissioning phase are to

- Verify accuracy of final TAB report
- Verify and document that all systems comply with the contract documents
- Verify functional performance testing of all systems
- Establish an as-delivered performance record for all systems
- Verify completion of the as-built records
- Conduct operations and maintenance personnel training
- Complete the final commissioning report
- Complete the systems manual
- Turnover all documents
- Complete the owner training program

Verification. Verification comprises a full range of checks and tests to determine that all components, equipment, systems, and interfaces between systems operate in accordance with contract documents. All operating modes, all interlocks, all control responses, and all specified responses to abnormal or emergency conditions are tested and verified. Operating modes, etc. can be verified concurrently with a physical point check of controllers and sensors. Verification also validates the TAB report. Each contractor may have some responsibility in verification.

Functional performance testing demonstrates the performance of systems. Documentation should include performance data for all equipment and systems. Operations and maintenance personnel should be made available to observe verification and functional performance tests. Conflicts and deficiencies identified during the acceptance phase should be addressed and resolved to the owner’s satisfaction.

At the end of the acceptance procedures, all systems will have been documented as proving operational performance in accordance with the contract documents. This includes both normal operation modes and abnormal or emergency conditions. Before functional performance testing can start, the following should be observed and documented:
Building Commissioning

- Systems and associated subsystems have been completed, calibrated, and started up and are believed to be operating in accordance with contract documents.
- Control systems have been completed and calibrated and are believed to be operating in accordance with contract documents.
- Testing, adjusting, and balancing procedures have been completed, and TAB reports have been submitted and reviewed and discrepancies corrected and accepted.

A statement should be issued certifying that work has been completed and equipment and systems are operational in accordance with the contract documents.

**Deficiencies.** Deficiencies that are identified in the building systems or when interfacing with other building systems during verification must be documented and reported to the commissioning team. A decision must be made whether to remedy the situation and if reverification is required.

A certificate of readiness should be issued stating that the specified equipment, systems, and controls are complete and ready for functional performance testing. This certificate should be supported by completed prestart/start-up checklists (signed by the responsible parties) and the verification report.

**Functional Performance Testing.** This testing should progress from testing the individual components within central equipment and systems, to testing the systems that distribute services throughout the building. The extent of these tests, as well as details of the services to be tested, are in accordance with the commissioning specifications.

In each of the individual spaces to be tested, the parties performing the functional performance tests may be required to make temporary modifications to control functions or provide supplementary internal loads to simulate desired load conditions up to design load conditions.

Functional performance testing of the major heat exchange components may be done at less than full-load capacity of the equipment using part-load performance curves provided by the manufacturer for comparison. However, deferred seasonal testing may be required to verify performance at near design conditions.

As each individual check or test is accomplished, physical responses of the system should be observed and compared to the specified requirements in order to verify the test results. Ideally, only actual physical responses of components are observed. Reliance on control signals or other indirect indicators is not adequate unless previously validated. The input and output signals for each control component also need to be observed to confirm that they are correct for each physical condition.

The specific tests required and the order of testing will vary depending on the type and size of system, number of systems, sequence of construction, relationship between building systems, and specific owner/tenant program requirements.

During functional performance testing, a failure in performance of a part of the system or of a component may be revealed. Any performance deficiencies must be evaluated to determine the cause and whether they are part of the contractual obligations. After corrective measures are completed, the functional performance test that failed may be repeated.

**Functional Performance Test Procedures.** Testing should be performed as defined in the commissioning specification and detailed in the contract documents. If any test cannot be completed because of a deficiency outside the scope of the system, the deficiency should be documented and reported to the owner. Deficiencies should then be resolved and corrected by appropriate parties and the functional performance tests rescheduled.

If the commissioning specification indicates that specific seasonal testing is to be conducted, the appropriate initial performance tests should be completed and documented and the additional tests scheduled. The parties responsible for the seasonal tests should return to the site to complete and document the tests as scheduled. This scheduling is represented in the commissioning plan.

**Test Reporting Requirements.** All measured data, data sheets, and a comprehensive summary describing the operation of the systems at the time of the test should be submitted to the commissioning authority or the owner’s representative. Sample functional performance test reports should be included in the commissioning specifications. Deviations from these contract documents or design intent should be resubmitted and approved, with a description included.

Systems constructed in accordance with contract documents but having performance deficiencies not covered in these documents force a decision as to whether modifications should be implemented to bring the performance up to the design intent criteria or if the test results should be accepted as submitted. If corrective work is performed, a decision must be made as to whether part or all of the functional performance testing should be repeated and a revised report submitted.

After the performance of all systems is evaluated, the results of the evaluation are included in the final commissioning report.

**Verification Report.** The final tabulated checklist data sheets should be assembled in a verification report and submitted to designated parties on the commissioning team for review. The verification report documents any unresolved deficiencies and may suggest a method of correction. The responsible party should determine if verification is complete and whether building systems are functioning in accordance with the contract documents.

**Documentation.** Documentation procedures during the acceptance phase include executing verification and functional performance tests forms, completing and assembling the final turnover records, and developing the final commissioning report. The commissioning documentation consists of the following:

- Verification checklist data sheets
- Functional performance test data records
- Final commissioning report, (including a summary of all issues resolved and unresolved)
- As-built drawings and other records
- Final updated operations manuals and maintenance manuals
- Systems manual (system operation description and final design intent)
- Training documents (may include videotapes)

**Final Acceptance.** For final acceptance, all documents should be turned over to the owner, the final commissioning report should be completed and submitted, and recommendation for acceptance of the facility determined. Some acceptance procedures (such as off-season tests) may not have yet been completed, but this should not impede final acceptance.

The final commissioning report should indicate if the systems have been completed in accordance with the contract documents and if the systems are performing in accordance with the final design intent document. The report should identify and discuss any substitutions, compromises, or variances between the final design intent, contract documents, and as-built conditions. This report should be used to evaluate the system and serve as a future reference document during operation of the systems. It should describe components and performance that exceed design intent and those that do not meet design intent. The report may make recommendations for resolution.

**Operations and Maintenance Training Program**

The objective of the O&M training program is to provide qualified technicians with the knowledge to operate and maintain building systems in accordance with design intent, manufacturers’ recommendations, and procedures contained in the systems manual. The program should be detailed such that it can be repeated for new and replacement personnel. Thorough documentation must be

supplied for future training activities. Videotaped training sessions may also be used to assist with future training.

The training program should be implemented as defined in the commissioning plan. Training should be performed by parties with specific expertise in each aspect of the building’s systems.

**Scope of Training.** The training program should furnish a thorough understanding of all equipment, components, systems, and their operation, including appropriate how-to skills. Training should include the following topics:

- Use of the systems manual with an emphasis on
  - Design intent
  - Description, capabilities, and limitations of the systems
  - Operation procedures for all modes of operation
  - Acceptable tolerances for adjustments in all operating modes
  - Procedures for dealing with abnormal conditions and emergency situations for which there is a specified response
  - Use of operation manuals
  - Use of maintenance manuals
- Recommended procedures for collecting and interpreting specific performance data
- Specialized manufacturers’ training programs

**Goal of Training.** The goal of training is to understand system performance and the general theory of operation. This level of understanding should typically include the following:

- Theory of operation on
  - Basic concepts of all pertinent systems
  - Energy efficiency
  - Indoor air quality
  - Occupancy comfort
  - Occupied versus unoccupied or partial occupancy
  - Seasonal modes of operation
  - Emergency conditions and procedures
- System operating procedures
- Operating parameters (i.e., setpoints, performance goals)
- Use of the control system, including
  - Sequence of operation
  - Problem indicators
  - Diagnostics
  - Corrective actions
- Use of reports and logs
- Service, maintenance, diagnostics, and repair

**Post-Acceptance Commissioning**

Post-acceptance commissioning is the continued adjustment, optimization, and modification of building systems to meet specified requirements. It may be used on existing buildings or even on a facility that has previously been commissioned. It includes updating documentation to reflect minor setpoint adjustment, maintenance and calibration, major modifications, and provision for ongoing training of operations and maintenance personnel.

The objective of post-acceptance commissioning is to maintain the performance throughout the useful life of the facility in accordance with the current design intent. The extent of post-acceptance commissioning is determined by the scope of modifications and occupancy changes that are made to the facility.

Post-acceptance commissioning starts from the base of existing documents. This documentation includes all available original commissioning documents plus any updates from the commissioning of previous modifications.

**Post-Acceptance Commissioning Procedures.** The three identifiable levels of post-acceptance commissioning are as follows:

- Ongoing commissioning activities
- Minor changes or modifications to systems and changes to occupancy and/or layout
- Major modifications to the facility’s layout and/or systems

Major modifications will impact overall system characteristics or performance through significant changes in design or central system capacities. Minor modifications do not anticipate such impacts; they will likely impact individual zones or rooms only.

**Minor modifications** require, as a minimum, the following:

- Revision of as-built records, such as the final design intent document, systems manual, operations manuals, maintenance manuals, and reports
- Testing, adjusting, and balancing of affected systems or sections
- Training on operations and maintenance procedures that are affected by the modifications

**Major modifications** require the same efforts, expanded to suit full commissioning of any system or subsystem impacted by modifications. Overall performance must be reestablished. When major modifications are carried out, normal commissioning procedures should be undertaken. For each level of modification, the impact of planned alterations must be reviewed to ensure that a comfortable environment and air quality standards for the occupied portions of the facility are maintained.

Ongoing commissioning activities strive to sustain a specific level of performance and documentation. Proper maintenance programs, training, and familiarization of the systems by the new operating staff are important to the support of the commissioning process. For example, a standard method of recording and responding to complaints should be in place and used consistently.

As equipment and controls are replaced through the maintenance program, calibration and performance should be checked, documents revised, and any changes or new equipment data sheets included in the systems manual.

Systems are periodically retested to measure and document their actual performance. Functional performance test (FPT) checklists used in the acceptance phase and subsequent activities should be a guide for retesting. Discrepancies between predicted performance and actual performance and/or an analysis of the complaints received may indicate a need to re-evaluate the current design intent or to consider returning to the program phase of commissioning.

Ongoing training includes refresher training of existing personnel, training of new personnel, and training of all personnel on newly installed equipment or revised operating procedures. It should be consistent with the training provided by the original commissioning process.

**Documentation.** Documentation is similar in scope to the requirements outlined for new construction commissioning. Where documents exist they need to be maintained or updated. Regardless of the form, nature, and scope of commissioning, all records (drawings, manuals, etc.) must be catalogued and well referenced.
CHAPTER 42

BUILDING ENVELOPES

Residential Foundations ............................................................... 42.1
Residential Walls ................................................................. 42.2
Residential Roof and Ceiling Assemblies ................................. 42.3
Fenestration ........................................................................ 42.4

THE BUILDING envelope comprises the outer elements of a building, including the foundation, walls, roof, windows, doors, and floors. This chapter describes the nature, functions, and performance of the building envelope. It concentrates on the interaction between the components of the building envelope and on the effects on the interior environment of a building. Understanding this interdependence is essential to executing a reliable building envelope.

The prime functions of the building envelope are to provide

• Shelter for occupants
• Strength and rigidity
• Stability and durability
• Control of heat, air, and moisture vapor flows
• Control of liquid water movement
• Indoor air quality control
• Fire resistance
• Cost-effectiveness
• Acoustical performance
• Aesthetic considerations
• Security

In buildings with a large ratio of volume to exterior surface area, the internal heat sources may be larger than gains or losses through the envelope. The effect of the envelope becomes increasingly important as the ratio decreases. In single-family dwellings, heat transfer through the envelope is the dominant factor in determining the overall heating and cooling loads. However, local control (e.g., in business offices) may depend on the ability of glazing to control heat gain or loss.

RESIDENTIAL FOUNDATIONS

Good foundation design entails not only structural soundness and good insulation, but also appropriate moisture, termite, and radon control. In North America, several building energy codes recommend foundation insulation in climates with more than 1,400 heating Kelvin-days (base 18°C). An uninsulated, conditioned basement may lose up to 50% of the heat in a tightly sealed house that is well insulated above grade.

Although saving energy is an important incentive, insulating basement foundations also creates a more comfortable, livable space at a relatively low cost. Raising basement temperatures reduces condensation, minimizes problems with mold and mildew, and helps maintain acceptable indoor air quality.

Construction

The three basic types of foundations are basement, crawl space, and slab-on-grade. Each uses specific insulation techniques. The cost of higher insulation levels must be compared with the savings. The comparison can be made in several ways, but a life-cycle cost analysis is the best method (Carmody et al. 1991). It takes into account a number of economic variables, including installation costs, mortgage rates, HVAC efficiencies, and energy costs.

The preparation of this chapter is assigned to TC 4.4, Building Materials and Building Envelope Performance.

Conditioned Basements. A concrete or masonry basement wall may be insulated by (1) insulating the exterior upper half, (2) insulating the entire exterior wall, or (3) insulating the entire interior wall.

Unconditioned Foundation Spaces. Unconditioned basements may be insulated in the same way as conditioned basements, or they may be insulated by placing insulation between or below the floor joists in the ceiling. The latter approach separates the basement thermally from the above-grade space and results in lower basement temperatures in winter, usually making it necessary to insulate exposed ducts and pipes.

A crawl space can be designed as a short basement (with a floor). Because the floor is above grade, it is less subject to moisture hazards than a slab floor. However, if moisture problems occur, they are more likely to be noticed in a basement because it is more accessible than a crawl space.

While most codes require operable louvered vents (670 mm² per square metre) near each corner of a crawl space, research has shown that a moisture-retardant ground cover is more effective and, in most locations, eliminates the need for vents (ASHRAE 1994).

Crawl Space Insulation. In a vented crawl space, insulation is placed between the floor joists. In an unvented crawl space, either the concrete or masonry walls or the floor above can be insulated. If the walls are insulated, air infiltration paths such as the interface between the crawl space wall and the bottom plate of the floor above must be sealed. Intersections of two hard surfaces are common air infiltration paths. Walls may be insulated by (1) insulating the entire exterior wall, (2) insulating the entire interior wall, or (3) insulating the entire interior wall and the perimeter of the crawl space floor to a depth of 600 mm. When the floor is insulated, an appropriate ground cover must be installed to control moisture in the crawl space; moisture degrades the thermal performance of insulation. In pressure-treated wood construction, insulation is placed in the cavities between the wood studs.

Vented Versus Unvented Crawl Spaces. The disadvantages of a vented crawl space are that (1) pipes and ducts must be insulated; (2) a larger area must be insulated (the floor area is greater than the wall area), which may increase the cost; and (3) in some climates, circulation of warm, humid outside air in the crawl space can cause the wood structure to have an excessive moisture content. Another advantage to designing crawl spaces as unvented, semiconditioned zones is that insulating the foundation at the perimeter instead of the floor above simplifies installation and minimizes condensation. On the other hand, venting can complement other moisture and radon control measures, such as ground covers and proper drainage.

While increased airflow can dilute ground source moisture and radon, it may not eliminate them. Venting crawl spaces may be desirable in areas of high radon hazard, but it should not be considered a reliable radon mitigation strategy. Pressurizing the crawl space is an effective method of minimizing soil gas uptake; however, the crawl space walls and ceiling must be tightly constructed for this approach to be effective. Vented crawl spaces are often provided with operable vents that can be closed to reduce winter heat losses (closing them may, however, increase radon levels). Also,
these vents can be closed in summer to keep out moist outside air that may have a dew point above the crawl space temperature. However, unless steps are taken to control air infiltration, closing vents does not ensure that the crawl space will have no air exchange with the outside; any exchange with outside air reduces the effectiveness of any wall insulation.

**Slab-on-Grade.** For slab-on-grade foundations with concrete or masonry walls, insulation is usually placed on the entire exterior surface of the foundation stem wall, on the interior surface of the foundation wall, or horizontally under the slab perimeter. When the insulation is placed on the interior, it is important to place it in the joint between the slab edge and the foundation wall. The insulation placed in this joint does not need to have an R-value greater than 0.88 m²K/W. Exterior vertical insulation with an R-value of 0.88 to 1.76 m²K/W is justified in most climatic zones (Labs et al. 1988).

Another method is to place insulation horizontally on the building exterior extending 600 to 1200 mm into the surrounding soil. Shallow footings (less than 600 mm below grade) or slabs with a thickened edge and no foundation wall are common in some regions. In these cases, additional insulation may be placed horizontally along the exterior edge.

**Thermal Performance**

A key question in foundation design is whether to place insulation inside or outside the basement or crawl space wall. Placing rigid insulation on the exterior of a concrete or masonry basement or crawl space wall has some advantages: it provides continuity without thermal bridges, maintains the waterproofing and structural wall at moderate temperatures, minimizes moisture condensation problems, does not reduce interior basement floor area, and includes the foundation in the thermal mass in the building. Exterior insulation at the rim joist leaves joists and sills open for inspection from the interior for termites and decay.

However, exterior insulation can provide a path for termites and can prevent inspection of the wall from the outside. A termite shield may need to be installed through the insulation where the sill plate rests on the foundation wall. Vertical, exterior insulation can extend as deep as the top of the footing and can be supplemented by extending the insulation horizontally from the face of the foundation wall.

Interior insulation is an effective alternative, and it is generally less expensive if the costs of the interior finish materials, including a flame spread cover, are not included. However, interior wall insulation increases the exposure of the wall to thermal stress and freezing and may increase the likelihood of condensation on sill plates, band joists, and joist ends.

Placing insulation in the basement ceiling is an alternative, but it should be used with caution in colder climates where pipes may freeze and structural damage may result from lowering the frost depth in the soil next to the foundation.

In a wood foundation, insulation is placed between studs. Insulation placed around the crawl space floor perimeter can provide additional thermal protection; however, it may also create additional paths for termite entry. A 50 mm air space between the lower end of the insulation in a crawl space or wall cavity and the bottom plate of the foundation wall allows inspection for insect infestation. Batt or tight-fitting rigid foam board insulation is commonly placed inside the rim joist.

**Crawl Space Wall Insulation.** A common, low-cost approach to insulating crawl space walls is to drape batts with a vapor retarder facing the inside of the wall. (Most building codes require that the vapor retarder be flame resistant.) The batts can be laid loosely on the ground at the perimeter to reduce heat loss through the footing. However, it is difficult to maintain the continuity of the vapor retarder around the joist ends and to seal the vapor retarders where they join the batts. Good installation is difficult because of cramped working conditions, and vapor-proof installation prevents easy inspection for termites. In a foundation system of wood pressure-treated with preservative, insulation is placed in the stud cavities similarly to above-grade insulation in a wood frame wall. Crawl space walls may also be insulated by spraying an insulating foam.

Insulation may also be incorporated in the concrete or masonry walls. Examples include rigid foam plastic insulation cast within the concrete wall; polystyrene beads or granular insulation poured into the cavities of conventional block walls, or foam insulation field-injected into the cores; concrete blocks with insulating foam inserts; formed interlocking rigid foam units that serve as a permanent, insulating form for cast-in-place concrete; and masonry blocks made with polystyrene beads or a low-density aggregate/regular-density concrete mixture. However, the effectiveness of construction that insulates only a portion of the wall area should be evaluated closely because thermal bridges can reduce the insulation’s effectiveness by as much as 80%.

**Slab-on-Grade Foundation Insulation.** For slab-on-grade systems, the greatest heat loss is through the small area of the foundation wall above grade. Heat is also lost from the slab to the soil. Heat losses to the soil are greatest at the slab edge and diminish rapidly with depth. Heat loss at the edge and through the soil must be considered in designing the insulation system.

Insulation can be placed vertically outside the foundation wall or grade beam. This approach effectively insulates the exposed slab edge above grade and extends downward to reduce heat flow from the floor slab to the ground surface outside the building.

**Vertical exterior insulation is the only method of reducing heat loss at the edge of an integral grade beam and slab foundation. A major advantage is that the interior joint between the slab and foundation wall need not be insulated, thus simplifying construction. However, there are several drawbacks to this method. The rigid insulation must be covered above grade with a protective board, coating, or flashing material; and brick facings that contact the covering can create a thermal short that bypasses both the foundation and the above-grade insulation. A further limitation is that the depth of the exterior insulation is controlled by the footing depth.**

Thermal insulation also can be placed vertically on the interior of the foundation wall or horizontally under the slab. In both cases, heat loss is reduced and the difficulty of placing and protecting exterior insulation is avoided. Interior vertical insulation is limited to the depth of the footing, but underslab insulation is not limited. Usually, the outer 600 to 1200 mm of the slab perimeter is insulated. The joint between the slab and the foundation wall must contain insulation whenever insulation is placed inside the foundation wall or under the slab. Otherwise, a significant amount of heat transfers through the thermal bridge at the slab edge. The insulation is generally limited to a thickness of 25 mm at this point.

Another option for insulating a slab-on-grade foundation is to place insulation above the floor slab. A wood floor deck can be placed on sleepers, leaving cavities that can be filled with rigid board or batt insulation; or a wood floor deck can be placed directly on rigid insulation above the slab. This approach avoids some of the construction detail problems inherent in the more conventional approaches, but it may cause a greater frost depth near the slab edge.

**Moisture Control**

High moisture levels in a foundation can rapidly degrade the thermal performance of most types of foundation insulation. Properly constructed foundations with good drainage and damp-proofing should keep moisture loads from foundations below 3 L/day; however, Christian (1994) reported on foundations that contribute 19 to 71 L/day. Elevated moisture levels increase the potential for mold and mildew growth, odors, pathogens, and serious health effects to occupants. Mold and mildew will grow where the relative humidity of a surface is greater than 70%. This level of relative
humidity can occur in the foundation of a building that has an interior with 50% rh. Because the surface temperature is colder during winter than the crawl space air temperature, the relative humidity of the crawl space air can be much lower than 70% and still result in 70% rh on the surface. Frequently, methods used to solve the problem in existing buildings are energy-intensive (e.g., year-round operation of dehumidifiers).

**Basement.** Rain is carried away by gutters, downspouts, grading away from the building, and a cap of low-permeability backfill material. Subgrade drainage by a drain screen (gravel and footer drain connected to daylight, sump, or storm sewer) prevents water from reaching the foundation wall.

Damp-proof or waterproof materials on the exterior of the foundation wall and over the top of the footing control moisture transport. Capillary moisture movement into the slab is controlled by a 100 mm thick granular layer under the slab.

All air leakage openings (i.e., floor slab/wall intersection, rim joist area) are sealed with durable caulking materials, closed with gasket systems, taped, or covered with moisture-vapor-permeable house wrap.

Damp-proofing on the wall and polyethylene under the slab control vapor diffusion. During heating periods, vapor diffusion from the interior of the basement may transport moisture into the rim joist framing, where it accumulates. Rigid insulation installed on the exterior of the rim joist limits periods of potential condensation.

**Slab-on-Grade.** The ground should be graded to direct water away from the building. A granular layer under the concrete slab provides a capillary break between the soil and the slab. This layer can also be integrated into a subslab ventilation system to reduce radon levels. Extending the vapor retarder over the top of the foundation wall and placing appropriate flashing for any brick facing provide a capillary break to protect the above-grade wall from ground moisture penetration.

A vapor retarder placed under the slab restricts both radon gas entry and water vapor diffusion through the slab. If ducts are placed in the slab, moisture may enter the conditioned space because groundwater and soil gas will likely seep into the ducts.

**Air Movement/Radon Control**

Construction techniques to minimize radon infiltration through the foundation are appropriate where radon is present. General approaches include sealing joints, cracks, and penetrations in the slab and walls and evacuating soil gas under the foundation.

A tight foundation and a discharge system reduce the chimney or stack effect that draws air from the foundation or basement into the house. If radon levels are excessive, a passive discharge system can be connected. If further relief is needed, an inline duct fan can be installed in the discharge system. [Figure 1]

Subslab depressurization effectively reduces radon concentrations to acceptable levels, even in houses with high concentrations (Dudney et al. 1988). This technique lowers the pressure around the foundation envelope, causing the soil gas to be routed into a collection and discharged to the outdoors.

A continuously operating fan should not be relied on as a discharge method. Ideally, a passive depressurization system should be installed, radon levels tested, and—if necessary—the system activated by adding a fan. The fan should be located in an accessible section of the stack so that any gas leaking from the positive pressure side of the fan does not enter the living space.

Active subslab depressurization also raises some long-term concerns. If the radon barrier techniques are not fully used, indoor air could be drawn into the basement and subsequently discharged, resulting in a larger than expected energy cost. Durability is another concern, particularly with motor-driven components. Also, the system is susceptible to owner interference.

**Low-Density Construction**

The most common type of low-density wall construction is the wood frame wall. Most houses built in the United States have exterior walls framed with wood studs, although steel studs offer several advantages; for example, they are more dimensionally stable and are truer than wood studs. Additionally, steel studs can be fabricated from recycled material and are themselves recyclable. However, these studs can create a significant thermal bridge across the cavity insulation, reducing its thermal resistance by up to 50%. Exterior foam sheathing insulation can be used to augment the R-value of the wall (Christian and Kosny 1996).

The interior side of the framing is typically sheathed with gypsum wallboard. In wood construction, to enhance the energy efficiency of the wall, foam insulation sheathing can be applied between the gypsum board and the framing. An advantage of this practice is that the low-permeance sheathing can take the place of a vapor retarder. The disadvantage is that it complicates the application of the gypsum board.

The cavities between framing members are filled with thermal insulation including batt, loose fill, stabilized loose fill, site-injected foam, and rigid foam boards. With all products, the level of performance is related to the quality of the installation. Batts should be installed to completely fill the cavities along the back corners and the depth of the cavity. Gaps created by framing members or voids in an insulation caused by material settling or by improper installation can significantly reduce thermal performance. Dry loose fill should be installed at the manufacturer’s recommended minimum density to avoid settling or the formation of voids. Wet loose fills should be installed with the proper amount of moisture, as recommended by the manufacturer. Stabilized loose fill insulations are applied with adhesive and water to prevent settling and movement.
within the cavity. As these products dry, some shrinkage has been observed; this shrinkage can affect the wall’s thermal performance. Before the cavity is sealed, enough time must be allowed to remove any excess water added by the application process. Site-injected foams are introduced with a hose and allowed to expand in the cavity and interstitial spaces. Rigid foam board, sometimes used as an insulation material, is cut to size and placed tightly between studs.

Commonly used exterior sheathing materials include gypsum sheathing, plywood, oriented strand board (OSB), and foam insulating sheathing. For low-rise buildings, usually less than three stories, airflow retarders are installed on the outside of the exterior sheathing and covered with an exterior finish such as vinyl or aluminum siding, stucco, or brick.

Airflow can be retarded by constructing a continuous, air-impermeable plane at the sheathing surface (e.g., tongue-and-groove gypsum board with taped joints). The sheathing/window, sheathing/roof, and sheathing/door joints are also taped.

When an insulating sheathing is used, vertical or horizontal spacer strips can be installed between the siding and the sheathing to (1) provide a rain screen, (2) increase thermal resistance by maintain an air space between the reflective foil on the sheathing and the siding, and (3) provide a nail base for the siding.

If the exterior finish is an exterior insulation finishing system (EIFS), a layer of insulation is attached to the exterior wall, and a synthetic glass-mesh-reinforced coating is attached to the insulation. An EIFS is usually applied by hand to the wall on site; it also can be prefabricated as panels in a factory. An EIFS is non-load-bearing and is vulnerable to wind loads; the critical wind load causes the panel to pull off the structure.

A specialized type of exterior sheathing that is very energy-efficient is the nonstructural truss (Canadian Home Builders 1989; Nisson and Dutt 1985; Wilson 1988). These trusses are installed on the exterior of a conventionally framed and sheathed wall. The trusses are easily installed, and they allow high levels of insulation to be installed, although the insulation near the truss must be installed carefully. The additional wall thickness complicates the framing required around wall openings such as windows and doors.

Panelized walls are composed of an insulation layer faced on both sides with a sheathing material. The insulation layer ranges in thickness from 50 to 300 mm. Oriented strand board is the most widely used sheathing material, but gypsum sheathing and plywood are also available. Because of evolving techniques for energy-efficient splines, panelized walls can have significantly fewer thermal bridges than wood frame construction.

Interior and exterior finishes for panelized walls are similar to those used in wood frame construction. Some panelized walls may already have suitably finished surfaces. Advantages of using panelized walls include (1) higher energy efficiency than typical wood frame walls; (2) little or no thermal bridging in the clear wall area, (3) tighter than average construction due to the reduction in jointing if large panels are used, and (4) integration of the insulation into the panel system, making insulation installation unnecessary. Potential problems with panelized walls are (1) faster delamination in improperly built assemblies, (2) fire safety concerns with the use of cellular plastics (however, this is an issue in any wall with insulating sheathing), and (3) insect control (carpenter ants have been reported to nest in hollows carved in the panels).

Masonry Construction

A common masonry wall is made with concrete masonry units (CMUs), blocks of concrete cast in various shapes and joined with mortar to form a wall. The concrete used to fabricate CMUs is produced with a variety of aggregates and typically varies in density from 1360 to 2160 kg/m³ (Andrews 1989). A CMU wall provides a finished, durable interior and exterior surface. Holes can be drilled through the wall to feed utilities through. Many CMUs are available with patterns cast into the exterior face, thus providing diverse exterior finishes. Interior or exterior sheathing, and/or an airflow retarder, can be applied to improve energy efficiency or to obtain a desired finish.

If an EIFS is attached to the exterior of the wall, the insulation separates the wall from the fluctuating outdoor temperatures. This method of insulation can be used to advantage in energy-efficient buildings in which the thermal energy stored in the wall mass is used to moderate indoor temperature swings. External placement also allows the wall cavity to be used for utilities that might be susceptible to freezing or heat loss. It is important that the edges of EIFS be tightly abutted so that thermal bridges are minimized.

Thermal Performance

James and Goss (1993) provide a summary of the heat transmission coefficient measurements and calculations for various wall, roof, ceiling, and floor systems. These data are for clear wall areas only and do not include subsystems or the effects of the joints created at intersections with another portion of the building envelope.

In a series of three-dimensional heat conduction simulations using a finite difference program on a single-family detached house, the average area-weighted R-value for the entire wall was 88% of the R-value of the clear wall. A similar two-dimensional analysis by Tulucu et al. (1997) showed the R-value for the entire wall system to be 40 to 50% of the clear wall R-value. Significant thermal bridging can occur through framing (wood or even more important, steel), metal ties through exterior sheathing, and exposed slab edges.

The thermal bridges created by the webs of CMUs dictate the maximum thermal efficiency that a CMU can attain. To reduce thermal bridging, blocks containing only two webs instead of the usual three have been used, and web thickness has been reduced by up to 40%.

The exterior surface of an EIFS expands and contracts significantly under the influence of changing outdoor temperatures and solar radiation. The thin, highly expansive coating has virtually no thermal storage capacity, but it is reinforced with glass mesh that helps moderate thermal movement. Because the coating is bonded to a layer of plastic insulation, which also is highly thermally expansive, the temperature of the coating fluctuates rapidly. This fluctuation places considerable stress on the coatings themselves and on adjacent sealing joints. This problem is exacerbated when dark colors are used and can become acute because the maximum service temperature of expanded polystyrene insulation, the type most typically used, is about 77°C.

Moisture

Historically, the primary moisture control strategy for walls is to restrict moisture entry. Another approach to envelope design is to provide walls that balance entry with removal and that control accumulation and pressure differential.

Recognizing that low-density wall systems can get wet or occasionally start out wet, the designer can promote weather protection and drying. A rain screen can be placed immediately behind the exterior cladding to control rain penetration by providing a pressure-equalized air space; or a house wrap, which is vapor-permeable and water impermeable, can be installed over the exterior sheathing to protect the wall from the weather yet allow it to dry if necessary.

For heating-dominated climates and for mixed climates with both significant heating and significant cooling seasons, a vapor retarder at the interior surface is advisable. Moisture originates from the interior of the building and migrates into the wall until it reaches the interior vapor retarder, which is kept warm because it is inside the thermal envelope. In cooling-dominated climates, exterior sheathing of impermeable rigid insulation can act as a vapor diffusion retarder. Moisture outside the building moves into the wall until it reaches the exterior vapor retarder, which is kept warm because it is outside of the thermal envelope. As a general rule, to keep moisture condensation accumulation to a minimum, this first condensing surface must be kept above the dew point.
Air Movement

Uncontrolled air movement across walls increases space conditioning costs and may cause moisture to condense. Air infiltration is the movement of air from the outside into the conditioned space. Air exfiltration is the movement of air from the conditioned space to the outside. Air intrusion is the penetration of air into the building envelope without entirely crossing it. For example, outside air can penetrate a wall at sheathing joints, move around or through the insulation and return to the outside. Similarly, inside air can penetrate a wall at electric outlets, move around or through the insulation and return to the conditioned space. Air leakage designs any type or combination of air movement in and across the envelope (see the sections on Basic Concepts and Residential Infiltration in Chapter 25 of the 1997 ASHRAE Handbook—Fundamentals).

In general, an airflow retarder should be installed in walls. The airflow retarder reduces both infiltration and exfiltration. It also prevents intrusion by exterior or interior air, depending on the location of the air seal plane. The airflow retarder reduces energy use and reduces or eliminates moisture condensation.

In heating-dominated climates, the airflow retarder can be positioned on either the exterior or the interior of the wall structure (e.g., framing). If placed to the exterior of stud construction that does not have insulating sheathing, the airflow retarder protects the insulation located between framing members from cold air intrusion. To avoid moisture condensation, such an airflow retarder must be moisture-permeable, because moist interior air can still intrude into the wall even though it cannot easily exfiltrate across the wall. Examples of exterior moisture-permeable airflow retarders are:

• Certain thin membranes, such as spun bonded polyolefin and other house wraps
• Gypsum board, particle board, or plywood sheathing taped and sealed at all joints and at the wall/window, wall/roof, and wall/floor junctions
• Pressed paper and cardboard products taped and sealed
• Thin polystyrene accordion-type wraps stapled, taped, and sealed; used only on houses built according to U.S. Housing and Urban Development Department codes

The airflow retarder can also be placed to the exterior of stud construction that has insulating sheathing, such as steel stud walls with fibrous insulation whose R-value is 1.9 m²·K/W, gypsum board sheathing, rigid insulation sheathing, and brick finish. If the airflow retarder is placed to the exterior of stud construction that has insulating sheathing, it can be moisture impermeable if the R-value of the rigid insulation is sufficient to maintain the airflow retarder above the dew point during winter conditions. Impermeable airflow retarders are usually bituminous, rubber-based, or plastic membranes. However, the airflow retarder can also be composed of a gypsum board layer with the junctions taped and sealed. Masonry construction usually includes air-impermeable airflow retarders.

If the airflow retarder is placed to the interior of a wall located in a heating-dominated climate, it protects the wall from intrusion by moist interior air. In theory, this type of retarder is more advantageous than an exterior retarder for structures where moisture condensation is likely, such as steel studs without insulating sheathing that define a space with high humidity in winter. In practice, it is difficult to achieve a continuous air seal at the interior surface of a wall, especially in multistory buildings, because of the wall/floor and wall/ceiling junctions. A continuous air seal plane could be achieved by gypsum board with or without a polyethylene vapor retarder if particular attention is paid to details and with special construction supervision.

In hot, humid climates, the airflow retarder for air-conditioned buildings should be vapor-permeable if it is placed nearest the interior of the wall because the outside moist air can condense on cold interior surfaces. The exterior airflow retarder can be either moisture-permeable or moisture-impermeable. If the retarder is moisture-impermeable, the insulated layer near the conditioned space must have a sufficient R-value to keep the membrane above the dew point. This caveat applies to each component of the insulated layer separately.

In climates with significant heating and cooling, the heating-dominated construction is usually indicated, but dew-point calculations need to be performed if layers with low vapor permeance are used. In climates with some heating, significant cooling, and high humidity, it is usually prudent to avoid vapor-impermeable airflow retarders and layers with low vapor permeance.

In general, with the exception of prefabricated wall panels, two layers with low vapor permeance (e.g., an exterior vapor-impermeable airflow retarder and an interior vapor retarder) should be avoided because moisture can be trapped in the wall during construction or operation.

RESIDENTIAL ROOF AND CEILING ASSEMBLIES

Thermal Performance

In pitched roof assemblies, the attic space is typically insulated with mineral fiber batts or blankets and/or mineral fiber or cellulose loose fill insulation. The total thermal resistance of the ceiling plus insulation, attic space, and roof is the sum of the conduction resistance of the ceiling plus insulation and the effective attic resistance. The roof resistance is generally negligible.
The thermal performance of the insulation varies with its mean temperature. In winter conditions, the thermal resistance of the insulation increases; in summer conditions, it decreases. In installing loose fill insulation, care must be taken to avoid overblowing the material to densities below the intended design density for a given R-value. At densities below the design, the material may not deliver the desired R-value. To prevent overblowing, the correct amount of material for a given coverage area and R-value should always be installed. Manufacturers of loose fill insulation are required to provide maximum net coverage information on all product packaging.

Some high-density loose fill products may gradually settle to a lower thickness after being installed. The reduced thickness decreases the thermal resistance despite the increased density. For materials subject to settling, initial installed and settled thickness information should be available on package labels or from manufacturers so that the desired settled R-values can be achieved.

Some low-density loose fill materials are porous enough that very low temperatures at the top of the insulation may lead to free convection in the insulation. For example, Wilkes et al. (1991) observed that effective thermal resistance decreased by nearly 50% from nominal values when temperature differences greater than 40 K were imposed. Free convection can be suppressed by placing a layer of batt insulation over the low-density loose fill insulation. Alternately, batts or blankets can be installed first and the low-density loose fill blown in on top of the batts or blankets. Mineral fiber batts or blankets should be installed at the proper width so that there are no air gaps between the batts.

In a roof assembly over a ventilated attic space in a cooling-dominated climate, insulation may be supplemented by a radiant barrier of high-reflectance material to reduce radiant heat transfer between the hot roof and the relatively cool ceiling. The radiant barrier can be attached to the roof rafters or fastened directly to the underside of the roof sheathing with the reflective surface facing down. Care should be taken to not disturb and damage the existing insulation when retrofitting an attic with a radiant barrier. Also, dust decreases the effective reflectance of the radiant barrier over time; however, if the operable surface faces down, the reduction in thermal performance should be minimal.

During the cooling season, a radiant barrier reduces temperatures affecting the air, insulated surfaces, and HVAC ducts and equipment located in the attic space. A ventilated radiant barrier combined with an equally divided, continuous soffit and ridge vents provides optimal performance. The most cost-effective use of radiant barriers is in cooling-dominated climates. Use of radiant barriers in other climates may result in a net annual increase in energy use because the beneficial attic heat gain in the noncooling seasons is lost. DOE (1991) compares the present value savings of radiant barriers with those of conventional fibrous insulation for several climates and circumstances.

During the cooling season, a radiant barrier under the roof sheathing increases the efficiency of a duct system located in an attic (Hageman and Modera 1996). DOE (1991) does not consider this case.

With or without a radiant barrier, powered ventilation increases the effective attic resistance by reducing the temperature difference between the inside conditioned space and the attic space (see Table 5 in Chapter 24 of the 1997 ASHRAE Handbook—Fundamentals). However, this method is rarely cost-effective because of the energy cost of the fan. Additionally, powered ventilation can draw air from the conditioned space into the attic.

In low- or no-slope roofs, the insulation is a layered assembly comprising the deck, insulation, and membrane. Although there are relatively small gaps between the components, the high thermal resistance of the insulation keeps the total heat flux low. However, the heat flow through metal penetrations can be more than 1000 times greater than that through adjacent insulation. Therefore, the area of these thermal bridges should be kept small in proportion to the roof area. Minimizing this area may require interrupting potential bridges; for example, staggering fasteners that secure the insulation to the deck and those that attach the membrane to the insulation.

Moisture

In addition to moisture normally present in construction materials, moisture can be trapped in the roof and ceiling assembly from rain during construction, leaks that were not fixed before water entered the assembly, or re roofing partially torn-off roofs. Additional moisture can enter a structure having no insulation vapor retarder. If porous insulation is used, water vapor can diffuse throughout the assembly. The amount of vapor may be insufficient to significantly affect the thermal conductivity of the insulation, but it may add a significant latent heat load. Diurnal temperature variations in the roof can cause water to evaporate, move as vapor through a porous system, and condense (Hedlin 1988). When conditions are right for this effect, the heat flow from this factor alone can easily exceed normal conduction flows.

Air Movement

Whether the roof is pitched, low-slope, or no-slope, a typical roof and ceiling assembly is impervious to significant air movement through the ceiling itself. With pitched roofs, the attic normally is ventilated by airflow from the edges of the assembly, over the insulation, and out through continuous ridge vents or occasional vents in the roof or gable ends of the attic. The ventilation may be by natural or forced convection, but natural convection by a combination of continuous ridge vents and continuous soffit vents seems most effective. A type of low- or no-slope roof called a ventilated cold deck system has vents at the eaves and at intervals over the roof to permit the circulation of dry outside air over the insulation. The effectiveness of such vents is uncertain in regions with a cold or a temperate but humid climate (IEA 1994). An alternative is a non-ventilated cold deck system with a vapor retarder on the ceiling consisting of staggered strips of polyethylene on the bottom and top and exposed fabric between them. Vapor inside the building effectively “sees” a continuous layer of polyethylene because of the staggering. Condensed water wicks through the exposed fabric on the top to the exposed fabric on the bottom and evaporates to the inside (Pedersen et al. 1992).

**FENESTRATION**

**Conduction/Convection and Radiation Effects**

Heat transfer through a window resulting from a temperature differential between the inside and outside (i.e., conduction, convection, and radiation) is a complex and interactive phenomenon. Although the glass itself is a poor insulator, it is used effectively in a window to create thin insulating air films on either side of single glazing or dead air/gas spaces between glazing layers. Glass can also decrease the direct transmission of radiant energy coming from the room or ambient sources. Chapter 29 of the 1997 ASHRAE Handbook—Fundamentals discusses fenestration in much greater detail.

An examination of the modes of heat transfer in a double-glazed window indicates that approximately 70% of the heat flow is through radiation from one glazing layer to another (Selkowitz 1979; Arasteh et al. 1985). Although the glass blocks the direct transmission of radiant energy, energy is still absorbed and reemitted. Low-emittance coatings that are transparent to the eye significantly reduce the amount of heat transfer through a glazing cavity.

With the radiation mode of heat transfer minimized, the conductive and convective modes dominate. To reduce these modes, gases with low conductivity (e.g., argon or krypton) are used in low-emittance-coated, multiple-glazed windows. Triple or quadruple glazing layers make additional reductions in heat transfer possible.
Building Envelopes

Air Infiltration Effects

Air infiltration is the uncontrolled movement of air from the outside to the inside of a building. It is a function of the pressure differential between the inside and outside environments (which is a function of wind speed and temperature differentials) as well as window sealing characteristics (Weidt and Weidt 1980; Klem 1983). The infiltration rate of a fenestration product is a function of its method of operating (if any), weatherstripping material used, and construction quality. See Chapter 29 of the 1997 ASHRAE Handbook—Fundamentals for design information.

Solar Gain

Solar gain through windows can play a significant role in the energy balance of a building. Glazings transmit, reflect, or absorb a given wavelength of solar radiation, depending on the glazing characteristics. Transmitted solar radiation contributes heat to a space. Absorbed solar radiation is reemitted and/or conducted either to the inside or to the outside (depending on the window’s glazing system configuration). Reflected solar radiation does not contribute heat to a space (Arasteh et al. 1989). Clear glass, the most common glazing material, transmits fairly evenly across the solar spectrum. Tinted or heat-absorbing glass absorbs solar radiation and gives the glass a specific color. Some tints exhibit a significant degree of spectral sensitivity (i.e., they do not transmit, absorb, and reflect evenly across the solar spectrum). These types of glazings offer great flexibility in that they can be tailor-made for specific climates or uses (e.g., provide ample daylighting without overheating an interior space).

Interactions Between Thermal Loss and Solar Gain

In heating-dominated applications, solar gain can provide a significant amount of heat. In many cases, the heat supplied by the window can offset that lost through the window. The amount depends on the site characteristics (i.e., how much solar gain is available, how cold the climate is) and window characteristics (i.e., its U-factor and how much incident solar radiation is transmitted). Typical passive solar applications try to maximize the amount of solar heat gain by installing significant amounts of south-facing glass, which receives the most solar radiation during the winter (in the northern hemisphere). However, high-performance windows facing north in a heating-dominated climate can provide more solar gain to a space than heat loss (Arasteh et al. 1989; Sullivan et al. 1992; Dubrios and Wilson 1992).

WALL/WINDOW INTERFACE

Air infiltration at the wall/window interface can cause serious damage to surrounding building materials and even to remote materials, depending on the leakage path. In cold climates, warm, humid inside air can condense in the wall cavity. The condensate can damage the interior finish, the seals of glazing units, the insulation, the exterior cladding, and possibly the structural elements. Cold air infiltration can affect the health and comfort of the occupants by creating a dry indoor environment, cold drafts, and condensation and mildew on inside window surfaces. Air infiltration can also allow rain to enter the wall. Many materials are installed by many trades at the wall/window interface, making it difficult to inspect and prone to leak.

Control of Air Leakage

The airflow retarder must be continuous across the entire building envelope to provide effective control. To ensure continuity at the window, the components that retard airflow must be unified. Examples include the following:

- In a metal and glass curtainwall, the glazing and sheet metal are the elements that retard airflow in the window and the wall, respectively. Gaskets and caulking make the airtightness plane continuous from the glazing to the metal mullion.
- In a masonry wall, a self-adhesive asphalt membrane mechanically fastened to the masonry makes the wall airtight. A bead of sealant preserves the airtightness between the glazing unit and the inner part of the metal window frame. Thus, the asphalt membrane and the inner part of the metal frame are the two materials joined to withstand large air pressure loads. The membrane is extended and mechanically clamped to the inner part of the frame.

Control of Moisture Diffusion

Vapor diffusion across a small gap at the window/wall junction causes little building damage under average environmental conditions. Moreover, typical interior finishes covering the joint, made of metal or plastic or painted drywall, offer some resistance to moisture diffusion.

Control of Heat Flow

Continuity of the plane of thermal insulation is important primarily to reduce the potential for condensation on interior surfaces of the window and the surrounding interior finish. Insulation can be inserted in the joint between the wall and the window frame to compensate for the expected differential movement between the frame and the wall rough opening.

Control of Surface Condensation

To reduce the potential for condensation on the glazing and the frame of windows, as well as on the surrounding interior finish of the wall, the inside surface temperature can be controlled in the following ways:

- Seal the wall/window interface and between the sash and frame of operable windows to keep air leakage to a minimum.
- Make the area of window frame exposed to the interior larger than the area exposed to the outside. Metal frame extensions on the inside have a higher resistance to condensation but contribute to heat loss.

Control of Rain Entry

Applying the rain screen principle at the wall/window interface requires the same features as applying it to the wall: (1) an airflow retarder, (2) a rain deflector on the outside of the interface, (3) much more venting on the outside face of the interface than on the inside, and (4) a drainage path toward the outside.

The line of airtightness is on the inside of the assembly, so the assembly is protected from water, ultraviolet rays, and extremes of temperature. The rain deflector on the outside acts as a rain deterrent only, not as a watertight/airtight seal. A nonairtight rain deflector does not threaten the weathertightness of the system because the pressure differences across the rain deflector are small. The key is to maintain airtightness on the inside of the joint. With little pressure across the rain deflector and with good detailing for outward drainage of the cavity, rain entry in the wall should be minimal.

Face Seal Approach

The face seal approach calls for perfect sealing of the outer face of the wall/window junction. This sealed surface protects against rain and air infiltration. Such a seal must remain perfect over time; its maintenance schedule is quite demanding. It is also complicated because water leaks can follow indirect paths for entry indoors, and in a large building, it may be difficult to trace these paths back to the entry points.
WALL/ROOF INTERFACE

Control of Air Leakage

The roofing membrane forms a plane of continuous airtightness and therefore can and should be connected to the wall airflow retarder. However, the wall airflow retarder could also be connected to other airtight roof components, such as the roof deck or the roof vapor retarder.

Many building systems provide for differential movement between the wall and roof assemblies; in those systems, a flexible airflow retarder connection is required at the location of the movement control joint. In all systems, the airflow retarder must withstand wind-induced pressures and fully adhere to a rigid, structurally adequate substrate.

Figure 3 shows an assembly that uses the concrete roof deck to achieve a continuous wall/roof airflow retarder. The retarder of the wall assembly is connected to the concrete slab using a sheet airflow retarder material. The connection between the wall and slab edge retarder sheets is designed to accommodate differential movement of the wall and roof.

Figure 4 shows a protected membrane roof assembly in which the roof membrane is an airflow retarder that extends over the edge of the roof perimeter to connect to the wall airflow retarder. A sheet metal backing is used around the roof deck perimeter for attachment and to provide for differential movement at the interface.

In some types of curtain walls, such as the wall in Figure 5, the air seal must be made continuous over the parapet wall. This allows connection of the wall air seal (the metal back pan of the spandrel panel) to the membrane flashing of the roof assembly or to the air/vapor retarder on the parapet, as in asphalt and roofing felt systems.

Control of Moisture Diffusion

The vapor retarder can also act as an airflow retarder, as in the curtain wall shown in Figure 5 in which the metal back pan of the wall spandrel connects to the air/vapor retarder membrane on the parapet upstand wall. Because the parapet is encased in vapor retarder sheets, it must be kept dry before it is enclosed because any moisture left in the parapet cannot disperse. A vapor retarder with wicking properties could provide a better solution.

Control of Condensation

Condensation at the connection between the roof and wall can occur in interstitial spaces because of a lack of continuity in either system. Condensation also occurs if the temperature of the vapor retarder falls below the dew point of the air on the high vapor pressure side. Thus, thermal insulation applied to the exterior (winter-cold surface) of the vapor retarder must be sufficient to ensure that the temperature at the retarder plane remains higher than the dew point of the air. The temperature of the interior space between the exterior wall system and the parapet upstand wall often falls below the temperature of the interior inhabited space because of poor air circulation above the ceiling. Therefore, the insulation applied over the parapet cap and upstand wall may need to have greater thermal resistance than the insulation for the wall or roof.

In exterior insulated wall systems, such as curtain walls and EIFSs, thermal bridging must be minimized to control condensation between the parapet cap and the parapet upstand wall.

THERMAL BRIDGES IN BUILDINGS

A thermal bridge is an envelope area with a significantly higher rate of heat transfer than the contiguous enclosure. An example of thermal bridging is a steel truss in an attic with glass fiber insulation placed between trusses. The thermal conductivity of steel is about 1000 times greater than that of glass fiber insulation, so strong thermal bridging results along the trusses. In most construction details, the ratio between the high and low conductivity areas is smaller. An
uninsulated CMU wall with brick facing could have a U-factor of 1.86 W/(m²·K) if the CMU is made with sand and gravel aggregate. A concrete column located within that wall has a U-factor about 50% higher. This 50% higher conductivity may justify classifying the column as a thermal bridge, but in typical construction this classification is relevant only if the concrete column proves to be detrimental for reasons other than energy use (e.g., moisture condensation).

Thermal bridges can be created by conduction, as in the previous examples; by radiation; by convection; or by a combination of those three modes of heat transfer (Silvers et al. 1985). Strong radiation effects occur, for instance, in an uninsulated brick wall that is retrofitted with metal cladding. The cladding is placed at some distance from the exterior of the brick wythe. The warmer brick wall radiates to the cold metal sheet. The different temperatures of the two surfaces also engender air convection.

Detrimental Effects of Thermal Bridges

Thermal bridges increase energy use, promote moisture condensation in and on the envelope, and create nonuniform temperatures in conditioned spaces. A comparison between the uninsulated slab edge detail of Figure 6A and the version with slab edge insulation with an R-value of 1.76 m²·K/W in Figure 6B illustrates the importance of designing to reduce thermal bridging. [Refer to Steven Winter Associates (1988) for numerical examples summarized in this section.] This example, and the others in this section, use the term total R-value, where $R_t = 1/U; R_t$ includes the effect of exterior and interior air films.

- **Increased energy use.** The portion of the wall that extends from the top of the slab edge to the shelf angle (Figure 6B) has $R_t = 0.4$ m²·K/W when the wall insulation is furred in. Moving the insulation into the wall cavity (Figure 6B) increases $R_t$ by about 2.2 times, to 0.93 m²·K/W.

- **Damage to structural components.** On cold days, the uninsulated wall area collects moisture on the interior surface of the steel beam and on the slab underside. At −7°C outside air temperature, 21°C indoor air temperature, and 50% indoor relative humidity, moisture condenses on about 0.2 m² of beam and slab for every linear metre of wall. This condensation can rust the metal beam and, if it penetrates into the concrete block, can rust the brick ties. The insulated detail (Figure 6B) generates moisture condensation only on the bottom flange of the beam.

- **Damage to interior finishes.** Moisture can drip from the slab underside and from the steel beam, staining the ceiling tiles and resulting in higher maintenance costs and loss of rental value. These effects are specific to the heating season and are magnified when thermal bridging is accompanied by air leakage because air transports and deposits moisture on thermal bridges.

In cold and temperate climates, thermal bridges may slightly decrease the peak cooling load and the cooling energy use. In hot climates, this effect could be reversed. When the climate is hot and humid, moisture condensation can create problems if the building is air conditioned or refrigerated.

**Thermal Bridge Mitigation**

The primary causes for conduction thermal bridging are (1) high thermal conductivity and (2) geometries that create zones where large exterior surfaces connect to much smaller interior surfaces. Thermal bridges can sometimes be eliminated, but usually they can be mitigated to create systems with significantly lower U-factors. Several examples of conduction thermal bridges and of mitigating details follow.

- **Factory-produced components with high conductivity**

  **Sandwich panel with insulation fully encased in concrete** (Figure 7A). One possible solution: Connect the exterior and interior wythes of the panel with metal or plastic tie rods (Figure 7B).

  This 1.8 m high sandwich panel has a 75 mm extruded polystyrene core completely encased in concrete. The concrete has a conductivity over 50 times higher than that of polystyrene, resulting in $R_t = 0.95$ m²·K/W. Moisture can collect on the top and bottom concrete edges of the panel. For $T_{OA} = −7°C, T_{IA} = 21°C$, and 50% rh, about 20% of the panel area can be covered with moisture.

  When the interior and exterior concrete wythes are attached with metal or plastic tie rods, $R_t$ of the panel increases by a factor of almost 3 to 2.66 m²·K/W or 2.82 m²·K/W, respectively. No moisture condensation on interior surfaces would be likely.

- **Assemblies that contain high-conductance components**

  **Steel studs in insulated wall with ceramic finish.** One possible solution: Provide insulating sheathing (Figure 8).

  This steel stud wall is used in low-cost multifamily, commercial, and industrial construction. The exterior gypsum board is provided for fire protection. If the wall has $R = 1.94$ m²·K/W insulation, the studs reduce the wall $R_t$ to 1.36 m²·K/W. For $T_{OA} = −7°C, T_{IA} = 21°C$, and 50% rh, every linear metre of steel stud can generate 0.046 m² of moisture condensation on the interior surface of the gypsum wallboard.
Extruded polystyrene sheathing 25 mm thick placed on the winter-cold surface of the gypsum board sheathing would reduce the thermal bridging, resulting in \( R_t = 2.55 \text{ m}^2 \cdot \text{K}/\text{W} \). For \( T_{OA} = -7^\circ \text{C} \), \( T_{IA} = 21^\circ \text{C} \), and 50% rh, moisture would be less likely to condense on interior surfaces. If polystyrene were placed on the steel studs directly, the increase in R-value would be even higher because the lateral heat flow would be reduced.

If all insulation were placed on the exterior surface of the steel studs, the studs would be kept at a temperature close to that of the conditioned space. Moisture condensation would be practically eliminated. This solution merits special consideration in spaces with high relative humidity such as kitchens, and pool buildings.

- Junction between envelope systems achieved with high-conductance components

Uninsulated slab edge and metal shelf angle, at junction between CMU wall and concrete floor (Figure 6A) One possible solution: Place insulation in the wall cavity (Figure 6B).

This detail shows an uninsulated slab edge and perimeter metal beam in a CMU/brick wall. For the wall segment that extends from the top of the slab edge to the shelf angle, \( R_t = 0.4 \text{ m}^2 \cdot \text{K}/\text{W} \). For

\[ T_{OA} = -7^\circ \text{C}, \quad T_{IA} = 21^\circ \text{C}, \quad \text{and} \quad 50\% \text{ rh}, \quad \text{about} \ 0.2 \text{ m}^2 \text{ of slab underside and steel beam could collect moisture along every linear metre of slab edge.} \]

The improved detail of Figure 7B uses \( R = 1.76 \text{ m}^2 \cdot \text{K}/\text{W} \) rigid insulation in the wall cavity. The perimeter metal beam would be insulated, and the shelf angle would remain as the only significant thermal bridge. The new total R-value of the wall segment would be about 2.2 times higher (i.e., \( R_t = 0.93 \text{ m}^2 \cdot \text{K}/\text{W} \)). Less moisture would be expected to condense along the slab edge.

Insulation is sometimes specified on the interior surface of the perimeter beam in an effort to increase the thermal resistance of this wall segment. Site conditions rarely allow the installation to be thorough, so the top and bottom flanges remain exposed, creating a strong thermal bypass and marginalizing the effectiveness of the insulation. Moreover, the insulation makes vapor condensation more likely because it decreases the temperature of the beam chord but does not stop water vapor migration.

- Combinations of geometry with high conductivity

Column in masonry wall with insulation located in steel stud furring (Figure 9A). One possible solution: Move the insulation in the wall cavity (Figure 9B).

Concrete columns within masonry walls are often left uninsulated. In this example, a 300 mm by 300 mm column is located at the junction of two exterior walls composed of 150 mm CMU and 100 mm brick. The walls are insulated with \( R = 1.76 \text{ m}^2 \cdot \text{K}/\text{W} \) polystyrene on metal furring. The corner, which includes the column and two CMU blocks on each side, has \( R_t = 1.06 \text{ m}^2 \cdot \text{K}/\text{W} \). This is 38% lower than the total R-value of the wall without the column (\( R_t = 1.71 \text{ m}^2 \cdot \text{K}/\text{W} \)).

For \( T_{OA} = -7^\circ \text{C}, \ T_{IA} = 21^\circ \text{C}, \quad \text{and} \quad 50\% \text{ rh}, \quad \text{every linear metre of column could collect moisture on about} \ 0.24 \text{ m}^2 \text{ of interior surfaces.} \]

If the insulation were placed in the wall cavity, the total R-value of the corner would more than double, from \( R_t = 1.06 \text{ m}^2 \cdot \text{K}/\text{W} \) to \( R_t = 2.17 \text{ m}^2 \cdot \text{K}/\text{W} \). No moisture condensation would be expected on interior surfaces of the column for the given temperature and relative humidity conditions.

Design Recommendations

Basic design principles that apply to any thermal bridge are listed in the following paragraphs.

Consider the combined effects of thermal bridging, air leakage, moisture condensation, and water intrusion. If one of these mechanisms of heat and mass transfer is involved, another one is commonly combined with it in a destructive synergy. In devising a solution for thermal bridging, ensure that moisture condensation
is not increased. In climates with significant heating, this is of special concern for insulation placed on the interior (winter-warm) surface of materials with low vapor permeance, such as CMU or steel beam. In hot, humid climates, the concern relates to insulation placed on the summer-hot surface of materials with low vapor permeance.

In addition, because many thermal bridges are discontinuities in the envelope system, the chance that air will enter the envelope along these paths should be assessed. To cause damage, air does not need to infiltrate into a space from outdoors or to exfiltrate from a space to the outside; it is sufficient that air intrude in the envelope. For example, outside air can enter a stud wall cavity, short-circuiting the insulation and intensifying the thermal bridging effect, after which it exits again to the outside. In another example, indoor air can seep from the conditioned space into a furred-in CMU wall, behind the insulation and vapor retarder, increasing the chance for moisture condensation on the CMU surface. Of all forms of air intrusion, exfiltration of moist air along thermal bridge surfaces can be the most damaging. Note that the entry and exit points of air in the envelope can be distant.

It is particularly important to reduce thermal bridging, air intrusion, and moisture condensation if the following conditions are true:

- The building or spaces in it have uses that are likely to generate a relatively high amount of moisture during winter; examples are residences, hospitals, nursing homes, restaurants, kitchens, natatoriums, and bathrooms.
- The building is located in an area that experiences cold winters or sustained periods of cold during moderate winters. Climates with humid winters with subfreezing periods can also create problems.
- The building is located in a warm but not dry or arid climate and has uses that require low temperatures (e.g., refrigeration), or it is located in a hot, humid area and has uses that require air conditioning.

Consider the potential for thermal bridging and air intrusion during schematic design when decisions about the envelope system are made. Some systems are inherently more difficult to insulate and air-proof, and changes during design development may create budget problems.

Use reasonably accurate methods to determine the effect of thermal bridging. Accurate formulas are available for most steel stud configurations (Kosny and Christian 1995), but they are not sufficiently accurate for many other construction types. Two- and three-dimensional models are available and provide better results. In mitigating a thermal bridge, several techniques can be used, often in combination. Such techniques include:

- Change the thermal bridge material to one with lower conductivity. Plastic ties nearly eliminate thermal bridging in concrete sandwich panels.
- Decouple the thermal bridging elements from the rest of the construction. If the steel stud furring is detached from the CMU wall, the pathway between two materials with high conductivity is broken. The best method to achieve the decoupling is to insert a thin, low-conductivity material, such as foam tape, at each stud. If an air space is created between the insulated steel stud layer and the CMU wythe, air convection can short-circuit the insulation.
- Change the geometry that creates thermal bridging. Figure 10 shows a mullion with a deep exterior projection. This projection acts like a fin during winter, enhancing the heat loss. One method of reducing the thermal bridging effect would be to reduce the exterior projection [Figure 10] dotted line). If this were not acceptable for aesthetic reasons, a better thermal break system should be implemented.
- Insulate the thermal bridge. For example, use insulating sheathing for steel stud walls.
- Change the insulation system. For example, a furred-in masonry wall with all the insulation located in the furring could be changed to a masonry wall with rigid insulation on the exterior (winter-cold) surface of the CMU.
- Change the construction system. In a natatorium, for instance, structural silicone glazing without an exterior projection [Figure 11] might be a solution to avoid moisture condensation on mullions.
THERMAL MASS

The term thermal mass is commonly used to mean the ability of materials to store significant amounts of thermal energy and delay heat transfer through a building component. This delay has three important results:

1. The slower response time tends to moderate indoor temperature fluctuations during outdoor temperature swings (Brandemuehl et al. 1990).
2. In hot or cold climates, energy consumption is less than that for a similar low-mass building (Wilcox et al. 1985; Newell and Snyder 1990).
3. Building energy demand can be moved to off-peak periods because energy storage is controlled through correct sizing of the mass and interaction with the HVAC system.

Thermal mass can be characterized by the thermal diffusivity \( \alpha \) of the building material, which is defined as

\[
\alpha = k/\rho c_p
\]

where \( k \) = thermal conductivity, \( \rho \) = density, and \( c_p \) = specific heat. Table 1 lists these properties for some basic building materials.

Heat capacity (HC) is defined as the amount of heat necessary to raise the temperature of a given mass by one kelvin:

\[
HC = mc_p
\]

where \( m \) = component mass. The heat capacity of a building element is the sum of the heat capacities of each of its components.

Heat transfer through a material with high thermal diffusivity is fast, the amount of heat stored in it is relatively small, and the material responds quickly to changes in temperature. The effect of thermal mass on building behavior varies primarily with the climate at the building site and the position of the wall insulation relative to the building mass.

The ideal climate for taking advantage of thermal mass is one that has large daily temperature fluctuations. The mass can be cooled by natural ventilation at night and be allowed to “float” during the warmer day. When outdoor temperatures are at their peak, the inside of the building remains cool because the heat has not yet penetrated the mass. Often, the benefits are greater during spring and fall, when some climates closely approximate this ideal case. In heating-dominated climates, thermal mass can be used effectively to collect and store solar gains or to store heat provided by the mechanical system, allowing the heating system to operate during off-peak hours.

The effectiveness of thermal mass also increases with the allowable temperature swing in the conditioned space. If, for instance, interior temperatures can fluctuate between 20 and 26°C without the intervention of HVAC systems, as is the case in many schools, the mass has the opportunity to charge during warm hours and discharge during cooler periods. Such opportunity is limited in a laboratory that requires temperature control within a 1 K range.

In nonresidential buildings, thermal mass is often more effective in reducing cooling loads than heating loads. In some climates, buildings with high thermal mass have better thermal performance than those with low mass, regardless of the level of insulation in the low-mass building (Wilcox et al. 1985).

For maximum effectiveness in moderating indoor temperatures, the thermal mass should be exposed to the interior, conditioned air and insulated from outdoor temperature variations. Studies to quantify the thermal mass effect have concentrated on three wall insulation strategies: interior, integral, and exterior. The latter is the most effective way to insulate the envelope of a thermal mass building.

Calibrated hot box tests have shown that in walls with identical heat capacities, those with higher R-values cause larger reductions in temperature swings (Van Geem 1986). Insulation is especially significant in very hot climates with large daily temperature variations (Wilcox et al. 1985).

To simulate the complex interactions of all envelope components, computer simulations are necessary. These programs account for material properties of the components, building geometry, orientation, solar gains, internal gains, and HVAC control strategy. The calculations are usually performed on an hourly basis, using a full year of weather data.

BUILDING AIR INTAKE AND EXHAUST DESIGN

Exhaust Stack and Air Intake Design Strategies ........................................................................ 43.1
Stack Height to Avoid Reentrainment .................................................................................. 43.3
Exhaust Dilation Calculations ............................................................................................... 43.6

A BUILDING outside air intake brings fresh air into a building. Likewise, building exhausts remove air contaminants from a building to the outdoors so that the wind can dilute the emissions. If the intake or exhaust system is not well designed, contaminants from nearby outdoor sources, such as vehicle exhaust, or contaminants emitted from the building itself, such as laboratory fume hood exhaust, can enter the building with insufficient dilution, causing odors, health impacts, and reduced indoor air quality. This chapter discusses the proper design of exhaust stacks and placement of air intakes to avoid air quality impacts. A companion chapter, Chapter 15 of the 1997 ASHRAE Handbook—Fundamentals, more fully describes wind and airflow patterns around buildings. Related information can also be found in Chapters 7, 13, 28, 29, and 30 of this volume, Chapters 12 and 13 of the 1997 ASHRAE Handbook—Fundamentals, and Chapters 24, 25, and 30 of the 2000 ASHRAE Handbook—Systems and Equipment.

EXHAUST STACK AND AIR INTAKE DESIGN STRATEGIES

Stack Design Strategies

The dilution a stack exhaust can provide is limited by the dispersion capability of the atmosphere. Before discharge, exhaust contamination should be reduced by filters, collectors, and scrubbers.

Central exhausts that combine flows from many collecting stations should always be used where safe and practical. By combining several exhaust streams, central systems dilute intermittent bursts of contamination from a single station. Also, the combined flow forms an exhaust plume that rises a greater distance above the emitting building. Additional air volume can be added to the exhaust near the exit with a makeup air unit to increase the initial dilution and exhaust plume rise. This added air volume does not need heating or cooling, saving on energy costs.

In some cases, separate exhaust systems are mandatory. The nature of the contaminants to be combined, recommended industrial hygiene practice, and applicable safety codes need to be considered. Separate exhaust stacks should be grouped in a tight cluster to take advantage of the larger plume rise of the resulting combined jet. In addition, a single stack location for a central exhaust system or a tight cluster of stacks allows building air intakes to be positioned as far as possible from the exhaust location. For a tight cluster to be considered as a single stack in dilution calculations, the stacks must be uncapped, have approximately the same exhaust velocities, and all lie within a two-stack diameter radius of the middle of the group. Stacks lined up in a row do not act as a single stack, as shown by Gregoric et al. (1982).

As shown in Figure 1, the effective stack height $h_s$ is the portion of the exhaust stack that extends above local recirculation zones and upwind and downwind obstacles. Wilson and Winkel (1982) demonstrated that stacks terminating below the level of adjacent walls and architectural enclosures do not effectively reduce roof-level exhaust contamination. To take full advantage of their height, stacks should be located on the highest roof of a building.

Architectural screens used to mask rooftop equipment adversely affect exhaust dilution, depending on such variables as porosity, relative height, and distance from the stack. Petersen et al. (1997) found that, in general, the more porous the screen, the better the exhaust dispersion. Stacks should extend above the architectural screen by the height $H_c$ of the flow recirculation zone due to the screen itself, in order to prevent exhaust contamination of equipment within the enclosure. This height $H_c$ depends on screen porosity, and is approximately the value from Equation (1) times $(1 - \text{porosity})$.

Large buildings, structures, and terrain close to the emitting building can have adverse effects on dilution of stack exhaust, because the

The preparation of this chapter is assigned to TC 4.3, Ventilation Requirements and Infiltration.

---

Fig. 1 Flow Recirculation Regions and Exhaust-to-Intake Stretched-String Distances
(Wilson 1982)
emitting building can be within the recirculation flow zones downwind of these nearby flow obstacles (Wilson et al. 1998). In addition, an air intake located on a nearby taller building can be contaminated by exhausts from the shorter building. Wherever possible, facilities emitting toxic or highly odorous contaminants should not be located near taller buildings or at the base of steep terrain.

As shown in Figure 2, stacks should be vertically directed and uncapped. Stack caps that deflect the exhaust jet have a detrimental effect on both the initial dilution of the exhaust jet and the exhaust plume rise. Conical stack caps often do not exclude rain, because rain does not usually fall straight down. Changnon (1966) shows that periods of heavy rainfall are often accompanied by high winds that deflect raindrops under the cap and into the stack. A stack exhaust velocity $V_e$ of about 13 m/s prevents condensed moisture from draining down the stack and keeps rain from entering the stack. For intermittently operated systems, protection from rain and snow should be provided by stack drains, as shown in Figure 2F through 2J, rather than stack caps.

**Recommended Stack Exhaust Velocity**

High stack exhaust velocity and temperature increase initial jet dilution and plume rise and reduce intake contamination by increasing plume dilution and elevating the plume trajectory. The exhaust velocity $V_e$ should be maintained above 10 m/s (even when there are drains in the stack) to provide adequate plume rise and jet dilution. Velocities above 10 m/s provide still more plume rise and dilution, but above 15 to 20 m/s, noise and vibration from exhaust fans becomes an important concern. An exit nozzle (Figure 2B) can be used to increase the exhaust velocity and plume rise.

An exception to these exhaust velocity recommendations may be required when corrosive condensate droplets are discharged. In this case, a velocity of 5 m/s in the stack and a condensate drain are recommended to reduce droplet emission. At this low exhaust velocity, an exit nozzle should be used to avoid plume downwash.

**Stack Wake Downwash** occurs where low-velocity exhausts are pulled downward by negative pressures immediately downwind of the stack, as shown in Figure 3. $V_e$ should be 1.5 times the design wind speed $U_H$ at roof level to avoid stack wake downwash. A meteorological station design wind speed $U_{met}$ that is exceeded less than 1% of the time can be used. This value can be obtained from Tables 1A, 2A, or 3A in Chapter 26 of the 1997 ASHRAE Handbook—Fundamentals, or it can be estimated by applying Table 2 of Chapter 15 of the 1997 ASHRAE Handbook—Fundamentals to the annual average wind speed. Because wind speed increases with height, a correction for roof height should be applied using Equation (4) and Table 1 of Chapter 15 of the 1997 ASHRAE Handbook—Fundamentals.

**Other Stack Design Standards**

Minimum heights for chimneys and other flues are discussed in the Uniform Building Code (ICBO 1994). The American Industrial Hygiene Association (AIHA) Standard Z9.5, recommends a minimum stack height of 3 m above the adjacent roof line; an exhaust velocity $V_e$ of 15 m/s, or 10 m/s when internal condensation may occur; and a stack height extending one stack diameter above any architectural screen. The stack must also be situated to avoid reentry (reentrainment) into the laboratory or nearby buildings at concentrations above 20% of allowable concentrations within the laboratory under any atmospheric condition. The National Fire Protection Association (NFPA) Standard 45, specifies (in its appendix) a minimum stack height of 3.0 m to protect rooftop workers. Toxic chemical emissions may also be regulated by federal, state, and local air quality agencies.

**Air Intake Locations to Minimize Contamination**

Stack height requirements can sometimes be reduced by careful location of air intakes. Rock and Moylan (1998) reviewed the literature on air intake locations.

Even in the absence of toxic building exhausts, intakes should be located to avoid other sources of contamination such as automobile traffic, kitchens, dust from streets and plants, evaporative cooling towers, emergency generators, and plumbing vents. Vehicle engine exhaust from loading docks and emergency generators can be nuisances (Smeaton et al. 1991, Ratcliffe et al. 1994). Kitchen exhaust can be a source of odors and can cause plugging and corrosion of heat exchangers. Exhaust air outlets should also not be located near these sources of outdoor contamination.
because outside air has been sometimes observed to inadvertently enter a building through exhaust air outlets, causing air quality problems (Seem et al. 1998).

Evaporative cooling towers located too closely to air intakes can have several effects: water vapor can increase air-conditioning loads, condensing and freezing water vapor can damage equipment, and ice can block intake grilles and filters. The effect on indoor air quality of escaping droplets of cooling tower water (drift) containing chemicals added to retard scaling and biological contamination is discussed by Vanderhayden and Schuyler (1994).

Intakes should not be located in the same architectural screen enclosure as contaminated exhaust outlets. If exhaust is discharged from several locations on a roof, intakes should be sited to minimize contamination. Where all exhausts of concern are emitted from a single, relatively tall stack or tight cluster of stacks, a possible intake location may be at the base of a tall stack, if this location is not adversely affected by exhaust from nearby buildings. However, leakage of contaminants between the exhaust fans and the stack exit has been observed (Hitchings 1997, Knutson 1997), so air intakes should not be placed next to highly toxic and odorous exhaust stacks.

Intakes near vehicle loading zones should be avoided. Overhead canopies on vehicle docks do not prevent hot vehicle exhaust from rising to intakes above the canopy. When the loading zone is in the flow recirculation region downwind from the building, vehicle exhausts may spread upwind over large sections of the building surface (Ratcliff et al. 1994).

When the wind is perpendicular to the upwind wall, the air flows up and down the wall, dividing at about two-thirds up the wall (Figures 4 and 5). The downward flow creates ground-level swirl (shown in Figure 4) that stirs up dust and debris. To take advantage of the natural separation of wind flow over the upper and lower half of a building, toxic or nuisance exhausts should be located on the roof and intakes located on the lower one-third of the building, but high enough to avoid wind-blown dust, debris, and vehicle exhaust. If ground-level sources such as wind-blown dust and vehicle exhaust are the major sources of contamination, a rooftop intake is desirable. If possible, inlet designs should take into account future sources of contamination, changes to building geometries, and construction of buildings nearby.

Cooling towers and similar heat-rejection devices are very sensitive to airflow around buildings. This equipment is frequently affected by wind direction and speed.
roof-mounted, with intakes close to the roof where air can be considerably hotter and at a higher wet-bulb temperature than air that is not affected by the roof. This can reduce the capacity of cooling towers and air-cooled condensers.

Heat exchangers often take in air on one side and discharge heated, moist air horizontally from the other side. Obstructions that are immediately adjacent to these horizontal-flow cooling towers can drastically reduce equipment performance by reducing the airflow. Exhaust to intake recirculation can be a serious problem for equipment that has an intake and exhaust on the same housing. Recirculation is even more serious than reduction in airflow rate for such devices. Recirculation of warm moist exhaust raises the inlet wet-bulb temperature, which reduces performance. Recirculation can be caused by an adverse wind direction, local disturbance of the airflow by an upwind obstruction, or by a close downwind obstruction. Vertical exhaust ducts may need to be extended to reduce recirculation and improve the effectiveness of this equipment.

STACK HEIGHT TO AVOID REENTRAINMENT

This section presents a geometric method of specifying stack height $h_s$ so that the lower edge of the exhaust plume is above intakes and recirculation zones on the emitting building roof. The method is based on flow visualization studies (Wilson 1979). This geometric method does not calculate exhaust dilution in the plume; instead, estimates are made of the size of recirculation and high turbulence zones; the stack height to avoid contamination is calculated from the shape of the exhaust plume. High exhaust momentum is accounted for with a plume rise calculation that shifts the plume upwards. Low exit velocity that causes stack wake downwash of the plume is also accounted for. This stack height should prevent most reentry of exhaust gases into the emitting building provided no large buildings, structures, or terrain are nearby to disturb the approaching wind. This geometric method considers only intakes on the emitting building. Additional stack height or an exhaust-to-intake minimum dilution calculation should be used if the exhaust plume can impinge on the air intake of a nearby building. Dilution calculations described in the next section should be used if this method produces an unsatisfactorily high stack height recommendation.

The geometric stack height design procedure starts by considering the flow recirculation regions shown in Figure 6. To avoid entrainment of exhaust gases, the stack plume must rise above the recirculation height $H_c$. Where capped stacks or exhaust vents discharge within this region, gases rapidly diffuse to the roof and may enter ventilation intakes or other openings. Figure 4 shows that this effluent is entrained into the zone of recirculating flow behind the downwind face and is brought back up to the roof.

Wilson (1979) found that for a flat-roofed building, the recirculation region maximum height $H_c$ at location $X_c$ and recirculation lengths $L_c$ and $L_r$ (shown in Figures 1 and 6) are given by the following equations:

$$H_c = 0.22R$$

$$X_c = 0.5R$$

$$L_c = 0.9R$$

$$L_r = 1.0R$$

where $R$ is the building scaling length given by:

$$R = B_s^{0.67} B_L^{0.33}$$

where $B_s$ is the smaller of the building upwind face dimensions of height or width and $B_L$ is the larger of these dimensions.

In Figure 6, the boundary $Z_1$ of the high-turbulence region downwind of the rooftop recirculation region can be approximated by a straight line sloping at 10.1° (5.7°) downward from $H_c$ to the roof. The dimensions of the recirculating zones are somewhat sensitive to the intensity and scale of turbulence in the approaching wind. High levels of turbulence from upwind obstacles can decrease the coefficients in Equations (1) through (4) by up to half. Turbulence in the recirculation region and in the approaching wind causes the reattachment locations shown in Figure 5 to fluctuate.

To account for changes in roof-level, a penthouse, or an equipment-housing, the scale length $R$ for each of these rooftop obstacles should be calculated from Equation (5) using the upwind face dimensions of the obstacle. The recirculation region for each obstacle is calculated from Equations (1), (2), and (3). The length $L_r$ of the recirculation region downwind from the obstacle, or from the

**Fig. 6** Design Procedure for Required Stack Height to Avoid Contamination
entire building, is given by Equation (4), with $R$ based on the dimensions of the downwind face of the obstacle. When an obstacle is close to the upwind edge of a roof or near another obstacle, the flow recirculation zones interact. Wilson (1979) gives methods for dealing with these situations.

Building-generated turbulence is confined to the roof wake region, whose upper boundary $Z_3$ in Figure 6 is given as

$$Z_3/R = 0.28(X/R)^{0.33}$$

where $X$ is the distance from the upwind roof edge where the recirculation region forms. Building-generated turbulence decreases with increasing height above roof level. At the edge of the rooftop wake boundary $Z_t$, the turbulence intensity is close to the background level in the approach wind. The high levels of turbulence below the boundary $Z_2$ in Figure 6 rapidly diffuse exhaust gases downward to contaminate roof-level intakes.

The next step is to calculate the height $h_c$ of a stack with a rain cap and, therefore, no plume rise. The $h_c$ required to avoid excessive exhaust gas reentry is estimated by assuming that the plume spreads upward and downward from the uncapped stack ($\beta = 1.0$), with a 5:1 slope (11.3°), as shown in Figure 6 (This slope represents a downward spread of approximately two standard deviations of a Gaussian plume concentration distribution.) Then, $h_c$ is raised until the lower edge of the plume avoids contact with all recirculation (Zone 1) and high turbulence (Zone 2) boundaries from rooftop obstacles such as air intake housings, architectural screens, or penthouses. The sizes of the recirculation zones are given by Equations (1), (2), and (3).

If air intakes are located on the downwind wall, the lower edge of the plume, sloping down at 5:1 must lie above recirculation and high-turbulence zone boundaries (Point A in Figure 6) at the downwind edge of the roof. For a highly toxic contaminant that requires high-turbulence zone boundaries (Point A in Figure 6) at the downwind edge of the roof. The high levels of turbulence where $\beta = 1.0$), Briggs (1973) recommends a stack wake adjustment $h_d$ of

$$h_d = 2.0d(1.5 - \beta V'/U_H)$$

where $d = (4A_e/\pi)^{0.5}$

For an uncapped stack, the capping factor is $\beta = 1.0$. For a capped stack, $\beta = 0$, so $h_c = 0$, and no credit is given for plume rise. $U_H$ is the maximum design wind speed at roof height for which air intake contamination must be avoided. One possible design wind speed is the wind speed exceeded 1% of the time listed for many cities in Table 4A of Chapter 2A of the 1997 ASHRAE Handbook—Fundamentals. For cities not on this list, set $U_H$ equal to 2.5 times the annual average hourly wind speed as recommended in Table 2 of Chapter 13 of the 1997 ASHRAE Handbook—Fundamentals.

Stack wake downwash is described in the section on Recommended Stack Exhaust Velocity. For a vertically directed jet from an uncapped stack ($\beta = 1.0$), Briggs (1973) recommends a stack wake downwash adjustment $h_d$ of

$$h_d = 2.0d(1.5 - \beta V'/U_H)$$

for $V'/U_H < 1.5$. For $V'/U_H > 1.5$, there is no downwash and $h_d = 0$. Rain caps are frequently used on stacks of gas- and oil-fired furnaces and packaged ventilation units, for which $\beta = 0$ and $h_d = 3.0d$.

The stack height $h_t$ recommended by this geometric method is

$$h_t = h_c - h_r + h_d$$

Equation (10).

The advantage of using an uncapped stack instead of a capped stack is considerable. If the minimum recommended exhaust velocity $V_c$ of 1.5$U_H$ is maintained for an uncapped stack ($\beta = 1.0$), plume downwash $h_d = 0$ and $h_r = 4.5d$. For a capped stack ($\beta = 0$), $h_d = 3.0d$ and $h_r = 0$. Using these values in $V'/U_H < 1.5$.

The largest flow recirculation, high turbulence, and wake regions occur when the wind direction is normal (90°) to the upwind wall of the building. The required stack height is the largest of the heights calculated for the four (or more) wind directions that are normal to an upwind wall.

Example 1. The stack height $h_t$ of the uncapped vertical exhaust on the building in Figure 1 must be specified to avoid excessive contamination of air intakes A and B by stack gases. The stack has a diameter $d$ of 0.5 m and an exhaust velocity $V_e$ of 9.0 m/s. It is located 16 m from the upwind edge of the roof. The penthouse’s upwind wall (with intake A) is located 30 m from the upwind edge of the roof, a height of 4 m, and a length of 7 m in the wind direction. The top of intake A is 2 m below the penthouse roof. The building has a height $H$ of 15 m and a length of 62 m. The top of intake B is 6 m below roof level. The width (measured into the page) of the building is 50 m, and the penthouse is 9 m wide. What is the required stack height $h_t$ for a design wind speed specified as twice the annual average hourly wind speed of 12.8 km/h at a nearby airport with an anemometer height $H_{met}$ of 10 m? The building is located in suburban terrain (Category 2 in Table 1 of Chapter 15 of the 1997 ASHRAE Handbook—Fundamentals).

Solution: The first step is to set the height $h_c$ of a capped stack by projecting lines with 5:1 slopes upward from points of potential plume impact. For intake A, the highest point of impact is the top of the recirculation zone on the roof of the penthouse. To find the height of this recirculation zone, start with Equation (5):

$$R = (4)^{0.67}(90)^{0.33} = 5.23 m$$

Then use Equations (1) and (2):

$$H_c = 0.22(5.23) = 1.15 m$$

$$X_c = 0.5(5.23) = 2.62 m$$

With the 5:1 slope of the lower plume boundary shown in Figure 6, the capped stack height in Figure 1 must be

$$h_c = 0.2(30 - 16 + 2.62) + 1.15 = 4.47 m$$

above the penthouse roof to avoid intake A. For intake B on the downwind wall, the plume boundary from the stack in Figure 1 must lie above the end of the roof. To avoid intake B, the capped stack height must be

$$h_c = 0.2(62 - 16) - 4 = 5.20 m$$

The design stack height is set by the condition of avoiding contamination of intake B, because intake A requires only a 4.47 m capped stack. Credit for plume rise $h_r$ from the uncapped stack requires calculation of the building wind speed $U_H$ at $H = 15$ m. The design wind speed for $H_{met} = 2(12.8) = 25.6 km/h = 7.1 m/s$. With the airport in open terrain (Category 3 in Table 1 of Chapter 15 of the 1997 ASHRAE Handbook—Fundamentals), and the building in urban terrain (Category 2), the wind speed adjustment parameters are $a = 0.14$ and $b = 270 m$ at the airport, and $a = 0.22$ and $b = 370 m$ at the building. Using $U_H = 7.1(270)^{0.14}(15)^{0.22}(370)^{0.22} = 5.6 m/s$
Because $V_e/U_f = 9.0/6.6 = 1.61$ is greater than 1.5, there is no plume downwash, and $h_2 = 0$ from Equation (9). Using Equation (7), the plume rise at the design wind speed is

$$h_1 = 3.0(0.5)(1.61) = 2.42 \text{ m}$$

Deducting this rise from the uncapped height $h_u$ for intake B,

$$h_u = 5.20 - 2.42 = 2.78 \text{ m}$$

As shown in Figure 1, this stack height is measured above the roof of the nearby penthouse. Adding the penthouse height of 4 m sets the required stack height at 6.78 m above roof level.

### EXHAUST DILUTION CALCULATIONS

This section describes several methods for computing the outdoor dilution of exhausts emitted from a rooftop stack. The resulting dilution can be converted to contaminant concentration for comparison to odor thresholds or health limits. First, definitions will be given, followed by results and equations obtained from wind tunnel studies of simple building shapes.

The dispersion of pollutants from building exhaust depends on the combined effect of atmospheric turbulence in the wind approaching the building and turbulence generated by the building itself. This building-generated turbulence is most intense in and near the flow recirculation zones that occur on the upwind edges of the building [Figures 1 and 5]. Because of turbulence and distortion of wind streamlines by the building, the concentration caused by a source near a building cannot be estimated accurately by the design procedures developed for tall isolated stacks. Meroney (1982), Wilson and Britter (1982), Hosker (1984), and Halitsky (1982) review procedures developed for tall isolated stacks. Halitsky (1985) gives details of the emissions on buildings of similar shape. Halitsky (1963), for situations where jet diameters and emission velocities were large enough to project the exhaust plume above the roof and sometimes through the recirculation cavity.

### Dilution and Concentration Definitions

A building exhaust system is used to release a mixture of building air and pollutant gas at concentration $C_e$ (mass of pollutant per volume of air) into the atmosphere through a stack or vent on the building. The exhaust mixes with the ambient air to produce a pollutant concentration $C$, which may contaminate an air intake or receptor if the concentration is larger than some specified allowable value $C_{allow}$ [Figure 4]. The dilution factor $D$ between source and receptor mass concentrations is defined as

$$D = C_e / C$$

where

- $C_e$ = contaminant mass concentration in exhaust, kg/m³
- $C$ = contaminant mass concentration at receptor, kg/m³

The dilution increases with distance from the source, starting from its initial value of unity. If $C$ is replaced by $C_{allow}$ in Equation (11), the atmospheric dilution $D_{req}$ required to meet the allowable concentration at the intake (receptor) is

$$D_{req} = C_e / C_{allow}$$

The exhaust (source) concentration is given by

$$C_e = \dot{m} / Q_e = \dot{m} / (A_e V_e)$$

where

- $\dot{m}$ = contaminant mass release rate, kg/s
- $Q_e = A_e V_e$ = total exhaust volumetric flow rate, m³/s
- $A_e$ = exhaust face area, m²
- $V_e$ = exhaust face velocity, m/s

The concentration units of mass per mixture volume are appropriate for gaseous pollutants, aerosols, dusts, and vapors. The concentration of gaseous pollutants is usually stated as a volume fraction $f$ (contaminant volume/mixture volume), or as ppm (parts per million) if the volume fraction is multiplied by $10^6$. The pollutant volume fraction $f_e$ in the exhaust is

$$f_e = Q_e / Q$$

where $Q$ is the volumetric release rate of the contaminant gas. Both $Q$ and $Q_e$ are calculated at the exhaust temperature $T_e$.

The volume concentration dilution factor $D_v$ is

$$D_v = f_e / f$$

where $f$ is the contaminant volume fraction at the receptor.

If the exhaust gas mixture has a relative molecular mass close to that of air, $D_v$ may be calculated from the mass concentration dilution $D$ by

$$D_v = (T_e / T_a) D$$

where

- $T_e$ = exhaust air absolute temperature, K
- $T_a$ = outdoor ambient air absolute temperature, K

Many building exhausts are close enough to ambient temperature to assume that volume fraction and mass concentration dilutions $D_v$ and $D$ are equal.

### Wind Tunnel Measurements of Exhaust Concentrations

When the exhaust source is in or near a flow recirculation zone, contours of the normalized concentration coefficient $K_e$ may be used (see Figure 7). For $C$ in contaminant mass per volume,

$$K_e = C U_p H W / \dot{m}$$

The contours of $K_e$ are developed from wind tunnel model studies on buildings of similar shape. Halitsky (1985) gives details of this technique. Surface concentrations for block buildings with uncapped exhaust vents and short stacks in a uniform nonturbulent wind tunnel airstream are reported by Halitsky (1963), for situations where jet diameters and emission velocities were large enough to project the exhaust plume above the roof and sometimes through the recirculation cavity.

### Dilution Prediction Equations

If a representative configuration with published surface concentration coefficients $K_e$ cannot be found to match the existing building, available data may be used to estimate the minimum dilution observed at the same receptor distance from the source.

The most important variables determining minimum dilution are the exhaust-to-intake stretched-string distance $S$ and the effective stack height $h_s$ [Figure 1]. Only the stack height extending above large rooftop obstacles such as penthouses and architectural barriers should be used to define the effective stack height.

The stretched-string distance $S$ is defined as the shortest length of string connecting the point on a stack where $h_s = 0$ to the nearest point on an air intake. The point where $h_s = 0$ is defined as the height...
of obstacles close to the stack, as shown in Figure 1 or the boundary of any roof recirculation region through which the stack passes.

**Adjustment for Averaging Time.** The following equations for minimum dilution $D_{min}$ were developed for exposures equivalent to 10 min averaging times in the atmosphere, and with nonbuoyant exhaust jets from roof vents. If the exhaust gases are hot, buoyancy increases the rise of the exhaust gas mixture and produces lower concentrations at roof level. By neglecting buoyant plume rise, the $D_{min}$ equations have an inherent safety factor, particularly at low wind speed, where buoyancy is most important.

The averaging time $t_a$ over which exhaust gas concentration exposures are measured is also important in determining minimum dilution. As the averaging time increases, the exhaust gas plume meanders more from side to side, thus reducing the time-averaged concentration at an intake location. The effect of changing the averaging time over a range of about 3 min to 3 h can be estimated by adjusting the 10 min values given in Equations (19) to (26) using the following equation (Wollenweber and Panofsky 1989):

$$D_{min,1}/D_{min,2} = (t_{a1}/t_{a2})^{0.2}$$  \[(18)\]

The ratio of minimum dilution at any two averaging times $t_{a1}$ and $t_{a2}$ applies for $t_{a1}/t_{a2} > 10$ to allow the exhaust jet to begin meandering. If the exhaust and intake are both located in the same flow recirculation region, dilution is less sensitive to averaging time than predicted by Equation (18). In this case, the $D_{min}$ values for 3 min averages also apply for averaging times from 3 to 60 min. Use Equation (18) to adjust the 10 min values in Equations (19) to (26) to 3 min values for this flow recirculation situation.

**Strong Jets in Flow Recirculation Cavity.** For block buildings with surface vents or short stacks that produce significant jet rise because of their large diameter, high-emission velocity, and free discharge, the minimum dilution at a surface intake on the same building or on the jet centerline above the building roof is given by Halitsky (1963) as

$$D_{min} = \left[\alpha + 0.11(1 + 0.2\alpha)S/A_e^{0.5}\right]^2$$  \[(19)\]

where $\alpha$ is a numerical constant related to building shape, emission velocity ratio $V_e/U_H$, building orientation to the wind, and stack height. Values of $\alpha$ can be found in Halitsky (1963). The smallest $D_{min}$ occurs along the elevated centerline of the jet plume, where $\alpha = 1.0$ is the appropriate value. Larger values of $D_{min}$ occur on the building surfaces, where $\alpha$ ranges from 2.0 to 20. The larger values are associated with greater stack height and buoyant exhaust.

**Strong Jets on Multiwinged Buildings.** For a strong vertical exhaust with $V_e/U_H \approx 2$ from surface vents or short stacks on the roof of a multiwinged building with different wing roof heights, Halitsky (1962, 1982) recommends a minimum dilution of

$$D_{min} = N \left[3.16 + 0.1S/A_e^{0.5}\right]^2$$  \[(20)\]

where $N$ is an intake location factor with values of $N = 1.5$ when the intake is on the same roof as the source, $N = 2.0$ when the source and intake are on different wings separated by an air space, and $N = 4.0$ when the intake is substantially lower than the source.

**Exhausts with Zero Stack Height.** This section presents dilution prediction equations that are an alternative to the strong jet equations of the last two sections. For buildings with exhausts of zero stack height on a flat roof, the minimum dilution $D_{min,o}$ at a roof or wall intake is given by Wilson and Lamb (1994), Wilson and Chui (1985, 1987), and Chui and Wilson (1988) as

$$D_{min,o} = N \left[D_{o}^{0.5} + D_{s}^{0.5}\right]^2$$  \[(21)\]

where

$$D_o = 1 + 13.0\beta(V_e/U_H)$$  \[(22)\]

and

$$D_s = 0.111(1 + 0.2\beta)(V_e/U_H)$$  \[(23)\]

$D_s$ is the apparent initial dilution at roof level caused by internal turbulence in the exhaust jet. $D_o$ is the distance dilution caused by the combined action of building and atmospheric turbulence. The wind speed $U_H$ at wall height $H$ may be calculated from Equation 4 and Table 1 in Chapter 15 in the 1997 ASHRAE Handbook—Fundamentals using either local airport weather data or data in Chapter 26 of the 1997 ASHRAE Handbook—Fundamentals. For vertically directed uncapped exhausts, the capping factor $\beta = 1.0$; for capped, louvered, or downward-facing exhausts, $\beta = 0$. The distance dilution parameter $B_1$ depends on the exhaust jet trajectory and on the intensity of turbulence in the approach wind and generated by the building. This upward turbulence is represented by $\sigma_\theta$, which is the standard deviation (in degrees) of wind direction fluctuations averaged over 10 min periods. The full-scale data of Wilson and Lamb (1994) suggest that

$$B_1 = 0.027 + 0.0021\sigma_\theta$$  \[(24)\]

Typically, $\sigma_\theta$ varies between 0° and 30° for 10 min averages. For buildings located in urban terrain, the recommended design value is $\sigma_\theta = 15°$, for which $B_1 = 0.059$.

Equations (21), (22), and (23) imply that minimum dilution does not depend on the location of either the exhaust or intake, only on the distance $S$ between them. This is true when exhaust and intake locations are on the same building wall or on the roof. The dilution may increase if the intake and exhaust are located on different faces, as indicated by the $N$ factor in Equation (20). For roof exhausts with wall intakes, the results of Li and Meroney (1983) suggest that the first term in Equation (24) may be increased from 0.027 to 0.10.

For buildings shorter than about 90 m high and also shorter than twice as high as the surrounding buildings, atmospheric turbulence makes a significant contribution to exhaust gas dilution. Wilson (1976, 1977) gives surface concentration contours (see Figure 7) for flat-roofed buildings in a simulated approach wind that is typical of an urban area. Flush vents with small exhaust velocity make these results suitable for estimates for capped exhaust stacks or louvered exhaust vents.
The effect of atmospheric turbulence is relatively insignificant for isolated highrises that are taller than 90 m and also twice the average height of buildings for 1 km upwind. On buildings where the effects of atmospheric turbulence are small, Wilson and Chui (1987) found that maximum surface concentrations for 10 min exposures were two to ten times higher than on an equivalent low-rise building. For these highrise buildings, use $\sigma_0 = 0'$ in Equation (24) for which $B_1 = 0.027$.

When exhaust from several collecting stations is combined in a single vent or in a tight cluster of stacks (as recommended in the section on Exhaust Stack and Air Intake Design Strategies) the effective exhaust flow area $A_e$ in Equation (25) increases, which causes the minimum distance dilution in Equation (21) to decrease. However, the exhaust concentration $C_e$ of each contaminant decreases by mixing with other exhaust streams, and the plume rise increases due to the higher momentum in the combined jets. For combined vertical exhaust jets, the roof level intake concentration $C_i$ is usually significantly lower than the intake concentration caused by separate exhausts. Where possible, exhausts should be combined before release to take advantage of this increase in overall dilution.

**Critical Wind Speed and Dilution.** At very low wind speed, the exhaust jet from an uncapped stack rises high above roof level, producing a large exhaust dilution $D_{crit,O}$ at a given intake location. Likewise, at high wind speed, the dilution is also large because of longitudinal stretching of the plume by the wind. Between these extremes, a critical wind speed exists at which the smallest amount of dilution occurs for a given exhaust and intake location. This critical, absolute minimum dilution $D_{crit,O}$ may be used to determine if an exhaust vent will be safe under all wind conditions. The critical wind speed for an uncapped vertical exhaust ($\beta = 1.0$) can be evaluated by finding the absolute minimum in Equations (21), (22), and (23). It is closely approximated by

$$U_{crit,O} = \frac{3.6}{S} \left( \frac{A_e}{B_1} \right)^{0.5}$$

where $U_{crit,O}$ is the critical wind speed producing the smallest minimum dilution for an uncapped vertical exhaust with negligible stack height. This critical dilution $D_{crit,O}$ is

$$D_{crit,O} = \left( 1 + 26V_e/U_{crit,O} \right)^2$$

To assess the severity of the hazard caused by intake contamination, it is useful to know how often the worst-case $D_{crit}$ is likely to occur. The number of hours per year during which the dilution is no more than twice the critical minimum value may be estimated from weather records by finding the fraction of time that the wind speed is between $0.5U_{crit,O}$ and $3.0U_{crit,O}$ (Wilson 1982, 1983). This fraction is then multiplied by the fraction of time the local wind direction lies in a sector 22.5° on each side of the line joining the exhaust and intake location.

**Critical Dilution for Non-Zero Stack Heights.** In this section, a method is presented for estimating the worst-case critical dilution $D_{crit}$ for a predetermined stack height, using the critical dilution equations of the last section as a starting point.

An increase in stack height or in exhaust velocity ratio $V_e/U_H$ reduces roof-level contamination by keeping the high concentrations on the plume centerline far enough above the roof so that the intakes see only intermittent concentrations in the fringes of the plume. An increase in stack height or exhaust velocity increases the critical wind speed at which the absolute minimum dilution occurs. This higher critical wind speed often significantly reduces the number of hours per year that high intake contamination (i.e., low dilution) is observed.

Using a Gaussian plume dispersion equation, with a 10-min averaged vertical plume spread standard deviation $\sigma_z = 0.093S$, a crosswind plume spread standard deviation $\sigma_x = (0.093 + 0.0072)\sigma_z$, where $\sigma_z$ is defined for Equation (24), and an uncapped vertical exhaust jet with no buoyancy and with plume rise inversely proportional to wind speed, the critical wind speed $U_{crit}$ at which the smallest minimum dilution $D_{crit}$ is observed is

$$\frac{U_{crit,O}}{U_{crit}} = (Y + 1)^{0.5} - Y^{0.5}$$

$U_{crit,O}$ is the critical wind speed for a flush (zero stack height) vertical exhaust, computed from Equation (20). The influence of stack height on the worst-case critical dilution for the standard 10-min exposure time may be calculated as follows:

$$\frac{D_{crit}}{D_{crit,O}} = \frac{U_{crit}}{U_{crit,O}} \exp \left[ Y + Y^{0.5} (Y + 1)^{0.5} \right]$$

where $Y$ is the height-to-speed parameter:

$$Y = \frac{0.25h_s^2}{(\sigma_z + \sigma_o)^2}$$

The initial plume spread $\sigma_o$ at the exhaust (where $S = 0$) produces the apparent initial dilution $D_o$ caused by the exhaust jet velocity. For a capped stack $\sigma_o = 0$. For an uncapped vertical exhaust jet, the initial dilution at the critical wind speed adds an initial spread $\sigma_o = 0.103$ to produce $D_o$. With this value for $\sigma_o$, and a distance spread of $\sigma_z = 0.093S$ for 10 min averages of atmospheric turbulence, Equation (29) becomes

$$Y = 6.7h_s^2/S^2$$

$D_{crit,O}$ in Equation (28) is the dilution at critical wind speed for a flush vertical roof exhaust with no stack height. Equation (26), Equations (27) and (28) are reliable only for $Y < 2.0$. Close to the stack, where $Y > 2.0$, use $Y = 2.0$ in Equations (27) and (28). At the upper limit of $Y = 2.0$ where Equations (27) and (28) apply, the maximum critical wind speed is $U_{crit} = 3.15U_{crit,O}$, and $D_{crit} = 270D_{crit,O}$. Because both wind speed and turbulence intensity vary strongly with height above the building roof, the plume rise $h_s$ of the exhaust jet may not be inversely proportional to wind speed so Equations (27) and (28) are only approximations. Because buoyancy is not included, the added rise due to buoyancy provides a safety factor, particularly at low wind speed.

Because Equations (27) and (28) give the effect of a stack relative to a flush exhaust with $h_s = 0$, they are useful for assessing the advantages of increasing stack height as a remedial measure. By comparing two different heights, this calculation allows the relative benefits of a stack to be estimated without knowing any details of the contaminant concentrations or exhaust velocity in the existing stack. For example, the stack height required using the simple geometrical design procedure (see Figure 6) has an $h_s/S$ of at least 0.2. Equations (27) and (28) show that the critical wind speed $U_{crit}$ for this stack height is about 1.6 times as large, and the critical dilution $D_{crit}$ about 3.8 times as large, as the $U_{crit,O}$ and $D_{crit,O}$ for the vertical jet from an uncapped exhaust with zero effective stack height.

**Example 2.** The uncapped stack from Example 1 (with $h_s = 2.78$ m above the penthouse roof) is used to exhaust a toxic contaminant. The stack gas concentration must be diluted by 1000:1 to be considered safe for 60 min exposures. (This required dilution is determined from occupational health standards and estimated emission rates.) Calculate the critical minimum dilution factor $D_{crit}$ and the critical wind speed $U_{crit}$ for contamination for intakes A and B. Is the stack height of 2.78 m sized in Example 1 sufficient to handle this toxic substance?

**Solution:** At intake A, the stretched-string distance is
Building Air Intake and Exhaust Design

\[ S_A = \left[ (30 - 16)^2 + 2 \right]^{0.5} = 14.1 \text{ m} \]

and the exhaust area of the 0.5 m diameter stack is \( A_x = 0.196 \text{ m}^2 \). The first step is to determine the critical wind speed and dilution for an uncapped stack with \( h_s = 0 \). The normalized exhaust-to-intake distance is

\[ S_A/A_x^{0.5} = 14.1/(0.196)^{0.5} = 31.8 \]

For dilution calculations, \( B_I = 0.059 \) from the text following Equation (24). The critical wind speed for a vent without a stack is calculated as follows from Equation (25) with \( V_e = 9.0 \text{ m/s} \):

\[ U_{crit,0} = \frac{9.0(3.6)}{31.8(0.059)^{0.5}} = 4.19 \text{ m/s} \]

From Equation (26), the worst-case minimum dilution at intake A for this critical wind speed is

\[ D_{crit,0} = \left[ \frac{1 + 26(9.0)/4.19}{1 + 13(9.0)/4.19} \right]^{0.5} = 112 \]

The effect of stack height \( h_s = 2.78 \text{ m} \) is calculated from Equations (27) and (28). The height-to-spread parameter \( Y \) in Equation (30) is

\[ Y = 6.7(2.78/14.1)^2 = 0.260 \]

This value of \( Y \) is less than the upper limit of 2.0 and can be used in Equation (27).

\[ U_{crit} = \frac{4.19}{(0.260 + 1)^{0.5} - (0.260)^{0.5}} = 6.84 \text{ m/s} \]

From Equation (28),

\[ D_{crit} = 112 \left( \frac{6.84}{4.19} \right) \exp \left[ 0.260 + (0.260)^{0.5}(0.260 + 1)^{0.5} \right] = 420 \]

The stack height has increased \( D_{crit} \) to a higher less frequently occurring 6.84 m/s (24.6 km/h), and increased the worst-case critical dilution by about a factor of 4 from the zero stack height baseline case \( D_{crit,0} = 112 \). The next step is conversion of the dilution from the 10 min exposure averaging time on which all the design equations are based, to the 60 min exposure required for the specified occupational health standard. Using Equation (187),

\[ D_{crit} = 420(60/10)^{0.2} = 601 \]

Thus, the 2.78 m stack height produces less than the required 1000:1 hourly-averaged dilution at intake A.

Repeating the calculations for intake B, the stretched-string distance Figure 4 is

\[ S_B = (30 - 16) + 7 + (25^2 + 4^2)^{0.5} + 6 = 52.3 \text{ m} \]

and the normalized exhaust-to-intake distance is

\[ S_B/A_x^{0.5} = 52.3/(0.196)^{0.5} = 118 \]

For the zero stack height baseline case, \( B_I = 0.059 \) and Equation (25) at intake B gives

\[ U_{crit,0} = \frac{9.0(3.6)}{118(0.059)^{0.5}} = 1.13 \text{ m/s} \]

From Equation (26), the zero stack height critical dilution for intake B is

\[ D_{crit,0} = \left[ \frac{1 + 26(9.0)/1.13}{1 + 13(9.0)/1.13} \right]^{0.5} = 414 \]

For the specified stack height \( h_s = 2.78 \text{ m} \), the height-to-spread parameter \( Y \) in Equation (30) is

\[ Y = 6.7(2.78/52.3)^2 = 0.019 \]

Then, from Equations (27) and (28),

\[ U_{crit} = \frac{1.13}{(0.019 + 1)^{0.5} - (0.019)^{0.5}} = 1.30 \text{ m/s} \]

\[ D_{crit} = 414(1.30/1.13)\exp \left[ (0.019 + 0.019)^{0.5} - (0.019)^{0.5} \right] = 558 \]

For intake B, which is further from the stack, the 2.78 m stack increases the critical wind speed by a factor of 1.15 (from 1.13 m/s to 1.30 m/s), and the critical worst-case dilution increases only by a factor of 1.35 (from 414 to 555). For intake A, which is closer to the stack, the 2.78 m stack increased the critical wind speed by a factor of 1.6 and increases critical dilution by a factor of 11. This shows that a stack has a diminishing benefit as the exhaust-to-intake distance increases. Using Equation (18), for a 60 min exposure at intake B,

\[ D_{crit} = 558(60/10)^{0.2} = 798 \]

This does not meet the required 1000:1 minimum hourly averaged dilution specified in the design requirement. Additional stack height must be added using a trial and error solution of Equations (27), (28) and (30).

Scale Model Simulation and Testing

For many routine design applications, exhaust dilution can be estimated using the data and equations presented in the previous sections, which are based on scale modeling of simple building shapes. However, in critical applications, such as where health and safety are of concern, or for complicated building configurations, physical modeling or full-scale field evaluations may be required to obtain more accurate estimates. Measurements on small-scale models in wind tunnels or water channels can provide the required design information. A discussion of scale modeling is presented in Chapter 15 of the 1997 ASHRAE Handbook—Fundamentals.

**SYMBOLS**

- \( A_x \) = stack or exhaust exit face area, \( \text{m}^2 \)
- \( B_I \) = air entrainment parameter in distance dilution \( D_s \), Equation (24)
- \( B_W \) = larger of the two upwind building face dimensions \( W \) and \( H \), \( \text{m} \)
- \( B_{IW} \) = smaller of the two upwind building face dimensions \( W \) and \( H \), \( \text{m} \)
- \( C \) = contaminant mass concentration at receptor at ambient air temperature \( T_r \), Equation (111), \( \text{kg/m}^3 \)
- \( C_{allow} \) = allowable concentration of contaminant at receptor, Equation (12)
- \( C_r \) = contaminant mass concentration in exhaust at ambient air temperature \( T_e \), Equation (111), \( \text{kg/m}^3 \)
- \( d \) = effective exhaust stack diameter, Equation (8), \( \text{m} \)
- \( D \) = dilution factor between source and receptor mass concentrations, Equation (11)
- \( D_{app} \) = apparent initial dilution factor for exhaust jet, Equation (21)
- \( D_{crit} \) = critical dilution factor at roof level for uncapped vertical exhaust at critical wind speed \( U_{crit} \) that produces smallest value of \( D_{min} \) for given exhaust-to-intake distance \( S \) and stack height \( h_s \), Equation (27)
- \( D_{crit,0} \) = critical dilution factor \( D_{crit} \) at roof level for uncapped vertical exhaust with zero stack height \( (h_s = 0) \), Equation (26)
- \( D_{min} \) = minimum dilution factor \( D_{crit} \) at given wind speed for all receptor locations at same fixed distance \( S \) from intake, Equation (18)
- \( D_{min,0} \) = minimum dilution factor \( D_{crit,0} \) at roof level for flush vent with zero stack height \( (h_s = 0) \), Equation (21)
- \( D_{req} \) = atmospheric dilution required to meet allowable concentration of contaminant \( C_{allow} \), Equation (12)
- \( D_s \) = distance dilution factor at fixed wind speed, Equation (23)
- \( D_{crit} \) = dilution factor between source and receptor volume fraction concentrations, Equation (15)
- \( f \) = contaminant volume concentration fraction at receptor; ratio of contaminant gas volume to total mixture volume, Equation (15)
- \( f_c \) = contaminant volume concentration fraction in exhaust gas; ratio of contaminant gas volume to total mixture volume, Equation (15)
- \( h_d \) = downwash correction to be subtracted from stack height, Equation (91), \( \text{m} \)
- \( h_r \) = plume rise of uncapped vertical exhaust jet, Equation (7), \( \text{m} \)
\[ h_s = \text{effective exhaust stack height above rooftop obstacles and enclosures, Equation (10), m} \]
\[ h_e = \text{required height of capped exhaust stack to avoid excessive intake contamination, Equation (10), m} \]
\[ H = \text{wall height above ground on upwind building face, Equation (4), m} \]
\[ H_e = \text{maximum height above roof level of upwind roof edge flow recirculation zone, Equation (1), m} \]
\[ K_c = \text{normalized concentration coefficient, Equation (17)} \]
\[ L = \text{length of building in wind direction, Figure 5, m} \]
\[ L_e = \text{length of upwind roof edge recirculation zone, Equation (3), m} \]
\[ L_r = \text{length of flow recirculation zone behind rooftop obstacle or building, Equation (25), m} \]
\[ m = \text{contaminant mass release rate, Equation (13), kg/s} \]
\[ N = \text{configuration factor, Equation (20)} \]
\[ Q_c = \text{contaminant volumetric rate, Equation (14), m}^3/\text{s} \]
\[ Q_{\text{ot}} = \text{total exhaust volumetric flow rate, Equation (15), m}^3/\text{s} \]
\[ R = \text{scaling length for roof flow patterns, Equation (5), m} \]
\[ S = \text{stretched-string distance; the shortest distance from exhaust to intake over and along building surface, Equation (9), m} \]
\[ t_p = \text{time interval over which receptor (intake) concentrations are averaged in computing dilution, Equation (16), s} \]
\[ T_{\text{a}} = \text{outdoor ambient air absolute temperature, Equation (6), }^\circ\text{C} \]
\[ T_e = \text{exhaust air mixture absolute temperature, Equation (6), K} \]
\[ u_{\text{crit,ot}} = \text{critical wind speed that produces smallest minimum dilution factor } D_{\text{crit,ot}}, \text{ for uncapped vertical exhaust at given } S \text{ and } h_s, \text{ Equation (27), m/s} \]
\[ u_{\text{crit,o}} = \text{critical wind speed for smallest minimum dilution factor } D_{\text{crit,o}}, \text{ for flush uncapped exhaust with zero stack height } (h_s = 0), \text{ Equation (28), m/s} \]
\[ u_{\text{in}} = \text{mean wind speed at height } H \text{ of upwind wall in undisturbed flow approaching building, Equation (7), m/s} \]

A MBIENT air contains nearly constant amounts of nitrogen (78% by volume), oxygen (21%), and argon (0.9%), with varying amounts of carbon dioxide (about 0.03%) and water vapor (up to 3.5%). In addition, trace quantities of inert gases (neon, xenon, krypton, helium, etc.) are always present. Gases other than those listed are usually considered contaminants. Their concentrations are almost always small, but they may have serious effects on building occupants, construction materials, or contents. Removal of these gaseous contaminants is often desirable or necessary.

Traditionally, indoor gaseous contaminants are controlled with ventilation air drawn from outdoors, but available outdoor air may contain undesirable gaseous contaminants at unacceptable concentrations. If so, it requires treatment by gaseous contaminant removal equipment before being used for ventilation. In addition, minimizing outdoor airflow by using a high recirculation rate and filtration is an attractive means of energy conservation. However, recirculated air cannot be made equivalent to fresh outdoor air by removing only particulate contaminants. Noxious, odorous, and toxic gaseous contaminants must also be removed by gaseous contaminant control equipment, which is frequently different from particulate filtration equipment.

This chapter covers design procedures for gaseous contaminant control for occupied spaces only. The control of gaseous contaminants from industrial processes and stack gases is covered in Chapter 25 of the 2000 ASHRAE Handbook—Systems and Equipment.

GASEOUS CONTAMINANTS

The only reason to remove a gaseous contaminant from an air-stream is that it has harmful or annoying effects on the ventilated space or its occupants. These effects are noticeable at different concentration levels for different contaminants. There are four categories of harmful effects: toxicity, odor, irritation, and material damage. In most cases, contaminants become annoying through irritation or their odors before they reach levels toxic to humans, but this is not always true. For example, the potentially toxic (even deadly) contaminant carbon monoxide has no odor.

Concentration Measures

These effects depend on the contaminant concentrations, which are usually expressed in the following units:

\[
\begin{align*}
\text{ppmv} &= \text{parts of contaminant by volume per million (10}^6\text{) parts of air by volume} \\
\text{ppbv} &= \text{parts of contaminant by volume per billion (10}^9\text{) parts of air by volume} \\
\text{mg/m}^3 &= \text{milligrams of contaminant per cubic metre of air} \\
\text{\(\mu\)g/m}^3 &= \text{micrograms of contaminant per cubic metre of air}
\end{align*}
\]

The preparation of this chapter is assigned to TC 2.3, Gaseous Air Contaminants and Gas Contaminant Removal Equipment.

The conversions between ppmv and mg/m\(^3\) (based on the ideal gas law) are

\[
\begin{align*}
\text{ppmv} &= \frac{8.314c(273.15 + t)}{M_p} \\
c &= \text{ppmv} \times M_p \left[\frac{8.314(273.15 + t)}{273.15 + t}\right]
\end{align*}
\]

where

\[
\begin{align*}
8.314 &= \text{gas constant, } L/(K \cdot g\text{-mole}) \\
c &= \text{concentration, } mg/m^3 \\
M_p &= \text{gram molecular mass of contaminant, } g/g\text{-mole} \\
p &= \text{mixture absolute pressure, kPa} \\
t &= \text{mixture temperature, } °C
\end{align*}
\]

Concentration data are often needed at a ventilation temperature and pressure of 25°C and 101.325 kPa, in which case

\[
\text{ppmv} = 24.46c/M
\]

Major chemical families of gaseous contaminants and examples of specific compounds are listed in Table 1, which illustrates the wide range of chemicals that may be encountered in gaseous air contaminant control. The groupings are significant because chemically similar contaminants tend to behave similarly in control devices. The Merck Index (Budavari 1996), the Toxic Substances Control Act Chemical Substance Inventory (EPA 1979), and Sax’s Dangerous Properties of Industrial Materials (Lewis 1994) are all useful in identifying contaminants, including some known by trade names only. Note that a single chemical compound, especially if it is organic, may have several scientific names.

Toxicity

The harmful effects of gaseous contaminants on a person depend on both short-term peak concentrations and the time-integrated exposure received by the person. Toxic effects are generally considered to be proportional to the exposure dose, though individual response variation can obscure the relationship. The allowable concentration for short exposures is higher than that for long exposures. In the United States, the Occupational Safety and Health Administration (OSHA) has defined three concentration-averaging periods for workplaces and has assigned allowable average concentrations for the three periods for over 490 compounds, mostly gaseous contaminants. The abbreviations for concentrations for the three averaging periods are

\[
\begin{align*}
\text{AMP} &= \text{acceptable maximum peak for a short exposure} \\
\text{ACC} &= \text{acceptable ceiling concentration, not to be exceeded during an 8-h shift, except for periods where AMP applies} \\
\text{TWA} &= \text{time-weighted average, not to be exceeded in any 8-h shift of a 40-h week}
\end{align*}
\]
In non-OSHA literature, ACC is sometimes called STEL (short-term exposure limit), and TWA8 is sometimes called TLV (threshold limit value). The medical community disagrees on what values should be assigned to AMP, ACC, and TWA8 for different contaminants. OSHA values, which change periodically, are published yearly in the Code of Federal Regulations (29 CFR 1900, 1000 ff) and intermittently in the Federal Register. A similar list is available from the American Conference of Governmental Industrial Hygienists (ACGIH 1997).

The National Institute for Occupational Safety and Health (NIOSH) is charged with researching toxicity problems, and it greatly influences the legally required levels. NIOSH annually publishes the Registry of Toxic Effects of Chemical Substances as well as numerous Criteria for Recommended Standard for Occupational Exposure to (compound). Some compounds not in the OSHA list are covered by NIOSH literature, and recommended levels are sometimes lower than the legal requirements set by OSHA. The NIOSH/OSHA Pocket Guide to Chemical Hazards (NIOSH 1990) is a condensation of these references and is convenient for engineering uses. This publication also lists values for the following toxic limit:

\[
\text{IDLH} = \text{immediately dangerous to life and health}
\]

Although this toxicity limit is rarely a factor in HVAC design, HVAC engineers should consider it when deciding how much recirculation is safe. Ventilation airflow must never be so low that the concentration of any gaseous contaminant could rise to the IDLH level. The levels set by OSHA and NIOSH define acceptable occupational exposures, but cannot be used by themselves as acceptable standards for residential or commercial indoor air concentrations. They do, however, suggest some upper limits for contaminant concentrations for design purposes.

Table 2 presents toxic health effects limits for selected gaseous air contaminants. The chemical family in which the contaminant resides is also given, as are a number of other chemical properties whose use is discussed in later sections.

</table>

*IDLH, AMP, ACC, and TW A8 are defined in the section on Toxicity.

**Chemical family numbers are as given in Table 1.

*Boiling point at 1 atmosphere pressure

*M = relative molecular mass

*Retentivities are for typical commercial-grade activated carbon, either measured at TW8 levels or corrected to TW8 inlet concentrations using the expression for breakthrough time \( t_b \) given in Nelson and Correia (1976):

\[
R_2 = \frac{R_1 (C_2/C_1)}{t_b^{1/3}}
\]

Both concentrations must be in the same units, here mg/m³.

Retentivities marked * were calculated from values given in ASTM Standard D 1605 (1988) and Turk (1954) assuming that the listed retentivities were measured at 1000 ppm.

ASPHY = Simple asphyxiant; causes breathing problems when concentration reaches about 1/3 atmospheric pressure.

Ozone life is extremely long; activated carbon assists the essentially complete conversion of ozone to normal oxygen by both chemisorption and catalysis.
Personnel exposure to radioactive gases is addressed not by OSHA regulations, but by rules promulgated by the Nuclear Regulatory Commission. Allowable concentrations, in terms of radioactivity, are listed annually in the Code of Federal Regulations (10 CFR 50). Radioactive gases are controlled in much the same way as nonradioactive gases, but their high toxicity demands more careful design. Chapter 25, Nuclear Facilities, introduces the procedures unique to nuclear systems.

Another toxic effect that may influence design is the loss of sensory acuity due to gaseous contaminant exposure. Carbon monoxide, for example, affects psychomotor responses and could be a problem in areas such as air traffic control towers. Clearly, waste anesthetic gases in operating suites should not be allowed to reach levels that affect the alertness of any of the personnel. NIOSH recommendations are frequently based on such subtle effects.

**Odors**

Concentrations as high as those set by OSHA regulations are rarely encountered in commercial or residential spaces. In such spaces, gaseous contaminant problems usually appear as complaints about odors or stuffiness that are the result of concentrations considerably below TWA8 values. Each individual has different sensitivities to odors, and this sensitivity decreases even during a relatively brief exposure. One contaminant may enhance or mask the odor of another. Odors are usually stronger when relative humidity is high. In addition, the human olfactory response is nonlinear; perceived intensities are approximate power functions of the contaminant concentration C:

$$S = kC^n$$

where n is about 0.6 and k is specific for each contaminant.

This nonlinear response means that the concentration of some odorants must be reduced substantially before the odor level is perceived to change. For these reasons, determining acceptable concentrations of contaminants on the basis of their odors is as imprecise as attempting to do so from their toxicity. Far fewer data are available on odors, because odors are more of an annoyance than a hazard. In fact, it is desirable for a toxic or explosive material to have an odor threshold well below toxic levels, for this can warn building occupants that the contaminant is present.

At some low concentration of an odorant, an individual ceases to be aware of its presence. Odor studies seek to establish the level at which a percentage of the general population—usually 50%—is no longer aware of the odor of the compound studied. This concentration is the odor threshold for that compound. Fazzalari (1978) compiled odor thresholds for a large number of gaseous compounds in commercial and industrial situations. Additional values, reflecting newer measurement techniques but largely limited to compounds found only in industrial workplaces, are listed in AIHA (1989), Moore and Houtala (1983), and Van Gemert and Mettenbreijer (1977). Table 2 shows the wide range of odor threshold values for different contaminants.

**Irritation and Allergic Response**

Although some gaseous contaminants may have no discernible continuing health effects, exposure to such contaminants may irritate or cause allergic reactions from building occupants. Coughing; sneezing; eye, throat, and skin irritation; nausea; breathlessness; drowsiness; headaches; and depression have all been attributed to gaseous air contaminants. Any of these symptoms could be occur as part of an allergic response, which is differentiated from a toxic response in that the magnitude of the response is not proportional to the exposure dose. A person sensitized to a contaminant can respond strongly at concentrations that are barely detected by other individuals in the space. This makes diagnosis very difficult.

**Table 2** does not include a trigger concentration for irritation or allergic effects because none have been determined. In general, it can be said that physical irritation does not occur at odor threshold concentrations. Rask (1988) suggests that when 20% of a single building’s occupants suffer such irritations, the structure may be said to suffer from “sick building syndrome” or “tight building syndrome.” For the most part, case studies of such occurrences have consisted of analyses of questionnaires submitted to building occupants. Some attempts to relate irritation to gaseous contaminant concentrations are reported (Lamm 1986, Cain et al. 1986, Berglund et al. 1986, Molhave et al. 1982). The correlation of reported complaints with gaseous contaminant concentrations is not strong; many factors affect these nontoxic responses to contamination.

**Damage to Materials**

Material damage from gaseous contaminants may take such forms as corrosion, embrittlement, and discoloration. Because such effects usually involve chemical reactions that need water, material damage from air contaminants is less in the relatively dry indoor environment than outdoors, even at similar gaseous contaminant concentrations. To maintain this advantage, indoor condensation should be avoided. However, some dry materials can be significantly damaged. These effects are most serious in museums, as any loss of color or texture changes the essence of the object. Libraries and archives are also vulnerable, as are pipe organs and textiles.

**Chemical Characteristics**

**Table 2** also includes are several chemical and physical properties that are needed to design control devices. Additional chemical properties can be obtained from handbooks such as the Merck Index (Budavari 1996), Sax’s Dangerous Properties of Industrial Materials (Lewis 1994), Handbook of Chemistry and Physics (Lide 1997), Perry’s Chemical Engineers Handbook (Perry et al. 1997), and chemistry textbooks.

**SOURCES**

The most commonly cited direct sources of indoor gaseous contaminants are tobacco smoke, cleaning agents and other consumer products, building materials and furnishings, occupants, and outdoor air. In addition, building materials and furnishings adsorb contaminants from indoor air that later desorb, at which time the building materials become secondary sources. This source/sink behavior can be an important contributor to indoor air pollution.

**Tobacco Smoke**

Tobacco smoke is a prevalent and potent source of indoor air contaminants. Almost all tobacco pollution arises from cigarette smoking. Cigar and pipe smoking produce somewhat different compounds than cigarette smoking, but overall contribute less contamination. Cigarette smoke is frequently categorized as:

- Mainstream smoke, which goes directly from the cigarette to the respiratory tract of the smoker
- Sidestream smoke, which is that smoke not directly inhaled by the smoker, including smoke produced between puffs

Table 2 also includes are several chemical and physical properties that are needed to design control devices. Additional chemical properties can be obtained from handbooks such as the Merck Index (Budavari 1996), Sax’s Dangerous Properties of Industrial Materials (Lewis 1994), Handbook of Chemistry and Physics (Lide 1997), Perry’s Chemical Engineers Handbook (Perry et al. 1997), and chemistry textbooks.
• Environmental tobacco smoke (ETS), which is composed of the aged and diluted combination of exhaled and sidestream smoke. ETS is the smoke category that must be controlled by gaseous air cleaning devices.

Table 3 lists market-share-weighted average concentrations and standard errors for some of the important compounds found in ETS, arranged by chemical family per Table 1. Several points are noteworthy:

- Not all effluents are listed. Carbon dioxide is an example.
- Different methods lead to different results for the VOCs, and different cigarettes have different emission rates.
- Total sorbed VOCs (19 mg/cigarette) was about 2/3 of total hydrocarbon emissions by FID (27.8 mg/cigarette), indicating that approximately 2/3 of the VOCs can be sorbed. The balance are low boiling or otherwise unsuitable for control by adsorption. Of this 2/3 of the total VOCs, about 60% are identified and quantified in Table 3.
- Respirable particulate generated per cigarette is less than the sorbed VOC mass per cigarette.

Both particles and gases should be controlled to control ETS.

Table 4 Generation of Gaseous Contaminants by Building Materials

Cleaning Agents and Other Consumer Products

Commonly used consumer products—liquid detergents and cleaning compounds, waxes, polishes, spot removers, disinfectants, and cosmetics—contain organic solvents that volatilize either slowly or quickly. Mothballs, pesticides, and other pest control agents can also emit organic volatiles that contaminate buildings. Knoeppel and Schauenburg (1989), Black and Bayer (1986), and Tichenor (1989) report data on the release of these volatile organic compounds (VOCs). Field studies have shown that such products contribute significantly to indoor pollution. However, a large variety of compounds are in use, and few studies have been made that allow calculation of typical emission rates.

Manufacturers are reformulating a wide range of products to reduce VOC emissions, but few data are available on the new products, and those that are available are of uncertain applicability.

Building Materials and Furnishings

Particle board is usually made from wood chips bonded with a phenol-formaldehyde or other resin and is a source of indoor gaseous contaminants. It is widely used in current construction, especially for mobile homes, carpet underlay, and case goods. This material, along with ceiling tiles, carpeting, wall coverings, office partitions, adhesives, and paint finishes, emit formaldehyde and other VOCs. Latex paints containing mercury emit mercury vapor. While the emission rates for these materials decline steadily with age, the half-life of emissions is surprisingly long. Black and Bayer (1986), Nelms et al. (1986), and Molhave et al. (1982) report on these sources. Measured emission rates for a few example materials are listed in Table 4. Increasing humidity typically increases emissions.

In addition to being primary sources of emissions, building materials frequently adsorb VOCs and other chemicals during high concentration periods and then re-emit them over an extended period. The complex interaction of primary and secondary emissions is
extremely difficult to characterize and understand in an actual building. As with consumer products, building materials are also being reformulated to reduce emissions. Emissions measurements are not yet standardized. Currently, the carpet industry has the only labeling program.

**Equipment**

Commercial and residential spaces contain equipment that produces gaseous contaminants, though generation rates are substantially lower than in the industrial environment. As equipment is rarely hooded, emissions go directly to the occupants. In commercial spaces, the chief sources of gaseous contaminants are office equipment, including electrostatic copiers, laser printers, and fax machines (ozone; diazo printers (ammonia and related compounds); and office supplies, including carbonless copy paper (formaldehyde), correction fluids, inks, and adhesives (various VOCs). Medical and dental activities generate contaminants from the use of disinfectants, escape of anesthetic gases (nitrous oxide and halomethanes), and sterilizers (ethylene oxide). The potential for asphyxiation is always a concern when compressed gases are present, even if the gas is nitrogen.

In residences, the main sources of equipment-derived contaminants are gas ranges, wood stoves, and kerosene heaters. Venting is helpful, but some contaminants escape into the occupied area. The contaminant contribution by gas ranges is somewhat mitigated by the fact that they operate for shorter periods than heaters. The same is true of showers, that can contribute to radon and halocarbon concentrations indoors if the water is contaminated.

Traynor et al. (1985a, 1985b) report on emission rates from indoor combustion devices [Table 5]. Emission rates for equipment depend greatly on equipment type and manner of use. Typical values are difficult to obtain (Traynor 1987). Equipment suspected to be a significant source of harmful contaminants should be controlled locally. General ventilation with filtration is not likely to be a safe solution to such problems.

**Occupants**

Humans and animals emit a wide array of contaminants by breath, sweat, and flatus. Some of these emissions are conversions from solids or liquids within the body. Many volatile organics emitted are, however, re-emissions of contaminants inhaled earlier, with the tracheobronchial system acting like a gas chromatograph or a saturated physical adsorber. Several studies (mostly in relation to spacecraft habitability) have measured contaminant generation by humans [Table 6].

**Outdoor Air**

The contaminants in outdoor air accompany it into buildings, in some cases to the detriment of the indoor air quality. The contaminants in the outdoor air may be local—such as from restaurants, traffic emissions, sewer vents—or widely distributed in a region—sulfur dioxide, ozone, and nitrogen oxides. The concentrations of these contaminants all vary with time and seasonally, and the air cleaner design must take them into account.

Outdoor concentrations of a few widely distributed contaminants are available for cities in the United States from Environmental Protection Agency (EPA) summaries of the National Air Monitoring Stations network data and in similar reports for other countries. A summary of this data is available (EPA 1990). In many cases, the concentrations listed in the National Ambient Air Quality Standards, which are the levels the EPA considers acceptable for six contaminants [Table 7], are satisfactory. [Table 8] gives outdoor concentrations for gaseous contaminants at urban sites. These values are typical; however, they may be exceeded if the building under consideration is located near a fossil fuel power plant, refinery, chemical production facility, sewage treatment plant, municipal refuse dump or incinerator, animal feed lot, or other major source of gaseous contaminants. If such sources
Control of Gaseous Indoor Air Contaminants

will have a significant influence on the intake air, a field survey or
dispersion model must be run. Many computer programs have been
developed to expedite such calculations.

Use of Source Data to Predict Indoor Concentrations

Meckler and Janssen (1988) described a model for calculating the
effect of outdoor pollution on indoor air quality, which is out-
lined in this section. A recirculating air-handling schematic is
shown schematically in Figure 1. In this case, mixing is not perfect;
the horizontal dashed line represents the boundary of the region
close to the ceiling through which air passes directly from the inlet
diffuser to the return-air intake. Ventilation effectiveness $E_v$ is
the fraction of the total air supplied to the space that mixes with the
room air and does not bypass the room along the ceiling. Meckler
and Janssen (1988) suggest a value of 0.8 for $E_v$. Any people in the
space are additional sources and sinks for gaseous contaminants. In
the ventilated space, the steady-state contaminant concentration

\[ C_{ss} = \frac{a}{b} \]  

where

\[ a = C_i(G_i + 0.01P E_v Q_v/f) + 2119(G_j + N Q_O) \]  

\[ b = Q_c + Q_h + Q_L + k_d A + N Q_O (1 - 0.01 P_O)/f \]  

and

\[ Q = \text{total flow, m}^3/\text{s} \]  

\[ Q_i = \text{exhaust airflow, m}^3/\text{s} \]  

\[ Q_v = \text{ventilation (makeup) airflow, m}^3/\text{s} \]  

\[ Q_L = \text{hood flow, m}^3/\text{s} \]  

\[ Q_c = \text{filtration (exfiltration) flow, m}^3/\text{s} \]  

\[ Q_i = \text{average respiratory flow for a single occupant, m}^3/\text{s} \]  

\[ P = \text{filter penetration for contaminant, } \% \]  

\[ Q_p = \text{penetration of contaminant through human lung, } \% \]  

\[ A = \text{surface area inside the ventilated space on which contaminant can be adsorbed, m}^2 \]  

\[ k_d = \text{deposition velocity on } A \text{ for contaminant, m/s} \]  

\[ C_s = \text{outdoor concentration of contaminant, mg/m}^3 \]  

\[ C_{ss} = \text{steady-state indoor concentration of contaminant, mg/m}^3 \]  

\[ G_i = \text{generation rate for contaminant by occupant, mg/s} \]  

\[ G_j = \text{generation rate for contaminant by nonoccupant sources, mg/s} \]  

\[ N = \text{number of occupants} \]  

\[ E_v = \text{ventilation effectiveness, fraction} \]  

\[ f = 1 - 0.01 P_i (1 - E_v) \]  

Flow continuity allows the expression for $b$ to be simplified to the
following alternate form, which may make it easier to determine
flows:

\[ b = Q_i + Q_h + k_d A + N Q_O (1 - 0.01 P_O) \]  

The parameters for this model must be determined carefully so that nothing significant is ignored. The leakage flow $Q_L$, for example, may include flow up chimneys or toilet vents.

The steady-state concentration is of interest for design. It may also be helpful to know how rapidly the concentration changes when conditions change suddenly. The dynamic equation for the building in Figure 1 is

\[ C_t = C_{ss} + (C_0 - C_{ss}) e^{-bt/V} \]  

where

\[ V = \text{volume of the ventilated space, m}^3 \]  

\[ C_t = \text{concentration in the space at time } \theta = 0 \]  

\[ C_{ss} = \text{concentration in the space } 0 \text{ minutes after a change of conditions} \]  

\[ C_0 = \text{given by Equation (5)}, \text{ and } b = \text{by Equation (7) or (7a)} \]  

with the parameters for the new condition inserted.

The reduction in air infiltration, leakage, and ventilation air
needed to reduce energy consumption raises concerns about indoor
contaminant buildup. A low-leakage structure may be simulated by
letting $Q_i = Q_L = Q_h = 0$. Then

\[ C_{ss} = \frac{0.01 P E_v Q_c / f + (G_i + N Q_O)}{Q_c + k_d A + N Q_O (1 - 0.01 P_O) + (E_v Q - Q_c) (1 - 0.01 P) / f} \]  

Even if ventilation airflow $Q_c$ is reduced to zero, a low-penetrat-
(44.7)

ation (high-efficiency) gaseous contaminant filter and a high recircu-
lation rate help lower the internal contaminant concentration. In

*Normal concentration of carbon dioxide in air. The concentration in occupied spaces

---

Fig. 1 Recirculatory Air-Handling and Gaseous Contaminant Schematic
commercial structures, infiltration and exfiltration are never zero. The only inhabited spaces operating on 100% recirculated air are space capsules, underwater structures, and those structures with life support that eliminates carbon dioxide and carbon monoxide and supply oxygen.

Real buildings may have many rooms, with multiple sources of gaseous contaminants and complex room-to-room air changes. In addition, mechanisms other than adsorption may eliminate gaseous contaminants on building interior surfaces. Nazaroff and Cass (1986) provide estimates for contaminant deposition velocity $k_d$ in Equations (5) through (9) that range from 3 to 600 m/s for surface adsorption only. A worst-case analysis, yielding the highest estimate of indoor concentration, is obtained by setting $k_d = 0$. Sparks (1988) and Nazaroff and Cass (1986) describe computer programs to handle these calculations.

The assumption of bypass and mixing used in the models presented here approximates the multiple-room case, since gaseous contaminants are readily dispersed by airflow. In addition, a gaseous contaminant diffuses from a zone of high concentration to a zone of low concentration even with low rates of turbulent mixing.

Quantities appropriate for the various flows in Equations (5) through (9) are discussed in the sections on Local Source Control and Dilution Through General Ventilation. Infiltration flow can be determined approximately by the techniques described in Chapter 25, Ventilation and Infiltration, of the 1997 ASHRAE Handbook—Fundamentals or, for existing buildings, by tracer or blower-door measurements. ASTM Standard E 741 defines procedures for tracer-decay measurements. Tracer and blower-door techniques are discussed by ASTM (1980); DeFrees and Amberger (1987) describe a useful variation on the blower-door technique applicable to large structures.

**PROBLEM ASSESSMENT**

Ideally, a design for control of gaseous contaminants is based on accurate knowledge of the identity and concentration (as a function of time) of the contaminants to be controlled. This knowledge may be based on close estimates made based on source strength and modeling as described previously or on direct measurements of the contaminants. Unfortunately, a definitive assessment is seldom possible, and then careful observation, experience, and best judgment must supplement data as the basis for the design.

Two general cases exist: (1) new ventilation systems in new buildings for which the contaminant loads must be estimated or measured, and (2) modification of existing ventilation systems to solve particular problems. For the first case, models such as those described previously must be used. Contaminant-generating activities are identified, the building sources estimated and added up, and outside air contaminants identified. Gaps in the contaminant load data must be filled with estimates or measurements. Once the contaminants and loads are identified, the design process can be implemented.

For the second case, measurements may also be required to identify the contaminant. Assessing the problem can become an indoor air quality investigation, including a building inspection, occupant questionnaires, and local sampling and analysis. The EPA Building Air Quality Guide (EPA 1991) is a useful resource for such investigations. Again, once the contaminants and loads are understood, the design process can begin.

**Contaminant Load Estimates**

Acceptable carbon dioxide content and odor conditions are defined in ASHRAE Standard 62. The alternative indoor air quality procedure outlined in that standard, which applies where outdoor air is reduced to low levels by filtering recirculated air, sets limits for indoor concentrations for several contaminants. The standard also recommends that any unusual contaminants be controlled to one-tenth the TLV levels specified by ACGIH (1997). When outdoor air levels are reduced, the actual gaseous contaminant concentrations must be measured to ensure that the requirements of ASHRAE Standard 62 are met.

The concentration of gaseous contaminants at or near levels that are acceptable for indoor air is not as easily measured as temperature or humidity. Relatively costly analytical equipment is needed and it must be calibrated and operated by experienced personnel. Measurement of gaseous contaminant concentrations has two inter-related aspects: sampling and analysis. Sampling and analysis may be (1) short-term (snapshot in time, instantaneous), (2) real-time (a succession of short-term samples with rapid analysis), or (3) integrated over time without the ability to recover detailed time history.

The most useful method depends on the time rate of change of the contaminants, the significance of missing a peak, and the performance characteristics of the control device. For example, if a control device can be saturated and overwhelmed by the peak, it must be redesigned. Also, the application must be understood in order to use the measurements properly. For example, nine hours of a contaminant at zero and one hour at twice a toxic level is not the same as ten hours at 20% of the toxic level, even though the concentration in both cases integrates to the same value. On the other hand, if the problem is odor rather than health effects, short-term excursions may be acceptable. A number of currently available sampling techniques are listed in Table 10 along with their advantages and disadvantages.

Analytical techniques are summarized in Table 10. Some analytical or detection techniques are specific to a single contaminant compound; others are capable of presenting a concentration spectrum for many compounds simultaneously. To be useful for gaseous control, contaminant concentration measurement instruments should be able to detect contaminants of interest at one-tenth TWA8 levels or lower. If odors are of concern, detection sensitivity must be at or below odor threshold levels. As indicated in Table 10, contaminants may be accumulated or concentrated over time so that very low average concentrations can be measured, albeit with the loss of the concentration time history. Procedures for evaluating odor levels are given in Chapter 13 of the 1997 ASHRAE Handbook—Fundamentals.

When sampling and analytical procedures appropriate to the application have been selected, a pattern of sampling locations and times must be carefully planned to cope with variations in concentration with time and throughout the space. The layout of the building and air-handling equipment and the space occupancy and use patterns must be considered so that representative concentrations will be measured. Traynor (1987) and Nagda and Rector (1983) offer guidance in planning such surveys.

**Contaminant Load Estimates**

The results of sampling and analysis identifies the contaminants and their concentrations at particular places and times or over known times. Several measurements are usually involved, and they may overlap or have gaps with regard to the contaminants analyzed and the times of measurement. These are then used to estimate the overall contaminant load. The measurements are used to develop a time-dependent estimate of the contamination in the building, either formally through a material balance or informally through experience with similar buildings and contamination. The degree of formality applied depends on the severity of the potential health or corrosion effects.
CONTROL STRATEGIES

Four control strategies may be used to improve the indoor air quality in a building: (1) elimination of sources, (2) local hooding with exhaust or recirculated air cleaning, (3) dilution with increased general ventilation, and (4) general ventilation air cleaning with or without an increase in ventilation rates. In most cases, the first three are favored. By its nature, control by general air cleaning is difficult because it is applied after the contaminants are fully dispersed and at their lowest concentration.

Elimination of Sources

This strategy is the most effective and often the least expensive. For instance, prohibition of smoking in a building, or its isolation to limited areas, greatly reduces indoor pollution, even when rules are poorly enforced (Elliott and Rowe 1975, Lee et al. 1986). Control of radon gas begins with the installation of traps in sewage drains and the sealing and venting of leaky foundations and crawl spaces to prevent entry of the gas into the structure (EPA 1986, 1987). The use of waterborne materials instead of those requiring organic solvents may reduce VOCs, although Girman et al. (1984) show that the reverse is sometimes true. The substitution of carbon dioxide for halocarbons in spray-can propellants is an example of the use of a relatively innocuous contaminant instead of a more troublesome one. The growth of mildew and other organisms that emit odorous contaminants can be restrained by controlling condensation and applying fungicides and bactericides provided they are registered for the use and carefully chosen to have low off-gassing potential.

Local Source Control

Local source control is more effective than control by general ventilation when discrete sources in a building generate substantial amounts of gaseous contaminants. If these contaminants are toxic, irritating, or strongly odorous, local control and outdoor exhaust is essential. Bathrooms and kitchens are the most common examples. Exhaust rates are sometimes set by local codes. In addition, some office equipment could benefit from direct exhaust. The minimum transport velocity required for the capture of large particles differs from that required for gaseous contaminants; otherwise, the problems of capture are the same for both gases and particles.

Hoods are normally provided with exhaust fans and stacks that vent to the outdoors. Hoods need large quantities of makeup air, which requires a great deal of fan energy for exhaust and makeup air; so hoods waste heating and cooling energy. Makeup for air exhausted by a hood should be supplied so that the general ventilation balance is not upset when a hood exhaust fan is turned on. Back diffusion from an open hood to the general work space can be eliminated by surrounding the work space near the hood with an isolation enclosure. Such a space not only isolates the contaminants, but also helps keep unnecessary personnel out of the area. Glass walls...
for the enclosure decrease the claustrophobic effect of working in a small space.

Increasingly, codes require filtration of hood exhausts to prevent toxic releases to the outdoors. Hoods should be equipped with controls that decrease their flow when maximum protection is not needed. Hoods are sometimes arranged to exhaust air back into the occupied space, thus saving heating and cooling of that air. This practice must be limited to hoods exhausting the most innocuous contaminants because of the risk of filter failure. The design and operation of effective hoods are described in Chapters 13, 14, 29, and 30 and in *Industrial Ventilation: A Manual of Recommended Practice* (ACGIH 1995).

### Dilution Through General Ventilation

In residential and commercial buildings, the chief use of local source control and hooding occurs in kitchens, bathrooms, and occasionally around specific point sources such as diazo printers. Where there is no local control of contaminants, the general ventilation distribution system provides contaminant control through dilution. Such systems must meet both thermal load requirements and contaminant control standards. Complete mixing and a relatively uniform air supply per occupant are desirable for both purposes. The guidelines for air distribution given in Chapters 3 and 5 of the 1997 ASHRAE Handbook—Fundamentals are appropriate for contamination control by general ventilation. In addition, the standards set by ASHRAE *Standard 62* must be met.

When local exhaust is combined with general ventilation, a proper supply of makeup air must equal the exhaust flow for any hoods present. Supply fans may be needed to provide enough pressure to maintain flow balance. Clean spaces are designed so that static pressure forces air to flow from clean to less clean spaces, and

Control of Gaseous Indoor Air Contaminants

the effects of doors opening and wind pressure, etc., dictate the need for backdraft dampers. Chapter 15 covers clean spaces in detail.

CONTROL BY AIR CLEANING

If elimination of sources, local hooding, or dilution cannot control contaminants, or are only partially effective, the air must be cleaned. Designing such a system requires an understanding of the capabilities and limitations of the control processes.

Gaseous Contaminant Air Cleaning Terminology

Several methods of measuring the performance of a gaseous control device have been developed, and some are unique to this application. In some cases the meaning of familiar terms from particle filtration are slightly different. In general, gaseous adsorber performance is a function of (1) the specific contaminant, (2) its concentration, (3) the airflow rate, and (4) environmental conditions.

Penetration is the ratio of control device outlet concentration to that at the inlet (the challenge concentration) for a constant challenge. Efficiency is a related concept defined as (1 minus penetration). Penetration and efficiency are usually expressed as percentages or decimal fractions. Unlike particulate filters, physical adsorbents and chemisorbents both decline in efficiency as they load. The decline can be very sudden, and it is not likely to be linear with time. Because their efficiency declines with use, the time at which the measurement is made must be given with efficiency or penetration readings.

The sudden decline in efficiency has led to the concept of breakthrough time, which is defined as the operating time (at constant operating conditions) before a certain penetration is achieved. For instance, the 10% breakthrough time is the time elapsed between beginning to challenge an adsorbent and the time at which air discharged contains 10% of the contaminant feed concentration. Continued operation leads to 50% breakthrough and eventually to 100% breakthrough, at which point a physical adsorbent is saturated. For a chemisorbent, the media is exhausted. Some commercial devices are designed to allow a portion of the challenge gas to bypass the sorbent. These devices “breakthrough” immediately, and breakthrough time, as defined above, does not apply.

At saturation, the physical absorbent contains all the contaminant it can hold at the challenge concentration, temperature, and humidity. This point is defined as its activity, and is expressed as a percentage of the carbon mass or fraction [i.e., g (contaminant)/g (adsorbent)]. Activity is an equilibrium property, and is not a function of airflow. (In most cases, commercial sorbent bed filters are changed for efficiency reasons well before the sorbent is saturated.) If a saturated adsorbent bed is then exposed to clean air, some of the adsorbed contaminant will desorb. The amount remaining after a saturated bed reaches equilibrium in clean air is the retentivity of the adsorbent, and gives retentivity values for many of the listed contaminants. Those marked with an asterisk were measured or corrected to 1000 ppm challenges. Those not marked with an asterisk were measured or corrected to the TWAST concentration as the challenge.

Residence time is the period, usually a fraction of a second, that the contaminant molecule is within the boundaries of the media bed and thus exposed to capture (and for chemisorption) chemical change. The efficiency of a particular gaseous contamination adsorbent bed, for a given contaminant and set of environmental conditions, is fixed by the bed residence time. The longer the residence time, the higher the efficiency. For gaseous contaminant control equipment residence time is computed as:

\[
\text{Residence time} = \frac{\text{Bed area exposed to airflow} \times \text{Bed depth}}{\text{Airflow rate}}
\] (10)

For example, a unitary adsorber containing trays totaling 4 m² of a 25 mm deep bed, challenged at 1 m³/s, has a residence time of 0.1 s. Given this definition, a deeper media bed, lower airflow rate, or adsorbers in series increase the residence time and thus the adsorber performance. Because gaseous contaminant air cleaners have traditionally tended to all have approximately the same granule size and have used the same kind of activated carbon, residence time has become a generally useful indicator of performance. Note that in some engineering disciplines, the volume of the adsorbent media is subtracted from the nominal volume of packed beds when calculating residence time. This definition gives a shorter residence time value and is not normally used for HVAC applications.

Different ways of arranging the carbon, different carbons, or different carbon granule sizes all change the residence time. In addition, the geometry and packaging of some adsorbent technologies makes computation of residence time difficult. For example, the flow pattern in pleated fiber-carbon composite media is difficult to specify, making residence time computation uncertain. Therefore, while residence times can be computed for partial bypass filters, fiber-adsorbent composite filters, or fiber bonded filters, they cannot be compared directly and may serve more as a rating than as an actual residence time. Manufacturers may publish equivalent residence time values that say, in effect, that this adsorber performs the same as a traditional deep bed adsorber. No standard test exists to verify such a rating, however.

Control Processes

Numerous chemical and physical processes remove gases or vapors from air. The gaseous contamination control processes of commercial interest to the HVAC engineer are physical adsorption and chemisorption. Other processes currently have extremely limited application in HVAC work, and they are only briefly discussed.

Physical Adsorption Description. Adsorption is a surface phenomenon similar in many ways to condensation. Adsorbed contaminant gas molecules are those that strike a surface and remain bound to it for an appreciable time. Surfaces of gaseous contamination control adsorption media are expanded in two ways to enhance its adsorptive characteristics. First, the media are provided in granular, pelletized, or fibrous form to increase the gross surface exposed to an airstream. Second, the surface of the adsorbent media is treated to develop pores of microscopic dimensions, greatly increasing the area available for molecular contact. Typical activated alumina has a surface area of 200 m² per gram; typical activated carbon has a surface area from 1000 to 1500 m²/g. Pores of various microscopic sizes and shapes provide minute traps that can fill with condensed contaminant molecules.

The most common granular adsorbents are millimetre-sized, and the granules are used in the form of packed beds. In general, packed beds composed of larger monodisperse particles have lower pressure drops per unit depth of sorbent than those composed of smaller monodisperse particles. On the other hand, more absorbent can be packed in a given volume with smaller particles, and that adsorbent is more accessible to the contaminant, but the pressure drop is higher at a fixed bed depth.

Several steps must occur in the adsorption of a molecule (see Figure 2): 1. The molecule must be transported from the carrier gas stream across the boundary layer surrounding the absorbent granule. This process is random, with molecular movement both to and from the surface; the net flow of molecules is toward the surface when the concentration of the contaminant in the gas flow is greater than at the granule surface. For this reason, adsorption action decreases as contaminant load on the absorbent surface increases. Very low concentrations in the gas flow also result in low adsorption rates.
2. The molecules of the contaminant must diffuse into the pores to occupy that portion of the surface. Diffusion distances are lower and adsorption rates higher for smaller particles of absorbent.

3. The contaminant molecules must be bound to the surface. (Sorption is exothermic, releasing energy. At the low concentrations and sorption rates generally encountered in HVAC applications, sorbents operate nearly isothermally.)

Fig. 2 *Steps in Contaminant Adsorption*

Any of these steps may determine the rate at which adsorption occurs. In general, Step 3 is very fast for physical adsorption, but reversible. This means that some adsorbed molecules can be desorbed at a later time, either when cleaner air passes through the adsorber bed or when another contaminant arrives that either binds more tightly to the adsorber surface or is present at a much higher concentration. Complete desorption usually requires that thermal energy be added to the bed.

When a contaminant is fed at constant concentration and constant gas flow rate to an adsorber of sufficient bed depth \( L \), the gas stream concentration varies with time \( \theta \) and bed depth, as shown in Figure 3A. When bed loading begins (\( \theta = 0 \)), the contaminant concentration decreases logarithmically with bed depth; deeper into the bed, the slope of the concentration-versus-bed depth curve flattens at a very low value. At later times, the entrance portion of the adsorber bed becomes loaded with contaminant, so contaminant concentrations in the gas stream are higher at each bed depth.

For the same constant contaminant feed, the pattern of downstream concentration versus time for an adsorber of bed depth \( L \) is shown in Figure 3B. Usually the downstream concentration is very low until time \( \theta_{BT} \), when the concentration rises rapidly until the downstream concentration is the same as the upstream. This penetration is called *breakthrough* because it occurs suddenly. However, not all adsorber-contaminant combinations show as sharp a breakthrough as Figure 3B might indicate.

Multiple contaminants produce more complicated penetration patterns than shown in Figure 3B. While individually each contaminant might behave as shown in Figure 3, each has its own time scale. The better adsorbing contaminants are captured in the upstream portion of the bed, and the poorer are adsorbed further downstream. As the challenge continues, the better adsorbing compound progressively displaces the other until the displaced component can leave the adsorber bed at a higher concentration than it entered.

Yoon and Nelson (1988) and Underhill et al. (1988) discuss the effect of relative humidity on physical adsorption. Essentially, water vapor acts as a second contaminant, altering the adsorption parameters by reducing the amount of the first contaminant that can be held by the adsorber and shortening the breakthrough times. For VOCs adsorbed on carbon, the effect of relative humidity is modest up to about 50%, and greater at higher relative humidities.

**Chemisorption Description.** The three physical adsorption steps explained and then shown in Figure 3 also apply to chemisorption. However, the third step in chemisorption is by chemical reaction with electron exchange between the contaminant molecule and the chemisorber. This action differs in the following ways from physical adsorption:

1. Chemisorption is highly specific; only certain contaminant compounds will react with a particular chemisorbent.
2. Chemisorption improves as temperature increases (reaction rate increases); physical adsorption improves as temperature decreases (vapor pressure drops).
3. Chemisorption does not generate heat, but instead may require heat input.
4. Chemisorption is not generally reversible. Once the adsorbed contaminant has reacted, it is not desorbed. However, one or more reaction products, different from the original contaminant, may be formed in the process, and these reaction products may enter the air as a new contaminant.
5. Water vapor often helps chemisorption or is necessary for it, while it usually hinders physical adsorption.
6. Chemisorption per se is a monomolecular layer phenomenon; the pore-filling effect that takes place in physical adsorption does not occur, except where adsorbed water condensed in the pores forms a reactive liquid.

Most chemisorptive media are formed by coating or impregnating a highly porous, nonreactive substrate (e.g., activated alumina, zeolite, or carbon) with a chemical reactant. The reactant will eventually become exhausted, but the substrate may have physical adsorption ability that remains active when chemisorption ceases.

**Other Processes.** Physical adsorption and chemisorption are the most commonly used processes; however the following processes are used in some applications.

**Liquid absorption devices (scrubbers)** and combustion devices are generally used to clean exhaust stack gases and process gas effluent. They are not commonly applied to indoor air cleanup. Additional information may be found in Chapter 25 of the 2000 *ASHRAE Handbook—Systems and Equipment*.

**Catalysts** can clean air by stimulating a chemical reaction on the surface of the media. Catalytic combustion or catalytic oxidation oxidizes unburned hydrocarbons in moderate concentrations in air. In general, the challenge with catalytic oxidation is to achieve an adequate reaction rate (contaminant destruction rate) at ambient temperature. Similarly, ultraviolet light (photocatalysis) uses ultraviolet energy to initiate reactions (not all oxidation) at temperatures...
below where they would normally occur. The products of complete combustion of hydrocarbons are CO₂ and water, and at indoor contaminant concentrations these would be acceptable reaction products. Reaction products are a concern, because oxidation of non-hydrocarbons or reactions other than oxidation can produce undesirable by-products. Commercial ultraviolet devices have not been demonstrated at this time.

Cryogenic condensation has been used in nuclear safety systems. Plants and occupants themselves remove some contaminants from indoor air. Odor counteractants and odor masking are not truly control methods that may apply only to specific odors and have limited effectiveness.

**Equipment**

**General Considerations.** With a few exceptions, adsorption and chemisorption media are supplied in granular or pelletized form, which are held in a retaining structure that allows the air being treated to pass through the media with an acceptable pressure drop at the operating airflow. Granular media has traditionally been a few millimetres in all dimensions. Pellets or flakes that pass through a screen with an aperture of 4.8 mm × 2.4 mm or 3.4 mm × 3.4 mm are typical because these sizes have an acceptable pressure drop at the required operating conditions.

Numerous other sizes are available. Typical configurations of units in which millimetre-sized granular or pelletized media are held between perforated retaining sheets or screens are shown in Figures 4A, 4B, and 4D. The perforated retainers or screens must have holes smaller than the smallest particle of the active media. A margin without perforations must be left around the edges of the retaining sheets or screens to minimize the amount of air that can bypass the active media. Media must be tightly packed in the structure so that open passages through the beds do not develop. Aluminum; stainless, painted, plated, or coated steel; plastics; and kraftboard are all used for retainers.

Adsorptive media may also be retained in fibrous filter media or other porous support structures that can be pleated into large filters as shown in Figures 4C and 4E. The adsorptive media must be bound to the supporting fibers in such a way that media micropores are preserved (i.e., not sealed by binders) and adequate overall adsorptive capacity is maintained.

Media supported in this way is generally much smaller in size (down to approximately 80 mesh). As described earlier, small particle adsorbents have higher efficiency than the same adsorbent in larger particles. The smaller particles must be uniformly distributed and supported such that the pressure drop of the composite is acceptable. Because the absorbent is intimately bound to, and its performance affected by the support structure, these adsorbents must be evaluated by tests on the complete composite structure, not the granular adsorbent alone.

Granular media adsorbers are available in two working classes: **total or full detention** and **partial detention** units. Full-detention units are those in which the mass transfer zone is initially contained totally within the bed as depicted by the θ = 0 curve of Figure 3A. Other popular commercial designs may allow the challenge gas to bypass the unit or have short residence times. Partial detention units are called partial bypass if large open areas are designed into the bed or device. Partial detention units are useful when 100% control is not needed to achieve design objectives or when high recirculation rates will allow them to effectively remove contaminants from a space.

Generally, total detention units are those in which all the air passes through a media bed that is usually a minimum of 12 mm thick with a residence time of 0.02 s or more. They can be much thicker and have longer residence times. At their rated flow, they have an initial efficiency of nearly 100% (full detention) for modest challenge concentrations of the contaminants they control well.

On the other hand, partial detention units operated at capacity have initial efficiencies of 80% or below. They typically have lower pressure drops than full detention units. They may allow 50% or more of the air approaching them to bypass the media bed and remain untreated, as do 50% fill honeycomb panels and some partial bypass unit adsorbers. Similarly, some adsorbent-bonded carbon panels operating at face velocities of approximately 1.5 m/s or more have very low residence times and are best classed as partial detention units even though all the air passes through the adsorber.

**Equipment Configurations.** The design engineer has a choice of either **unitary adsorbers** in built-up banks or **side access housings** holding individual media-filled trays, modules, or cells. Built-up banks require space upstream of the filter bank to install the adsorbers and for maintenance. Larger equipment benefits from the maintenance simplicity of built-up front access banks. Side access housings are an integral part of a duct run, and are usually selected if the system is small (about 1.4 m³/s or less) or if inline space is limited.

A **unitary adsorber** has either a permanent holding frame that is filled with multiple trays, modules, or panels or a single, disposable box-type unit or adsorbent-bonded media cell. Unitary adsorbers incorporate channels to retain trays, modules, or panels in either the vertical or horizontal position. Their size depends on what they are intended to hold.

**Media trays** in Figure 4A may use multiple media-filled trays, modules, or panels or a single, disposable box-type unit or adsorbent-bonded media cell. They may be refillable or completely disposable.

**Panel adsorbers** usually use a base of fibrous honeycomb material to hold the granular media. The efficiency and pressure drop of these panels can be controlled by the amount of media placed in each honeycomb opening; 50%, 75% and 100% fills are common.

**Dispersible, box-type units** may use multiple media-filled panels arranged in a V configuration and sealed into frames with or without headers. Fiber-adsorbent composite media may be pleated and assembled into disposable box-type unitary filters, which may be of heavy or light-weight construction depending on the capacity of the filter.
Adsorbent-bonded media is often pleated into a cardboard or metal frame and provide both gaseous and particulate contamination control. These filters usually are only used for extremely light duty peak-shaving applications because the available adsorbent is relatively limited.

A partially-filled granular media holder can have a preferred orientation because the media may have freedom to move. For example, a vertical, 50%-filled honeycomb panel adsorber has about 50% open area and 50% carbon granules in the direction of flow through the panel. The same panel adsorber, oriented horizontally in downflow, becomes a packed bed having a media thickness of about half the panel depth because the media packs against the bottom retaining screen. In upflow, the absorbent is lifted by the airflow and forms a packed or percolating bed against the retaining screen at the top, causing sorbent abrasion. The pressure drop and adsorption performance of each of these orientations is different. Most manufacturers rate their products in only one orientation and do not investigate other applications.

Side access adsorber housings hold the same types of trays, modules, and panels used with unitary adsorbers. The housings have doors on one or both sides and often include channels for particulate prefilters and afterfilters. The adsorber units slide into place on rails or channels that require tight seals to prevent bypass leakage. The housings are often mounted adjacent to the air handler.

AIR CLEANING DESIGN

In an ideal situation, the designer for gaseous contaminant control would have the following information:

1. Exact chemical identity of the contaminants present in significant concentrations
2. Rates at which the contaminants are generated in the space
3. Rates at which contaminants are brought into the space with outdoor air
4. Time-dependent performance of the proposed air cleaner for the contaminant mixture at the concentration and environmental conditions to be encountered
5. A clear goal concerning what level of air cleaning is needed

This information is usually difficult to obtain. The first three items can be obtained by sampling and analysis, but funding is usually not sufficient to obtain samples except in very simple contamination cases. Designers must often make do with a chemical family name (e.g., aldehydes) and a qualitative description of generation (e.g., from graphics arts department) or perceived concentration (e.g., at odorous levels).

Experimental measurements of air cleaner performance (Item 4) are in most cases not available. However, the performance of an air cleaner can be estimated using the equations presented in the section on Use of Source Data to Predict Indoor Concentrations when the exact chemical identity of a contaminant is known. The chemical and physical properties influencing a contaminant’s collection by control devices can usually be obtained from handbooks and technical publications. Contaminant properties of special importance are relative molecular mass, normal boiling point (i.e., at standard pressure), heat of vaporization, polarity, chemical reactivity, and chemisorption velocity.

The performance of air cleaners with mixtures of chemically dissimilar compounds is very difficult to predict. Some gaseous contaminants, including ozone, radon, and sulfur trioxide, have unique properties that require design judgment and experience.

Finally, design goals must be considered. For a museum or archive, the proper design goal is total removal of the target contaminants and no subsequent desorption. For any chemical having or potentially having a health impact, the design goal is to reduce the concentration to below the level of health effects. Again, desorption back into the space must be minimized. For odor control, however, 100% removal may be unnecessary and desorption back into the space at a later time with a lower concentration may be an economical and acceptable mode of operation.

The first step in design is selecting an appropriate adsorption medium. Next, the location of the air cleaner in the HVAC system must be decided. Then the air cleaner must be sized such that sufficient media is used to achieve design efficiency and capacity goals and to estimate media replacement requirements. Finally, the commercial equipment that most economically meets the needs of the particular application can be selected. These steps are not completely independent.

Air Cleaner Location and Other HVAC Concerns

Outside Air Intakes. Proper location of the outside air intake is especially important for applications requiring gaseous contaminant filters because the contaminants load the filters and reduce their operating lifetime. Outside air should not be drawn from areas where point sources of gaseous contaminants are likely. This means outside air intakes should be distant from building exhaust discharge points, roads, loading docks, parking decks and spaces, and similar locations. See Chapter 43 for more information on air inlets.

Outside Air Volume. To further aid in reducing the amount of contaminants from outside air, at least on days of high ambient pollution levels, the quantity of outside air should be minimized.

Air Cleaner Locations. The three principal uses for gaseous contaminant control equipment in an HVAC system are:

Outside Air Treatment. Air cleaning equipment can be located at the outside air intake to treat outside air only. This treatment is used principally when indoor gaseous contaminants are adequately controlled by outdoor air ventilation, but the outdoor air needs to be cleaned to achieve satisfactory air quality.

Bypass or Partial Supply Air Treatment. Bypass can be achieved with a bypass duct and control damper or by installing an air cleaner that allows substantial bypass. Partial supply air treatment may be appropriate where a specific threshold contamination level is targeted, when outside and inside contamination rates are known, and the required level of reduction is small to moderate.

Full Supply Air Treatment. Full treatment achieves the best contaminant control, albeit with the highest cost and largest equipment volume. This approach is most often used in ventilation strategies that reduce outdoor air while striving to maintain good indoor air quality.

When outdoor air quality is adequate, treatment of recirculated ventilation air alone may be adequate to control indoor contaminants such as bioeffluents. Full or bypass treatment of the supply air may be appropriate, depending on the source strength.

Media Selection

Table 11 lists some physical adsorption and chemisorption media used for indoor air applications. Activated carbon, impregnated activated carbon, and potassium permanganate-impregnated alumina are the three adsorbents used most widely. Activated carbon is by far the most popular because of the wide range of contaminants it can adsorb.

Table 12 is a general guide to the relative effectiveness of unimpregnated activated carbon on a range of odors and compounds under typical average air purification duty conditions. The table is widely used in the industry, but it is only a guide. Adsorption capacity for a particular chemical or application may vary from these guidelines with changes in

- Competitive adsorption. Multiple contaminants confound performance estimates
- Temperature. Activity decreases with a temperature increase
- Humidity. Effect of humidity (generally for rh > 50%) depends on the contaminant. Carbon capacity for water-miscible solvents

increases, while capacity for immiscible or partially-miscible solvents decreases

• Concentration. Increased contaminant concentration improves activity.

Some chemically reactive gases such as ammonia or formaldehyde are not adsorbed well by standard activated carbon, but specially impregnated carbon can be used successfully. These gases are noted with an asterisk (*) in Table 12. The capacity index values in the table were developed from data obtained at concentrations well above those encountered indoors. The ratings are noted below and remain useful for comparative purposes. With that qualification, the ratings have the following meaning:

4 Activated carbon has a high capacity for these materials, adsorbing 20 to 40% of its mass of the contaminant. (They average 30% at high concentrations.) At indoor concentrations, the capacities are about 8 to 15%. More than 70% of the materials listed fall into this category.

3 Activated carbon has a satisfactory capacity for these materials, adsorbing 10 to 25% of its mass of the contaminant (with an average 17% at high concentrations, lower at indoor concentrations).

2 Activated carbon has a relatively low adsorption capacity for these materials, and its use is borderline.

1 Activated carbon has a very low or negligible capacity for these materials and is generally not recommended.

In general, gaseous contaminants that have the same boiling point as water or greater can be removed by the physical adsorption process using standard activated carbon. Those with a lower boiling point usually require chemisorption for removal. A graphical representation of the media and equipment selection process is shown in Figure 5.

Fig. 5 Media and Equipment Selection Schematic

Special Cases

Ozone will reach an equilibrium concentration in a ventilated space without a filtration device. It does so partly because ozone molecules react to form oxygen, but also because it reacts with people, plants, and materials in the space. This oxidation is harmful to all three, and therefore natural ozone decay is not a satisfactory way to control ozone except at low concentrations (< 0.2 mg/m³). Fortunately, activated carbon adsorbs ozone readily, both reacting with it and catalyzing its conversion to oxygen.

Radon is a radioactive gas that decays by alpha-particle emission, eventually yielding individual atoms of polonium, bismuth, and lead. These atoms form extremely fine aerosol particles, called radon daughters or radon progeny, which are also radioactive; they are especially toxic in that they lodge deep in the human lung, where they emit cancer-producing alpha particles. Radon progeny, both attached to larger aerosol particles and unattached, can be captured by particulate air filters. Radon gas itself may be removed with activated carbon, but in HVAC systems this method costs too much for the benefit derived. Control of radon emission at the source and ventilation are the preferred methods of radon control.

Another gaseous contaminant that often appears in particulate form is sulfur trioxide (SO₃), which should not be confused with sulfur dioxide (SO₂). It reacts rapidly with water vapor at ambient temperature to form a fine mist of sulfuric acid. If this mist collects on a particulate filter and no means is provided to remove it, the acid will vaporize and reenter the protected space.
The pressure drop across the contaminant filter has a direct impact on energy use. Data on the resistance of the filter as a function of airflow and on the resistance of the heating/cooling coils must be provided by the manufacturer. Currently no standard test of the pressure drop across a full-scale gaseous air cleaner is specified, but users could require that the initial pressure drop measured for the pressure drop across a full-scale gaseous air cleaner is specified, but users could require that the initial pressure drop measured...
ECONOMIC CONSIDERATIONS

Capital and operating costs for each competing system should be identified. Chapter 35, Owning and Operating Costs, provides general information on performing an economic analysis. Table 13 is a checklist of those filtration items to be considered in an analysis. An important question for an in-line air cleaner is whether the fan can maintain adequate flow with the air cleaner in place. If a larger blower is required, space must be available. Modifying unitary equipment that was not designed to handle the additional pressure drop through air cleaning equipment can be expensive. With built-up designs, the added initial cost of providing air cleaners and their pressure drop can be much less because the increases may be small fraction of the total.

The life of the adsorbent medium is very important to any economic analysis. The economic benefits of regenerating spent carbon should be evaluated in light of the cost and generally reduced activity levels of regenerated material. Regeneration of impregnated carbon or any carbon containing hazardous contaminants is never permitted. Spent alumina- or zeolite-based adsorbents cannot be regenerated.

SAFETY

Gaseous contaminant removal equipment generally has a low hazard potential. The contaminant concentrations are low, the temperature moderate, and the equipment is normally not closed in. Alumina- or zeolite-based media do not support combustion, but carbon filter banks have been known to catch fire, usually from an external source such as a welder’s torch. Check local codes and fire authorities for their regulations concerning carbon. One such authority requires automatic sprinklers in the duct upstream and downstream of carbon filter banks. As a minimum, a smoke detector should be installed downstream of the filter bank to shut down the fan and sound an alarm in case of fire.

Access for safe maintenance and change out of adsorbent beds must be provided. Adsorbers are much heavier than particulate filters. Suitable lifting equipment must be available during installation and removal to prevent injury.

If adsorbent trays are going to be refilled on-site, safety equipment must be provided to deal with the dust that is generated during the operation. Hooding, dust masks, and gloves are all required to refill adsorber trays from bulk containers.

INSTALLATION, START-UP, AND COMMISSIONING

This section provides general guidance on the installation of gaseous contaminant removal equipment. Most manufacturers can also provide complete details and drawings for design.

Particulate Filters. A minimum 25 to 30% efficiency particulate filter (as per ASHRAE Standard 52.1) should be installed ahead of the adsorber bank. A higher efficiency is desirable. Adsorbers and chemisorbers cannot function properly if their surfaces are covered and their pores clogged with dirt. If the air is extremely dirty (from diesel exhaust for example), the filter should be one with a much higher efficiency. One manufacturer requires a 90 to 95% efficiency filter for such applications. Weschler et al. (1994) report that carbon service life for ozone control was lengthened by using improved prefiltration.

After filters are often used in those critical applications where dust from the media at start-up is likely, or where vibration of the adsorber bank may cause the granular media to shed particles. These filters are frequently 25 to 30% efficiency filters, but higher efficiencies may be needed in some applications.

Equipment Mass. Adsorption equipment is much heavier than particulate filtration equipment, so supporting structures and frames must be designed accordingly. A typical 600 mm by 600 mm adsorber consisting of a permanent holding frame and sorbent-loaded trays has an installed mass of approximately 90 kg.

Eliminate Bypass. Adsorbers and ducts in the outside air supply and in the exhaust from hoods must be tightly sealed to prevent bypass of contaminants. Bypass leakage is not critical in most recirculating indoor air systems, but it is good practice to caulk all seams and between individual holding frames. Granular media retainers, such as trays or modules, must be loaded with media per manufacturers’ recommendations to eliminate the possibility of bypass through the media bed.

When to Install Media. The decision as to when to install adsorbers in their holding frames depends on building circumstances. If they are installed at the same time as their holding frames and if the HVAC is turned on during the latter phases of construction, the adsorbers will adsorb paint and solvent vapors and other contaminants before the building is ready for beneficial occupancy. In some situations, those adsorption of vapors and gases in the ventilation system prior to official start-up may be what is desired or needed. However, adsorber life will be reduced correspondingly. If adsorber frames are not loaded until the building is ready for occupancy, the unadsorbed contaminants may seriously reduce the initial indoor air quality of the building. Thus the shortened life is an acceptable trade-off for the quality of air at the time of occupancy (NAFA 1997). If the media is not in place during fan testing, the test and balance contractor must be instructed to place blank-offs or restrictions in the frames to simulate adsorber pressure drop. The HVAC designer’s job specifications must clearly state when media is to be installed.

Pressure Gages. Provided prefiltration is adequate, adsorber pressure drop will not increase during normal operation. A pressure drop measuring device (gage or manometer) is therefore not required as it is for a particulate filter bank. However, a gage may be useful to detect fouling or unintentional bypass. If the prefiltrers or afterfilters are installed immediately adjacent to the adsorbers, it may be more feasible to install the gage across the entire assembly.

Provision for Testing. At any time following installation of new media, determining the remaining adsorbent capacity or operating life may be required. (See the section on When to Change Media under Operation and Maintenance.) The installation should provide access ports to the fully mixed air stream both upstream and downstream of the air cleaner. If media samples will be removed to determine remaining life, access must be provided to obtain those samples. No standard method for field evaluation of media life currently exists.

Start-Up and Commissioning

Special procedures are not required during start-up of an air handler incorporating adsorbers. The test and balance contractor will normally be required to take and record a measurement of the resistance of all installed filter banks, including adsorbers, for comparison with design conditions.

The commissioning authority may require an activity test on a sample of media selected at random. This test will determine if the new media has suffered prior exposure that has reduced its life or if it meets specifications. An in-situ air sampling test may also be required on the adsorber filter bank; however, no standard method for this test exists.
OPERATION AND MAINTENANCE

Bypass units and filters with adsorbent-infused media require frequent changing to maintain even low efficiency, but frequent maintenance is not required for complete removal units. Complete removal media adsorbers usually have a replaceable cell that cannot be regenerated or reactivated. This section covers maintenance of complete removal equipment with refillable trays or modules only.

When to Change Media

The changeout point of an adsorbent is difficult to determine. Sometimes the media is changed when breakthrough occurs and occupant’s complain; but if the application is sensitive, tests for estimated residual activity may be made at periodic intervals. A sample of the media in use is pulled from the adsorber bank or from a pilot cell placed in front of the bank. The sample is sent to the manufacturer or an independent test laboratory for analysis, and the changeout time is estimated knowing the time in service and the life remaining in the sample. In extremely critical installations, “coupons” plated with precious metals are placed in the space being protected by the adsorbent. After some time, usually a month, the coupons are sent to an analytical lab for measurement of corrosion thickness. These measurements indicate the effectiveness of the gaseous contaminant control as well as provide an indication of the system life. Standardized methodology for these tests is not available.

Replacement and Reactivation

The process of replacing media in permanent adsorber trays or modules is not the same as reactivation (regeneration), which is the restoration of spent activated carbon media to its original efficiency (or close to it). Spent carbon is regenerated in special high temperature kilns in the absence of oxygen to drive off the contaminants it has acquired. Chemisorber modules can be replaced (media changed) but chemisorber media, including impregnated carbon, cannot be regenerated.

Building operating personnel may choose to dump and refill trays and modules at the site after replacing those removed with a spare set already loaded with fresh media. They may also choose to dump the trays locally and send the empty trays to a filter service company for refilling; or they may simply exchange their spent trays for fresh ones. Disposing of spent sorbent by dumping must be limited to building air quality applications where no identifiable hazardous chemicals have been collected.

ENVIRONMENTAL INFLUENCES ON AIR CLEANERS

Environmental conditions, particularly temperature and humidity, affect the performance of most gaseous contaminant control equipment. Physical sorbents such as activated carbon are particularly susceptible. The user should confirm performance for any control device at the expected normal environmental conditions as well as at extremes that might be encountered during equipment outages. The following information is an overview.

High relative humidity in the treated airstream lowers the gaseous contaminant removal efficiency of physical adsorbents such as carbon due to competition for sorption sites from the much more numerous water molecules. In many cases performance is relatively stable up to 40 to 50% rh, but some compounds can degrade at higher humidities. The chemical nature of the contaminant(s) and the concentration both affect the degradation of performance as a function of relative humidity. On the other hand, very low relative humidities may make some chemisorption activity impossible. Therefore, the performance of these media must be evaluated over the expected range of operation, and the relative humidity and temperature of the gaseous contaminant control should be held within design limits.

The impact of relative humidity swings can be better understood by considering a hypothetical adsorber that has a saturation capacity for a contaminant and inlet concentration of 10% at 50% rh and 5% at 70% rh. Over an extended period at its normal operating condition of 50% rh, the sorbent might reach a loading of 2%. At this point a humidity swing to 70% rh would not cause a problem, and the sorbent could load on up to 5% capacity. Should the humidity then swing back to 50%, the sorbent could continue to adsorb up to 10% by mass of the contaminant. However, if the sorbent was loaded to 8% by mass at 50% rh and the humidity rose to 70% rh, the carbon would be above its equilibrium capacity and desorption would occur until equilibrium was reached.

In a similar way, temperature swings and contaminant concentration swings can affect physical sorbent performance. Increasing temperature reduces capacity, while increasing concentration increases capacity. Additionally, changes in the identity of the contaminant can affect overall performance as strongly-sorbed contaminants displace weakly held contaminants.

All adsorption media have a modest ability to capture dust particles and lint, which eventually plug the openings in and between the media granules and cause a rapid rise in the pressure drop across the media or a decrease in airflow. All granular gaseous adsorption beds need to be protected against particulate buildup by installing particulate filters upstream. A prefilter with a minimum ASHRAE Standard 52.1 dust spot efficiency of 25 to 30% is recommended. Vibration breaks up the granules to some degree, depending on the granule hardness. ASTM Standard D 3802 describes a test procedure for measuring the resistance of activated carbon to abrasion.

Critical systems using activated carbon require hardness above 92%, as described by Standard D 3802.

Adsorption and chemisorption media sometimes accelerate the corrosion of metals that they touch. For this reason, media holding cells, trays, and modules should not be constructed of uncoated aluminum or steel. Painted steel or ABS plastic are common and exhibit good material service lives in many applications. Coated or stainless steel components may be required in more aggressive environments.

TESTING OF MEDIA, EQUIPMENT, AND SYSTEMS

Testing may be conducted in the laboratory with small-scale media beds or small pieces of treated fabric or composite material; on full-scale air cleaners in a laboratory test rig capable of generating the test atmosphere; or in the field. Laboratory tests with specific challenge gases are generally intended to evaluate media for developmental, acceptance, or comparative purposes. Full-scale tests using specific challenge contaminants are required to evaluate a complete adsorber as constructed and sold, and ultimately are needed to validate performance claims. Field tests under actual job conditions are used to ensure that the air cleaners were properly installed and to evaluate remaining media life.

Laboratory Testing

Testing of small granular media samples in a laboratory has been done for many years, and most manufacturers have developed their own methods. ASTM Standard D 5288 describes a test method. But this method is not entirely applicable to HVAC work because indoor air tends to have a wide range of contaminants at concentrations several orders of magnitude lower than used in testing.

Field Testing

Upstream and downstream measurements are evaluated by converting them to efficiency or fractional penetration and comparing them to measurements made at installation. Efficiency is most
directly interpreted if there is a single contaminant and the challenge concentration is relatively constant. For multiple contaminants at multiple concentrations, judgment and experience are needed to interpret downstream measurements. Media samples can be evaluated by the manufacturer for remaining life in fractions of the original capacity.

**BIBLIOGRAPHY**

Automatic control of HVAC systems and equipment usually includes control of temperature, humidity, pressure, and flow rate. Automatic control sequences equipment operation to meet load requirements and provides safe operation of the equipment, using pneumatic, mechanical, electrical, and electronic control devices.

This chapter covers (1) the control of HVAC elements, (2) control of typical systems, (3) limit control for safe operation, and (4) the design of controls for specific HVAC applications. Chapter 37 of the 1997 ASHRAE Handbook—Fundamentals covers the fundamentals of control, types of control components, and commissioning of the control system.

**CONTROL OF HVAC ELEMENTS**

**Boiler**

Load affects the rate of heat input to a hydronic system. Rate control is accomplished by cycling and modulating the flame and by turning boilers on and off. Flame cycling and modulation are handled by the boiler control package. The control designer decides under what circumstances to add or drop a boiler and at what temperature to control the boiler supply water.

Hot water distribution control includes temperature control at the hot water boilers or converter, reset of heating water temperature, and control for multiple zones. Other factors that need to be considered include (1) minimum water flow through the boilers, (2) protection of boilers from temperature shock, and (3) coil freeze protection. If multiple or alternate heating sources (such as condenser heat recovery or solar storage) are used, the control strategy must also include a means of sequencing hot water sources or selecting the most economical source.

**Fan**

The most efficient way to change the output of a fan is to change its speed. Because of their simplicity and high efficiency, variable-frequency drives are widely used. While less efficient, eddy current drives are also an option for electronically controlling the fan speed. Another way of controlling the fan’s output is to use various types of dampers including inlet vane dampers, discharge dampers, and scroll dampers. Axial fans can be controlled by varying the pitch of the blade. Also, dampers and ducting can simply bypass some of the air from the supply side of the fan to the return side.

The preparation of this chapter is assigned to TC 1.4, Control Theory and Application.
Static pressure control is required in systems having variable flow rates. To conserve fan energy, the static pressure controller should be set at the lowest control point permitting proper air distribution at design conditions. The controller requires proportional-plus-integral (PI) control because it eliminates offset while maintaining stability. In proportional-only control, the low proportional gain required to stabilize fan control loops allows static pressure to offset upward as the load decreases, which causes the supply fan to consume more energy.

Static pressure control is used to pressurize a building or space relative to adjacent spaces or the outdoors. Typical applications include clean rooms (positive pressure to prevent infiltration), laboratories (positive or negative, depending on use), and various manufacturing processes, such as spray-painting rooms. The pressure controller usually modulates dampers in the supply duct to maintain the desired pressure as exhaust volumes change. Control of the return fan requires measuring the space and outdoor static pressures. The location for measuring indoor static pressure must be selected carefully—away from doors and openings to the outside, away from elevator lobbies, and, when using a sensor, in a large representative area shielded from drafts. The outdoor location must likewise be selected carefully, typically 3 to 4.5 m above the building and oriented to minimize wind effects from all directions. The amount of minimum outdoor air varies with building permeability and exhaust fan operation. Control of building pressurization can affect the amount of outside air entering the building.

Duct static pressure control for variable air volume (VAV) and other terminal systems maintains a static pressure at a measurement point. The most common application for static pressure control is fan output control in VAV systems. The pressure sensor must be properly placed to maintain optimum pressure throughout the supply duct. Experience indicates that performance is satisfactory when the sensor is located at 75 to 100% of the distance from the first to the most remote terminal. If the sensor is located at less than 100% of the distance, the control set point should be adjusted higher to account for the pressure loss between the sensor and the remote terminal. Care must be taken in selecting the reference sensor location. Controller upset due to opening and closing doors, elevator shafts, and other sources of air turbulence should also be prevented. The pressure selected provides a minimum static pressure to all air terminal units during all supply fan design conditions.

Multiple static sensors are required when more than one duct runs from the supply fan. The sensor with the highest static requirement controls the fan. Because duct run-outs may vary, a control that uses individual set points for each measurement is preferred.

VAV systems typically incorporate a duct static pressure control loop to control the flow. In a single-duct VAV system, the duct static pressure set point is usually selected by the designer. The sensor should be located in the ductwork where the established set point ensures proper operation of the zone VAV boxes under varying load (supply airflow) conditions. A shortcoming of this approach is that static pressure control is based on the readings of a single sensor that is assumed to represent the pressure available to all VAV boxes. If
the sensor malfunctions or is placed in a location that is not representative, operating problems will result.

An alternative approach to supply fan control in a VAV system uses flow readings from the direct digital control (DDC) zone terminal boxes to integrate zone VAV requirements with supply fan operation. Engleman and Norford (1992) suggest that duct static pressure and fan energy can be reduced without sacrificing occupant comfort or adequate ventilation. They compared modified PI and heuristic control algorithms via simulation and demonstrated that either static pressure or fan speed can be regulated directly using a flow error signal from one or more zones. They noted that component modeling limitations constrain their results primarily to a comparison of the control algorithms. The results show that both PI and heuristic control schemes work, but the authors suggest that a hybrid of the two might be ideal.

Supply fan warm-up control for systems having a return fan must prevent the supply fan from delivering more airflow than the return fan maximum capacity during warm-up mode (Figure 7). Return fan static control from returns having local (zoned) flow control is identical to supply fan static control (Figure 5). This open loop (no feedback) control requires similar supply and return fan airflow modulation characteristics. The return fan airflow is adjusted at minimum and maximum airflow conditions. The airflow turndown should not be excessive, typically no more than 50%. Provisions for warm-up and exhaust fan switching are impractical.

Airflow tracking uses duct airflow measurements to control the return air fans (Figure 9). Typical sensors, called flow stations, are multiple-point, pitot tube, and averaging. Provisions must be made for exhaust fan switching to maintain pressurization of the building. Warm-up is accomplished by setting the return airflow equal to the supply fan airflow, usually with exhaust fans turned off and limiting supply fan volume to return fan capability. During night cool-down, the return fan operates in the normal mode.

VAV systems that use return or relief fans require control of airflow through the return or relief air duct systems. Return fans are commonly used in VAV systems to help ensure adequate air distribution and acceptable zone pressurization. In a return fan VAV system, there is significant potential for control system instability due to the interaction of control variables (Avery 1986). In a typical system, these variables might include supply fan speed, supply duct static pressure, return fan speed, mixed air temperature, outside and return air damper flow characteristics, and wind pressure effect on the relief louver. The interaction of these variables and the selection of control schemes to minimize or eliminate interaction must be considered carefully. Mixed air damper sizing and selection are particularly important. Zone pressurization, building construction, and outdoor wind velocity must be considered. The resultant design helps ensure proper air distribution, especially through the return air duct. Using the technique described by Dickson, the designer may be able to eliminate the return fan altogether.

Sequencing fans for VAV systems reduces airflow more than other methods and results in greater operating economy and more stable fan operation if airflow reductions are significant. Alternation of fans usually provides greater reliability. Centrifugal fans are controlled to keep system disturbances to a minimum when additional fans are started. The added fan is started and slowly brought to capacity while the capacity of the operating fans is simultaneously reduced. The combined output of all fans then equals the output before fan addition.

Supply fan temperature reset can be used to avoid fan instability by resetting the cooling coil discharge temperature higher (Figure 10), so that the building cooling loads require greater airflow.
Because of the time lag between temperature reset and demand for more airflow, the value at which reset starts should be selected on the safe side of the fan instability point. When this technique is used, it must be ascertained that dehumidification requirements can be met.

**Cooling Coil**

Chilled water or brine cooling coils are controlled by two- or three-way valves. These valves are similar to those used for heating control, but are usually closed to prevent cooling when the fan is off. The valve typically modulates in response to coil air discharge temperature or space temperature.

Direct-expansion (DX) cooling coils are usually controlled by solenoid valves in the refrigerant liquid line. Face and bypass dampers are not recommended because they permit ice to form on the coil when airflow is reduced. Control can be improved by using two or more stages; the solenoid valves are controlled in sequence, and there is a differential of about 1 K between stages. The first stage should be the first coil row on the entering air side; the following rows form the second and succeeding stages. Side-by-side stages tend to generate icing on the stage in use, which causes reduction of airflow and loss of control. Modulating control is achieved using a variable suction pressure controller. This type of control is uncommon but necessary if accurate control of discharge or space temperature is required.

**Cooling Tower**

The most common packaged mechanical-draft cooling towers for comfort air-conditioning applications are counterflow induced-draft and forced-draft. They are controlled similarly, depending on the manufacturer’s recommendations. On larger towers, two-speed motors or variable-speed drives can reduce fan power consumption at part-load conditions and stabilize condenser water temperature.

In colder areas that require year-round air conditioning, cooling towers may require sump heating and continuous full flow over the tower to prevent ice formation. In that case, the cooling tower sump...
thermostat would control a hot water or steam valve to keep water temperature above freezing.

**Economizer Cycle**

Economizer cycle control reduces cooling costs when outside conditions are suitable, that is, when the outdoor air is cool enough to be used as a cooling medium. If the outdoor air is below a high-temperature limit, typically 18°C, then economizer cycle control becomes activated. The relief dampers are interlocked to close, and the return air dampers to open, when the supply fan is not operating. When the outdoor air temperature exceeds the high-temperature limit set point, the outdoor air damper is closed to a fixed minimum and the return air dampers close and open, respectively.

In enthalpy economizer control, the high-temperature limit interlock system of the economizer cycle is replaced in order to further reduce energy costs when latent loads are significant. The interlock function can be based instead on (1) a fixed enthalpy upper limit, (2) a comparison with return air so as not to exceed return air enthalpy, or (3) a combination of enthalpy and high-temperature limits.

VAV warm-up control during unoccupied periods requires no outdoor air; typically, outdoor and exhaust dampers remain closed. However, in systems with a return fan, the outdoor air damper should be positioned at its minimum position, and supply airflow (volume) should be limited to return air airflow (volume) to minimize positive or negative duct pressurization.

Night cool-down control (night purge) provides 100% outdoor air for cooling during unoccupied periods. The space is cooled to the space set point, typically 5 K above outdoor air temperature. Limit controls prevent operation if outdoor air is above space dry-bulb temperature, if outdoor air dew-point temperature is excessive, or if outdoor air dry-bulb temperature is too cold, typically 10°C or below. The night cool-down cycle is initiated before sunrise, when overnight outside temperatures are usually the coolest. When outside air conditions are acceptable and the space requires cooling, the cool-down cycle is the first phase of the optimum start sequence.

**Heating Coil**

Heating coils that are not subject to freezing can be controlled by simple two-way or three-way modulating valves. Steam distributing coils are required to ensure proper steam coil control. The valve is controlled by coil discharge air temperature or by space temperature, depending on the HVAC system. Valves are set to limit heating if control power fails. In many systems, the outdoor air temperature resets the heating discharge controller.

To provide unoccupied heating or preoccupancy warm-up, a heating coil can be added to the central fan system. During warm-up or unoccupied periods, a constant supply duct heating temperature is maintained and the cooling coil valve is kept closed. Once the heating coil is energized, the valve is modulated to the required position. Steam preheat coils should have two-position valves and vacuum breakers to prevent a buildup of condensate in the coil. The valve should be fully open when outdoor air (or mixed air) temperature is below freezing. This causes unacceptably high coil discharge temperatures at times, necessitating face and bypass dampers for final temperature control. The bypass damper should be sized to provide the same pressure drop at full bypass airflow as the combination of face damper and coil does at full airflow.

Hot water preheat coils must maintain a minimum water velocity in the tubes of 0.9 m/s to prevent freezing. A two-position valve combined with face and bypass dampers can usually be used to control the water velocity. More commonly, a secondary pump control is used. The control valve modulates to maintain the desired coil discharge temperature, while the pump operates to maintain the minimum water temperature when outdoor air is below freezing. This causes unacceptably high coil discharge temperatures at times, necessitating face and bypass dampers for final temperature control. The bypass damper should be sized to provide the same pressure drop at full bypass airflow as the combination of face damper and coil does at full airflow.

Hot water preheat coils must maintain a minimum water velocity in the tubes of 0.9 m/s to prevent freezing. A two-position valve combined with face and bypass dampers can usually be used to control the water velocity. More commonly, a secondary pump control is used. The control valve modulates to maintain the desired coil discharge temperature, while the pump operates to maintain the minimum water temperature when outdoor air is below freezing. This causes unacceptably high coil discharge temperatures at times, necessitating face and bypass dampers for final temperature control. The bypass damper should be sized to provide the same pressure drop at full bypass airflow as the combination of face damper and coil does at full airflow.

The system in Figure 21 may be required on small systems with only one or two air handlers, or where constant main water flow is needed.
Some systems may use a glycol solution in combination with any of these methods.

Electric heating coils (duct heaters) are controlled in either two-position or modulating mode. Two-position operation uses power relays with contacts sized to handle the power required by the heating coil. Timed two-position control requires a timer and contactors. The timer can be electromechanical, but it is usually electronic and provides a time base of 1 to 5 min. Step controllers provide cam-operated sequencing control of up to 10 stages of electric heat. Each stage may require a contactor, depending on the step controller contact rating. Thermostat demand determines the percentage of on-time. Because rapid cycling of mechanical or mercury contactors can cause maintenance problems, solid-state controllers are preferred. These devices make cycling so rapid that the control is proportional; therefore, face and bypass dampers are not used. A control system with a solid-state controller and safety controls is shown in Figure 22.

Heat Pump

A heat pump is a refrigeration device in which the evaporator is used for cooling and heat that is normally rejected from the condenser is used for heating. Many conventional means used to control refrigeration equipment can be used to control heating and cooling cycles. Chapters 8 and 15 of the 2000 ASHRAE Handbook—Systems and Equipment include details.

Humidity Control

Humidity control is based on the output of a humidity sensor located either in the space or in the return air duct. Most comfort cooling processes involve some dehumidification. The amount of dehumidification is a function of the effective coil surface temperature and is limited by the freezing point of the coolant. If water condensing out of the airstream freezes on the coil surface, airflow is restricted and, in severe cases, may be shut off. The practical limit is about 5°C dew point on the coil surface. As indicated in Figure 23, this results in a relative humidity of about 30% at a space temperature of 24°C, which is adequate for most commercial applications. When a lower humidity is necessary, a chemical dehumidifier is required.

Dehumidification can be achieved in several ways. One is to override the control of the cooling coil. The temperature of the coil is lowered until sufficient moisture is removed from the supply air to maintain the humidity set point. When maximum relative humidity control is required, a space or return air humidistat is provided in addition to the space thermostat. To limit maximum humidity, a control function selects the higher of the output signals from the two devices and controls the cooling coil valve accordingly. A reheat coil may be required to maintain the space temperature if the moisture removal process results in too low a supply air temperature (Figure 24). If humidification is also provided, this cycle is sometimes called a constant temperature, constant humidity cycle. Although simple cooling by refrigeration maintains an upper limit to space humidity, without additional equipment it does not control humidity.

Sprayed coil dehumidifiers (Figure 25) have been used for dehumidification. Space relative humidity ranging from 35 to 55% at 24°C can be obtained with this equipment; however, the cost of maintenance, reheat, and removal of solid deposits on the coil make the sprayed coil dehumidifier less desirable than other methods.
A desiccant-based dehumidifier can lower space humidity below that possible with cooling/dehumidifying coils. This device adsorbs moisture using silica gel or a similar material. For continuous operation, heat is added to regenerate the material. The adsorption process also generates heat (Figure 26). Figure 27 shows a typical control.

Humidification can be achieved by adding moisture to the supply air. Evaporative pans (usually heated), steam jets, and atomizing spray tubes are all used for space humidification. A space or return air humidity sensor provides the necessary signal for the controller. A humidity sensor in the duct should be used to minimize moisture carryover or condensation in the duct (Figure 28). With proper use and control, humidifiers can achieve high space humidity, although they more often maintain design minimum humidity during the heating season.

Outdoor Air Control

Fixed, minimum outdoor air control provides ventilation air, space pressurization (exfiltration), and makeup air for exhaust fans. For systems without return fans, the outdoor air damper is interlocked to remain open only when the supply fan operates (Figure 29). The outdoor air damper should open quickly when the fan turns on to prevent excessive negative duct pressurization. In some applications, the fan on-off switch opens the outdoor air damper before
the fan is started. The rate of outdoor airflow is determined by the opening of the damper and by the pressure difference between the mixed air plenum and the outdoor air plenums.

For systems with return fans, two variations of fixed minimum outdoor air control are used. Minimum outdoor airflow is determined by the pressure (airflow) difference between the supply and return fans (Figure 30). If the outdoor air supplied is greater than the difference between the supply and return fan airflows, a variation of economizer cycle control is used (Figure 31).

In systems using 100% outdoor air, all air goes to the fan and no air is returned (Figure 32). The outdoor air damper is interlocked and usually opens before the fan starts.

Radiant Cooling and Heating

Radiation can be used either to totally heat a room or to supplement another heater. The control strategy depends on the function performed. For a total heating application, rooms are usually controlled individually; each radiator and convector is equipped with an automatic control valve. Depending on room size, one thermostat may control one valve or several valves in unison. The thermostat can be placed in the return air to the unit or on a wall at occupant level. Return air control is generally less accurate and results in wider space temperature fluctuations. When the space is controlled for the comfort of seated occupants, wall-mounted thermostats give the best results.

For supplemental heating applications, where perimeter radiation is used only to offset perimeter heat losses (the zone or space load is handled separately by a zone air system), outdoor reset of the water temperature to the radiation should be considered. Restoration can be zoned by exposure, and the compensating outdoor sensor can be located to sense compensated indoor (outdoor) temperature, solar load, or both.

Radiant panels combine controlled-temperature room surfaces with central air conditioning and ventilation. The radiant panel can be in the floor, walls, or ceiling. Panel temperature is maintained by circulating water or air or by electric resistance. The central air system can be a basic one-zone, constant temperature, constant volume system, with the radiant panel operated by individual room control thermostats; or it can include some or all the features of dual-duct, reheat, multizone, or VAV systems, with the radiant panel operated as a one-zone, constant temperature system. The one-zone radiant heating panel system is often operated from an outdoor temperature reset system to vary panel temperature as outdoor temperature varies.

Radiant panels for both heating and cooling require controls similar to those described for the four-pipe heating/cooling single-coil fan coil. To prevent condensation, ventilation air supplied to the space during the cooling cycle should have a dew point below that of the radiant panel surface.

Terminal Units

The system is considered to be a variable volume system if the airflow to the space varies. The airflow from the fan may be constant for some terminal units.

Single-Duct Constant Volume. Reheat terminals use a single, constant volume fan system that serves multiple zones (Figure 33). All delivered air is cooled to satisfy the greatest zone cooling load. Air delivered to other zones is then reheated with heating coils (hot water, steam, electric) in individual zone ducts. The reheat coil valve (or electric heating element) is reset as required to maintain the space condition. Because these systems consume more energy than VAV systems, they are generally limited to applications with fixed ventilation needs, such as hospitals and special processes or laboratories.

No fan control is required because the design, selection, and adjustment of fan components determine the air volume and duct static pressure. The same temperature air is supplied to all zones. However, the controller can allow the supply temperature to respond to the demand from the greatest cooling load, thus conserving energy.

Single-Duct Variable Volume. A throttling terminal has a damper in the inlet that controls the flow of supply air (Figure 34).
For spaces requiring heating, a reheat coil can be installed in the discharge. As the temperature in the space drops below the set point, the damper begins to close and reduce the flow of air to the space. When the airflow reaches the minimum limit, the valve on the reheat coil begins to open.

Single-duct VAV systems, which supply warm air to all zones when heating is required and cool air to all zones when cooling is required, have limited application and are used where heating is required only for morning warm-up. They should not be used if some zones require heating at the same time that others require cooling. These systems, like single-duct cooling-only systems, are generally controlled during occupancy.

An induction terminal controls the space temperature by reducing the supply airflow to the space and by inducing return air from the plenum space into the airstream for the space [Figure 35]. Both dampers are controlled simultaneously, so as the primary air opening decreases, the return air opening increases. When the space temperature drops below the set point, the supply air damper begins to close and the return air damper begins to open.

A bypass terminal has a damper that diverts part of the supply air into the return plenum [Figure 36]. Control of the diverting damper is based on the output of the space temperature sensor. When the temperature in the space drops below the set point, the bypass damper begins to open, routing some of the supply air to the plenum, which reduces the amount of supply air entering the space. When the bypass is fully open, the control valve for the reheat coil opens as required to maintain the space temperature. A manual balancing damper in the bypass is adjusted to match the resistance in the discharge duct. In this way, the supply of air from the primary system remains at a constant volume. The maximum airflow through the bypass must be restricted in order to maintain the minimum airflow into the space. Although the airflow to the space is reduced, the total airflow of the fan remains constant, so the fan power and associated energy cost are not reduced. These terminals can be added to a single-zone constant volume system to provide zoning without the energy penalty of a conventional reheat system.

A fan-powered terminal unit has an integral fan that supplies a constant volume of air to the space [Figure 37]. In addition to enhancing air distribution in the space, a reheat coil can be added to maintain a minimum temperature in the space when the primary system is off. When the space is occupied, the fan runs constantly to provide a constant volume of air to the space. The fan can draw air from the return plenum to compensate for the reduced supply air. As the temperature in the space decreases below the set point, the supply air damper begins to close and the fan draws more air from the return plenum. Units serving the perimeter area of a building can include a reheat coil. Then, when the supply air reaches its minimum level, the valve to the reheat coil begins to open.

A plenum fan terminal has a fan that pulls air from the return plenum and mixes it with the supply air [Figure 38]. A reheat coil may be placed in the discharge to the space or in the return plenum.
opening. The fan provides a minimum level of airflow to the space. Total airflow to the space is the sum of the fan output and the supply air quantity. When the space temperature drops below the set point, the supply air damper begins to reduce the quantity of supply air entering the terminal. Once the supply damper has reached its minimum position, the reheat coil valve starts to open.

**Dual-Duct Constant Volume.** A mixing box terminal generally is used where large amounts of ventilation at a low static pressure is required. The hot-duct damper and cold-duct damper are linked to operate in reverse directions. A space thermostat positions the mixing dampers through a damper actuator to mix warm and cool supply air. The discharge air volume depends on the static pressure in each supply duct at that location. Static pressures in the supply ducts vary because of the varying airflow in each duct (Figure 39).

Dual-duct constant volume mixing box terminals are typically used in high static pressure applications where the airflow quantity to each space is critical. The units are the same as those described in the previous paragraph, except that they include either an integral mechanical constant volume regulator or an airflow constant volume control furnished by the unit manufacturer (Figure 40).

**Dual Duct Variable Volume.** Mixing box terminals have inlet dampers on the heating and cooling supply ducts. These dampers are interlinked to operate in opposite directions, and each requires a single control actuator. Also, a sensor in the discharge monitors total airflow. The space thermostat controls inlet mixing dampers directly, and the airflow controller controls the volume damper. The space thermostat resets the airflow controller from maximum to minimum flow as the thermal load on the conditioned area changes. Figure 41 shows the control schematic and damper operation. Note that in a portion of the control range, heating and cooling supply air mix.

**CONTROL OF SYSTEMS**

**Air Handling**

Generally, air is distributed by either single-duct or dual-duct systems. Airflow to each zone is controlled by some type of a terminal box. A special case of a dual-duct system is a multizone unit with terminal boxes incorporated into the air handler package. In this case, the hot and cold ducts are referred to as the hot and cold decks. One special multizone configuration has three decks, which may be used as an alternative in a multizone system (Figure 43). Zone dampers in this unit operate with sequenced dampers to either mix hot supply air with bypass air when the cold deck damper is
closed or mix cold supply air with bypass air when the hot deck damper is closed.

A single-zone system uses a constant volume air-handling unit (usually factory-packaged). No fan speed control is required because fan volume and duct static pressure are set by the design and selection of components. Single-zone systems do not require terminal boxes because the zone temperature can be maintained by varying the temperatures of the heating and cooling coils.

During warm-up, as determined by a time clock or manual switch, a constant heating supply air temperature is maintained. Because the terminal unit may be fully open, uncontrolled overheating can occur. It is preferable to allow unit thermostats to maintain complete control of their terminal units by reversing their action to the unit. During warm-up and unoccupied cycles, outdoor air dampers should be closed.

A unit ventilator is designed to heat, ventilate, and cool a space by introducing up to 100% outdoor air. Optionally, it can cool and dehumidify with a cooling coil (either chilled water or direct expansion). Heating can be by hot water, steam, or electric resistance. The control of these coils can be by valves or face and bypass dampers. Consequently, controls applied to unit ventilators are many and varied. The three most commonly used control schemes are Cycle I, Cycle II, Cycle III, and Cycle W.

**Cycle I Control.** Except during the warm-up stage, Cycle I (Figure 45), supplies 100% outdoor air at all times. During warm-up, the heating valve is open, the OA damper is closed, and the RA damper is open. As temperature rises into the operating range of the space thermostat, the OA damper opens fully, and the RA damper closes. The heating valve is positioned to maintain space temperature. The airstream thermostat can override space thermostat action on the heating valve to prevent discharge air from dropping below a minimum temperature. Figure 47 shows the positions of the heating valve and ventilation dampers in relation to space temperature.

**Cycle II Control.** During the heating stage, Cycle II (Figure 45) supplies a set minimum quantity of outdoor air. Outdoor air is gradually increased as required for cooling. During warm-up, the heating valve is open, the OA damper is closed, and the RA damper is open. As the space temperature rises into the operating range of the space thermostat, ventilation dampers move to their set minimum ventilation positions. The heating valve and ventilation dampers are operated in sequence as required to maintain space temperature. The airstream thermostat can override space thermostat action on the heating valve and ventilation dampers to prevent discharge air from dropping below a minimum temperature. Figure 49 shows the relative positions of the heating valve and ventilation dampers with respect to space temperature.

**Cycle III Control.** During the heating, ventilating, and cooling stages, Cycle III (Figure 46) supplies a variable amount of outdoor air as required to maintain the air entering the heating coil at fixed temperature (typically 13°C). When heat is not required, this air is
used for cooling. During warm-up, the heating valve is open, the OA air damper is closed, and the RA damper is open. As the space temperature rises into the operating range of the space thermostat, ventilation dampers control the air entering the heating coil at the set temperature. Space temperature is controlled by positioning the heating valve as required. Figure 47 shows the relative positions of the heating valve and ventilation dampers with respect to space temperature.

Day/night thermostats are frequently used with any of these control schemes to maintain a lower space temperature during unoccupied periods by cycling the fan with the outdoor air damper closed. Another common option is a freezestat placed next to the heating coil that shuts the unit off when near-freezing temperatures are sensed.

**Cycle W Control.** Cycle W is similar to Cycle II, except the heating valve is controlled by the room thermostat and the dampers are controlled by the low-limit thermostat (Figures 45 and Figure 47).

**Makeup air units** (Figure 48) replace air exhausted from the building through exfiltration or by laboratory or industrial processes. Makeup air must be at or near space conditions to minimize uncomfortable air currents. The makeup air fan is usually turned on, either manually or automatically, whenever exhaust fans are turned on. The two-position outdoor air damper remains closed when the makeup fan is not in operation. The outdoor air limit control opens the preheat coil valve when outdoor air temperature drops to the point where the air requires heating to raise it to the desired supply air temperature. The discharge temperature controller then positions the face and bypass dampers to maintain that temperature. A capillary element thermostat located adjacent to the coil shuts the fan down for freeze protection if air temperature approaches freezing at any spot along the sensing element.

**Multizone, Single-Duct System**

This system (Figure 49) is most effective where all zones are in either heating or cooling mode at the same time. When necessary and where energy regulations allow it, reheat can be used to accommodate systems with simultaneous heating and cooling loads.

**Multizone Dual-Duct Systems**

A single supply fan system uses a single fan to supply separate heating and cooling ducts (Figure 50). Terminal mixing boxes are used to control the zone temperature. Static control is similar to that in VAV single-duct systems, except that static pressure sensors are
Fig. 49  Multizone Single-Duct System

Fig. 50  Dual-Duct Single Supply Fan System

Fig. 51  Dual Supply Fan System
needed in each supply duct. A controller allows the sensor sensing the lowest pressure to control the fan output, thus ensuring that there is adequate static pressure to supply the necessary air for all zones.

Control of a return air fan is similar to that described previously in the section on Fans in the paragraph on Return Fan Static Control. Flow stations are usually located in each supply duct, and a signal corresponding to the sum of the two airflows is transmitted to the RA fan volume controller to establish the set point of the return fan controller.

The hot deck has its own heating coil, and the cold deck has its own cooling coil. Each coil is controlled by its own discharge air temperature controller. The controller set point may be reset from the greatest representative demand zone: based on zone temperature, the hot deck may be reset from the zone with the greatest heating demand, and the cold deck from the zone with the greatest cooling demand.

Control based on the zone requiring the most heating or cooling increases operation economy because it reduces the energy delivered at less-than-maximum load conditions. However, the expected economy is lost if air quantity to a zone is too low, temperature in a space is set to an extreme value, a zone sensor is placed so that it senses spot loads (due to coffee pots, the sun, copiers, etc.), a sensor is located in an unoccupied zone, or a zone sensor malfunctions. In these cases, a weighted average of zone signals can recover the benefit at the expense of some comfort in specific zones.

Ventilation dampers (OA, RA, and EA) are controlled for cooling, with outdoor air as the first stage of cooling in sequence with the cooling coil from the cold deck discharge temperature controller. Control is similar to that in single-duct systems. A more accurate OA flow-measuring system can replace the minimum positioning switch.

Dual supply fan systems use separate supply fans for the heating and cooling ducts. Static pressure control is similar to that for VAV dual-duct single-supply fan systems, except that each supply fan has its own static pressure sensor and control. If the system has a return air fan, volume control is similar to that described in the section on Fans in the paragraph on Return Fan Static Control. Temperature, ventilation, and humidity control are similar to those for VAV dual-duct single supply fan systems.

Chillers

The manufacturer almost always supplies chillers with an automatic control package installed. Control functions fall into two categories: capacity and safety.

Because of the wide variety of chiller types, sizes, drives, manufacturers, piping configurations, pumps, cooling towers, distribution systems, and loads, most central chiller plants, including their controls, are designed on a custom basis. Chapter 43 of the 1998 ASHRAE Handbook—Refrigeration describes various chillers (e.g., centrifugal and reciprocating). Chapter 11 of the 2000 ASHRAE Handbook—Systems and Equipment covers variations in piping configurations (e.g., series and parallel chilled water flow) and some associated control concepts.

Chiller plants are generally one of two types: variable flow (Figures 52 and 53) or constant flow (Figure 54). The figures show a parallel-flow piping configuration. Control of the remote load determines which type should be used. Throttling coil valves vary the flow in response to the load and a temperature differential that tends to remain near the design temperature differential. The chilled water supply temperature typically establishes the base flow rate. To improve energy efficiency, the set point is reset for the zone with the greatest load (load reset) or other variances.

The constant flow system (Figure 54) is only constant flow under each combination of chillers on line: a major upset occurs whenever a chiller is added or dropped. The load reset function ensures that the zone with the largest load is satisfied, while supply or return water control treats average zone load.
Refrigerant Pressure Optimization

Chiller efficiency is a function of the percent of full load on the chiller and the difference in refrigerant pressure between the condenser and the evaporator. In practice, the pressure is represented by condenser water exit temperature minus chilled water supply temperature. To reduce the refrigerant pressure, the chilled water supply temperature must be increased and/or the condenser water temperature decreased. An energy saving of about 3% is obtained for each degree 1 K reduction.

The following methods are used to reduce refrigerant pressure:

1. Use chilled water load reset to raise the supply set point as load decreases. Figure 55 shows the basic function of this method. Varying degrees of sophistication are available, including computer control.
2. Lower condenser temperature to the lowest safe temperature (use manufacturer’s recommendations) by keeping the cooling tower bypass valve closed, operating at full condenser water pump capacity, and maintaining full airflow in all cells of the cooling tower until water temperature is within about 2 K of the outdoor air wet-bulb temperature. However, the additional pump and fan power as well as the fan power of the VAV air handlers must be considered in calculating net energy savings.

Operation Optimization

Multiple-chiller plants should be operated at the most efficient point on the part-load curve. Figure 56 shows a typical part-load curve for a centrifugal chiller operated at design conditions. Figure 57 shows similar curves at different pressure-limiting conditions. Figure 58 indicates the point at which a chiller should be added or dropped in a two-unit plant. In general, the part-load curves are plotted for all combinations of chillers; then, the break-even point between n and n + 1 chillers can be determined.

Daily start-up of the chiller plant should be optimized to minimize run time based on start-up time of the air-handling units. Chillers are generally started at the same time as the first fan system. Chillers may be started early if the water distribution loop has great thermal mass; they may be started later if outdoor air can provide cooling to fan systems at start-up.

The condenser water circuit and control arrangement for the central plant are shown in Figure 59. The control system designer works with liquid chiller control when the equipment is integrated into the central chiller plant. Typically, cooling tower, chiller pump, and condenser pump control must be considered if the overall plant is to be stable and energy-efficient.

Water Heating

A basic constant volume hydronic system is shown in Figure 60. A variable speed drive could be added to the pump motor and the
three-way valves could be changed to two-way valves to save energy.

SPECIAL APPLICATIONS

Mobile Unit Control

The operating point of any control that relies on pressure to operate a switch or valve varies with atmospheric pressure. Normal variations in atmospheric pressure do not noticeably change the operating point, but a change in altitude affects the control point to an extent governed by the change in absolute pressure. This pressure change is especially important with controls selected for use in land and aerospace vehicles that are subject to wide variations in altitude. The effect can be substantial; for example, barometric pressure decreases by nearly one-third as altitude increases from sea level to 3000 m.

Explosive Atmospheres

Sealed-in-glass contacts are not considered explosion-proof; therefore, other means must be provided to eliminate the possibility of a spark in an explosive atmosphere.

When using electric control, the control case and contacts can be surrounded with an explosion-proof case, permitting only the capsule and the capillary tubing to extend into the conditioned space. It is often possible to use a long capillary tube and mount the instrument case in a nonexplosive atmosphere. The latter method can be duplicated with an electronic control by placing an electronic sensor in the conditioned space and feeding its signal to an electronic transducer located in the nonexplosive atmosphere.

Because a pneumatic control uses compressed air, it is safe in otherwise hazardous locations. However, many pneumatic controls interface with electrical components. All electrical components require appropriate explosion-proof protection.

Sections 500 to 503 of the National Electrical Code (NFPA Standard 70) include detailed information on electrical installation protection requirements for various types of hazardous atmospheres.

Duct Static Pressure Limit Control

In addition to the remote static pressure controllers, a high-limit static pressure controller should be placed at the fan discharge to turn the fan off or limit discharge static pressure in the event of excessive duct pressure (e.g., when a fire or smoke damper closes between the fan and the remote sensor). Supply-fan static pressure control devices such as inlet guide vanes and variable-speed drives should be interlocked to move to the minimum flow or closed position when the fan is not running; this precaution prevents fan overload or damage to ductwork upon start-up.

When selecting automatic controls, the type needed to control high or low limits (safety) must be considered. This control may be inoperative for days, months, or years, and then it must operate immediately to prevent serious damage to equipment or property. Separate operating and limit controls are always recommended, even for the same functions.
The local loop controller can be a direct digital controller (DDC) labor and energy costs. Control is frequently extended to a central control point to diagnose sensory or remote functions such as reset and start-stop. However, local devices used with a single HVAC system and excludes any supervisory control to increase fan modulation; however, the controlling high limit will override.

Steam or hot water exchangers tend to be self-regulating and, in that respect, differ from electrical resistance heat transfer devices. For example, if airflow through a steam or hot water coil stops, coil surfaces approach the temperature of the entering steam or hot water, but cannot exceed it. Convexion or radiation losses from the steam or hot water to the surrounding area take place, so the coil is not usually damaged. Electric coils and heaters, on the other hand, can be damaged when air stops flowing around them. Therefore, control and power circuits must interlock with heat transfer devices (pumps and fans) to shut off electrical energy when the device shuts down. Flow or differential pressure switches may be used for this purpose; however, they should be calibrated to energize only when there is airflow. This precaution shuts off power in case a fire damper closes or some duct lining blocks the air passage. Limit thermostats should also be installed to turn off the heaters when temperatures exceed safe operating levels.

Duct Heaters

The current in individual elements of electric duct heaters is normally limited to a maximum safe value established by the National Electrical Code or local codes. Two safety devices in addition to the airflow interlock device are usually applied to duct heaters: (1) the automatic reset high-limit thermostat normally turns off the control circuit. If the control circuit has a inherent time delay or uses solid-state switching devices, a separate safety contactor may be desirable. The manual reset backup high-limit safety device is generally set independently to interrupt all current to the heater in case other control devices fail. An electric heater must have a minimum airflow switch and two high-temperature limit sensors; one with a manual reset and one with automatic reset.

DESIGN CONSIDERATIONS AND PRINCIPLES

In designing and selecting the HVAC system for the entire building, the type, size, use, and operation of the structure must be considered. Subsystems such as fan and water supply are normally controlled by local automatic control or a local loop control. A local loop control includes the sensors, controllers, and controlled devices used with a single HVAC system and excludes any supervisory or remote functions such as reset and start-stop. However, local control is frequently extended to a central control point to diagnose malfunctions that might result in damage from delay, and to reduce labor and energy costs.

Distributed processing using microprocessors has augmented computer use at many locations other than the central control point. The local loop controller can be a direct digital controller (DDC) instead of a pneumatic or electric thermostat, and some energy management functions may be performed by a DDC.

Because HVAC systems are designed to meet maximum design conditions, they nearly always function at partial capacity. Because the system must be adjusted and operated for many years, the simplest control that produces the necessary results is usually the best.

Mechanical and Electrical Coordination

Even a pneumatic control includes wiring, conduit, switchgear, and electrical distribution for many electrical devices. The mechanical designer must inform the electrical designer of the total electrical requirements if the controls are to be wired by the electrical contractor. Requirements include (1) the devices to be furnished and/or connected, (2) electrical load, (3) location of electrical items, and (4) a description of each control function.

Coordination is essential. Proper coordination should produce a control diagram that shows the interface with other control elements to form a complete and usable system. As an option, the control engineer may develop a complete performance specification and require the control contractor to install all wiring related to the specified sequence. The control designer must run the final checks of drawings and specifications. Both mechanical and electrical specifications must be checked for compatibility and uniformity.

Building and System Subdivision

The following factors must be considered in the building and mechanical system subdivision:

- Heating and cooling loads as they vary—the ability to heat or cool the interior or exterior areas of a building at any time
- Occupancy schedules and the flexibility to meet needs without undue initial and/or operating costs
- Fire and smoke control and possibly compartmentation that matches the air-handling layout and operation

Control Principles for Energy Conservation

Temperature and Ventilation Control. VAV systems are typically designed to supply constant temperature air at all times. To conserve central plant energy, the temperature of the supply air can be raised in response to demand from the zone with the greatest load (load analyzer control). However, because more cool air must then be supplied to match a given load, the mechanical cooling energy saved may be offset by an increase in fan energy. Equipment operating efficiency should be studied closely before implementing temperature reset in cooling-only VAV systems.
Outdoor air (OA), return air (RA), and exhaust air (EA) ventilation dampers are controlled by the discharge air temperature controller to provide free cooling as the first stage in the cooling sequence. When outdoor air temperature rises to the point that it can no longer be used for cooling, an outdoor air limit (economizer) control overrides the discharge controller and moves ventilation dampers to the minimum ventilation position. An enthalpy control system can replace outdoor air limit control in some climatic areas.

After the general needs of a building have been established, and the building and system subdivision has been made, the mechanical system and its control approach can be considered. Designing systems that conserve energy requires knowledge of (1) the building, (2) its operating schedule, (3) the systems to be installed, and (4) ASHRAE Standard 90.1. The principles or approaches that conserve energy are as follows:

1. **Run equipment only when needed.** Schedule HVAC unit operation for occupied periods. Run heat at night only to maintain internal temperature between 10 and 13°C to prevent freezing. Start morning warm-up as late as possible to achieve design internal temperature by occupancy time, considering residual space temperature, outdoor temperature, and equipment capacity (optimum start control). Under most conditions, equipment can be shut down some time before the end of occupancy, depending on internal and external load and space temperature (optimum stop control). Calculate shutdown time so that space temperature does not drift out of the selected comfort zone before the end of occupancy.

2. **Sequence heating and cooling.** Do not supply heating and cooling simultaneously. Central fan systems should use cool outdoor air in sequence between heating and cooling. Zoning and system selection should eliminate, or at least minimize, simultaneous heating and cooling. Also, humidification and dehumidification should not take place concurrently.

3. **Provide only the heating or cooling actually needed.** Reset the supply temperature of hot and cold air (or water).

4. **Supply heating and cooling from the most efficient source.** Use free or low-cost energy sources first, then higher cost sources as necessary.

5. **Apply outdoor air control.** When on minimum outdoor air, use no less than that recommended by ASHRAE Standard 62. In areas where it is cost-effective, use enthalpy rather than dry-bulb temperature to determine whether outdoor or return air is the most energy-efficient air source for the cooling mode.

**System Selection**

The mechanical system significantly affects the control of zones and subsystems. The type of system and the number and location of zones influence the amount of simultaneous heating and cooling that occurs. For exterior building sections, heating and cooling should be controlled in sequence to minimize simultaneous heating and cooling. In general, this sequencing must be accomplished by the control system because only a few mechanical systems (e.g., two-pipe systems and single-coil systems) have the ability to prevent simultaneous heating and cooling. Systems that require engineered control systems to minimize simultaneous heating and cooling include the following:

- **VAV cooling with zone reheat.** Reduce cooling energy and/or air volume to a minimum before applying reheat.
- **Four-pipe heating and cooling for unitary equipment.** Sequence heating and cooling.
- **Dual-duct systems.** Condition only one duct (either hot or cold) at a time. The other duct should supply a mixture of outdoor and return air.
- **Single-zone heating/cooling.** Sequence heating and cooling.

Some exceptions exist, such as of dehumidification with reheat.

Control zones are determined by the location of the thermostat or temperature sensor that sets the requirements for heating and cooling supplied to the space. Typically, control zones are for a room or an open area of a floor.

Many jurisdictions in the United States no longer permit constant volume systems that reheat cold air or that mix heated and cooled air. Such systems should be avoided. If selected, they should be designed for minimal use of the reheat function through zoning to match actual dynamic loads and resetting cold and warm air temperatures based on the zone(s) with the greatest demand. Heating and cooling supply zones should be structured to cover areas of similar load. Areas with different exterior exposures should have different supply zones.

Systems that provide changeover switching between heating and cooling prevent simultaneous heating and cooling. Some examples are hot or cold secondary water for fan coils or single-zone fan systems. They usually require small operational zones, which have low load diversity, to permit changeover from warm to cold water without occupant dissatisfaction.

Systems for building interiors usually require year-round cooling and are somewhat simpler to control than exterior systems. These interior areas normally use all-air systems with a constant supply air temperature, with or without VAV control. Proper control techniques and operational understanding can reduce the energy used to treat these areas. Reheat should be avoided. General load characteristics of different parts of a building may lead to selecting different systems for each.

**Load Matching**

With individual room control, the environment in a space can be controlled more accurately and energy can be conserved if the entire system can be controlled in response to the major factor influencing the load. Thus, water temperature in a water heating system, steam temperature or pressure in a steam heating system, or delivered air temperature in a central fan system can be varied as building load varies. Control on the entire system relieves individual space controls of part of their burden and provides more accurate space control. Also, modifying the basic rate of heating or cooling input in accordance with the entire system load reduces losses in the distribution system.

The system must always satisfy the area or room with the greatest demand. Individual controls handle demand variations in the area the system serves. The more accurate the system zoning, the greater is the control, the smaller are the distribution losses, and the more effectively space conditions are maintained by individual controls.

Buildings or zones with a modular arrangement can be designed for subdivision to meet occupant needs. Before subdivision, operating inefficiencies can occur if a zone has more than one thermostat. In an area where one thermostat activates heating while another activates cooling, the terminals should be controlled from a single thermostat until the area is properly subdivided.

**Size of Controlled Area**

No individually controlled area should exceed about 500 m² because the difficulty of obtaining good distribution and of finding a representative location for the space control increases with zone area. Each individually controlled area must have similar load characteristics throughout. Equitable distribution, provided through competent engineering design, careful equipment sizing, and proper system balancing, is necessary to maintain uniform conditions throughout an area. The control can measure conditions only at its location; it cannot compensate for nonuniform conditions caused by improper distribution or inadequate design. Areas or rooms having dissimilar load characteristics or different conditions to be maintained should be controlled individually. The
smaller the controlled area, the better the control and the better the performance and flexibility.

**Location of Space Sensors**

Space sensors and controllers must be located where they accurately sense the variables they control and where the condition is representative of the area (zone) they serve. In large open areas having more than one zone, thermostats should be located in the middle of their zones to prevent them from sensing conditions in surrounding zones. Typically, space temperature controllers or sensors are placed in the following locations.

- **Wall-mounted thermostats or sensors** are usually placed on inside walls or columns in the space they serve. Avoid outside wall locations. Mount thermostats where they will not be affected by heat from sources such as direct sun rays; wall pipes or ducts; convectors; or direct air currents from diffusers or equipment (e.g., copy machines, coffee makers, or refrigerators). Air circulation should be ample and unimpeded by furniture or other obstructions, and the thermostat should be protected against mechanical injury. Thermostats located in spaces such as corridors, lobbies, or foyers should be used to control those areas only.

- **Return air thermostats** can control floor-mounted unitary conditioners such as induction or fan-coil units and unit ventilators. On induction and fan-coil units, the sensing element is behind the return air grille. On classroom unit ventilators that use up to 100% outdoor air for natural cooling, however, a forced flow sampling chamber should be provided for the sensing element. The sensing element should be located carefully to avoid radiant effect and to ensure adequate air velocity across the element. If return air sensing is used with a central fan system, locate the sensing element as near as possible to the space being controlled to eliminate any influence from other spaces and the effect of any heat gain or loss in the duct. Where supply/return light fixtures are used to return air to a ceiling plenum, the return air sensing element can be located in the return air opening. Be sure to offset the set point to compensate for the heat from the light fixtures.

- **Diffuser-mounted thermostats** usually have sensing elements mounted on circular or square ceiling supply diffusers and depend on aspiration of room air into the supply airstream. They should be used only on high-aspiration diffusers adjusted for a horizontal air pattern. The diffuser on which the element is mounted should be in the center of the occupied area of the controlled zone.

**Lowered Night Temperature**

When temperatures during unoccupied periods are lower than those normally maintained during occupied periods, an automatic timer often establishes the proper day and night temperature time cycle. Allow sufficient time in the morning to pick up the conditioning load well before there is any heavy increase. Night setback temperatures are often monitored and controlled more closely with control systems. These computer based systems take into account variables such as outdoor temperature, system capacity, and building mass to determine optimal start-up and shutdown times.

CHAPTER 46
SOUND AND VIBRATION CONTROL

MECHANICAL equipment is one of the major sources of sound in a building. Primary considerations often given to the selection and use of mechanical equipment in buildings have generally been those directly related to the intended use of the equipment, like cooling, heating, and ventilation. However, for environmental considerations in critical listening spaces, like conference rooms and auditoria, and for many other spaces with light building structures and variable-volume air distribution systems, the sound generated by mechanical equipment and its effects on the overall acoustical environment in a building must be considered. Thus, the selection of mechanical equipment and the design of equipment spaces should be undertaken with an emphasis on (1) the intended uses of the equipment and (2) the goal of providing acceptable sound and vibration levels in occupied spaces of the building in which the equipment is located.

The system concept of noise control is used throughout, in that each of the components is related to the source-path-receiver chain. The noise generation is the source; it travels from the source via a path, which can be through the air (airborne) or through the structure (structure-borne) until it reaches the ear of the receiver. When the combination of this chain is complex, it can be referred to it as a system effect. So, noise propagates from the sources through the air distribution ducts, through the structure, and through combinations of paths, reaching the occupants. All mechanical components, from dampers to diffusers to junctions, may produce sound by the nature of the airflow through and around them. As a result, almost all components must be considered. Since sound travels effectively in the same or opposite direction of airflow, upstream and downstream paths are often equally important.

Adequate noise and vibration control in a heating, ventilating, and air-conditioning (HVAC) system is not difficult to achieve during the design phase of the system, providing basic noise and vibration control principles are understood. This chapter discusses basic sound and vibration principles and data needed by HVAC designers. Divided into two main sections, one on sound, the other on vibration, this chapter is organized differently than versions in Handbooks prior to 1995. This chapter includes more information on acoustic design guidelines and system design requirements. Most of the equations associated with sound and vibration control design in HVAC systems have been replaced by related tables and simpler design procedures. The equations that have been removed can be found in the 1991 and 1992 ASHRAE Handbooks. In addition, technical discussions and detailed HVAC component and system design examples can be found in Algorithms for HVAC Acoustics (Reynolds and Bledsoe 1991).

Other publications that cover sound and vibration control in HVAC systems include the 1997 ASHRAE Handbook—Fundamentals, which covers fundamentals associated with sound and vibration in HVAC; Schaffer (1991), who provides specific guidelines for the acoustic design and related construction phases associated with HVAC systems, troubleshooting sound and vibration problems, and HVAC sound and vibration specifications; Ebbing and Blazier (1998), who interpret and clarify how users can make the best use of HVAC manufacturers’ acoustical data and application information; and Reynolds and Bevirt (1994), who cover instrument requirements, instrument and measurement calibration procedures, measurement procedures, and specification and construction installation review procedures associated with sound and vibration measurements relative to HVAC systems.

DATA RELIABILITY

The data in this chapter comes both from consulting experience and research studies. When applying the data, especially to situations that extrapolate from the original data, use caution. While specific uncertainties are not stated for each data set, the sound levels or attenuation data are probably within 2 dB of measured or expected results. However, significantly greater variations may occur, especially in the low frequency ranges and particularly in the 63 Hz octave band. While specific data sets may have a wide uncertainty range, experience has demonstrated the usefulness of combining data sets for estimating the sound level. If done correctly, these estimates usually result in space sound pressure levels within 5 dB of measured levels.

SOUND

ACOUSTICAL DESIGN OF HVAC SYSTEMS

The solution to nearly every HVAC system noise and vibration control problem involves examining the sound sources, the sound transmission paths, and the receivers. For most HVAC systems, the sound sources are associated with the building mechanical and electrical equipment. As indicated in Figure 1, sound travels between a source and receiver through many possible sound and/or vibration paths.
transmission paths. Sound sources are the components that either generate noise, like electric motors, or produce noise when air passes by them, like dampers or diffusers. Sound receivers are generally the people who occupy a building. For most HVAC systems, designers can not always modify or change the sound source or receiver characteristics. Thus, system designers are most often constrained to modifying the sound transmission paths as a means of achieving desired sound levels in occupied areas of a building.

Different sources produce sounds that have different frequency distributions. For examples, fan noise generally contributes to the sound levels in the 16 Hz through 250 Hz octave frequency bands (Figure 3 as curve A). Variable air volume (VAV) valve noise usually contributes to the sound levels in the 63 Hz through 1000 Hz octave frequency bands (curve B, Figure 2). Diffuser noise is usually in the 250 Hz through 8000 Hz octave frequency bands (curve C, Figure 2). The overall sound pressure level associated with all of these sound sources combined is shown as curve D in Figure 2.

Occupants may complain when an acceptable sound spectrum is not achieved in an occupied space. Figure 3 shows the frequency ranges of the most likely sources of HVAC sound-related complaints. Figure 4 shows the frequencies at which different types of mechanical equipment generally control the sound spectra in a room.

### BASIC DESIGN TECHNIQUES

When selecting fans and other related mechanical equipment and when designing air distribution systems to minimize the sound transmitted from different components to the occupied spaces that they serve, consider the following:

1. Design the air distribution system to minimize flow resistance and turbulence. High flow resistance increases the required fan pressure, which results in higher noise being generated by the fan. Turbulence increases the flow noise generated by duct fittings and dampers in the air distribution system, especially at low frequencies.

2. Select a fan to operate as near as possible to its rated peak efficiency when handling the required quantity of air and static pressure. Also, select a fan that generates the lowest possible noise but still meets the required design conditions for which it is selected. Using an oversized or undersized fan that does not operate at or near rated peak efficiency can result in substantially higher noise levels.
3. Design duct connections at both the fan inlet and outlet for uniform and straight air flow. Failure to do this can result in severe turbulence at the fan inlet and outlet and in flow separation at the fan blades. Both of these can significantly increase the noise generated by the fan.

4. Select duct silencers that do not significantly increase the required fan total static pressure. Duct silencers can significantly increase the required fan static pressure if improperly selected. Selecting silencers with static pressure losses of 87 Pa. or less can minimize silencer airflow regenerated noise.

5. Place fan-powered mixing boxes associated with variable-volume air distribution systems away from noise-sensitive areas.

6. Minimize flow-generated noise by elbows or duct branch takeoffs, whenever possible, by locating them at least four to five duct diameters from each other. For high velocity systems, it may be necessary to increase this distance to up to ten duct diameters in critical noise areas. The use of flow straighteners or honeycomb grids, often called “egg crates”, in the necks of short-length takeoffs that lead directly to grilles, registers, and diffusers is preferred to the use of volume extractors that protrude into the main duct airflow.

7. Keep airflow velocity in the duct as low as possible (7.5 m/s or less) near critical noise areas by expanding the duct cross-section area. However, do not exceed an included expansion angle of greater than 15°. Flow separation, resulting from expansion angles greater than 15°, may produce rumble noise. Expanding the duct cross-section area will reduce potential flow noise associated with turbulence in these areas.

8. Use turning vanes in large 90° rectangular elbows and branch takeoffs. This provides a smoother transition in which the air can change flow direction, thus reducing turbulence.

9. Place grilles, diffusers and registers into occupied spaces as far as possible from elbows and branch takeoffs.

10. Minimize the use of volume dampers near grills, diffusers and registers in acoustically critical situations.

11. Vibration isolate all vibrating reciprocating and rotating equipment if mechanical equipment is located on upper floors or is roof-mounted. Also, it is usually necessary to vibration isolate the mechanical equipment that is located in the basement of a building as well as piping supported from the ceiling slab of a basement, directly below tenant space. It may be necessary to use flexible piping connectors and flexible electrical conduit between rotating or reciprocating equipment and pipes and ducts that are connected to the equipment.

12. Vibration isolate ducts and pipes, using spring and/or neoprene hangers for at least the first 15 m from the vibration-isolated equipment.

13. Use barriers near outdoor equipment when noise associated with the equipment will disturb adjacent properties if barriers are not used. In normal practice, barriers typically produce no more than 15 dB of sound attenuation in the mid frequency range.

Table lists several common sound sources associated with mechanical equipment noise. Anticipated sound transmission paths and recommended noise reduction methods are also listed in the table. Airborne and/or structure-borne sound can follow any or all of the transmission paths associated with a specified sound source. Schaffer (1991) has more detailed information in this area.

Table 1 lists several common sound sources associated with mechanical equipment noise. Anticipated sound transmission paths and recommended noise reduction methods are also listed in the table. Airborne and/or structure-borne sound can follow any or all of the transmission paths associated with a specified sound source. Schaffer (1991) has more detailed information in this area.
EQUIPMENT SOUND LEVELS

An accurate acoustical analysis of HVAC systems depends on reliable equipment sound data. These data are often available from equipment manufacturers in the form of sound pressure levels at a specified distance from the equipment or, more preferably, equipment sound power levels. Standards used to determine equipment and component sound data are listed at the end of this chapter.

When reviewing manufacturers’ sound data, require certification that the data have been obtained according to one or more of the relevant industry standards. If they have not, the equipment should be rejected in favor of equipment whose data have been obtained according to relevant industry standards.

Fans

Prediction of Fan Sound Power. The sound power generated by a fan performing at a given duty is best obtained from a manufacturer’s test data taken under approved test conditions (AMCA Standard 300 or ASHRAE Standard 68/AMCA Standard 330). Applications of air-handling products range from stand-alone fans to systems with various modules and appurtenances. These appurtenances and modules can significantly affect the air handler’s sound power levels. In addition, different types of fans that provide similar aerodynamic performance can have significant acoustical differences.

Fan sound levels, even when determined by test, may be quite different once the fan is installed in an air handler, which in effect creates a new acoustic environment. Proper testing to determine the resulting sound power levels once a fan is installed in an air handler is essential. Fan manufacturers are in the best position to supply information on their products, and should be consulted for data when evaluating the acoustic performance of fans for an air handler application. Similarly, air handler manufacturers are in the best position to supply acoustic information on air handlers. For all of these reasons, information obtained directly from manufacturers should be preferred over generic fan-only sound power levels.

For a detailed description of fan operations, see Chapter 18 in the 2000 ASHRAE Handbook—Systems and Equipment. Different fan types have different noise characteristics and within a fan type, several factors influence noise.

Point of Fan Operation. Fan selection at the calculated point of maximum efficiency is common practice to ensure minimum power consumption. In general, fan sound is at a minimum near the point of maximum efficiency. Noise increases as the operating point shifts to the right (higher airflow and lower static pressure) and low frequency noise can increase substantially at operating points to the left of maximum efficiency (lower airflow and higher static pressure). These operating points should be avoided.

Blade-Pass Frequency. The blade-pass frequency is represented by the number of times per second a fan impeller passes a stationary item of \( f_{bp} = \frac{rpm \times \text{number of impeller blades}}{60} \). All fans generate a tone at this frequency and its multiples. Whether this tone is objectionable or barely noticeable depends on the type and design of the fan and the point of operation.

Housed Centrifugal Fans. For instance, some fans are commonly used in many air handlers. The blade pass of FC fans is typically less prominent and at a higher frequency than other fans. The most distinguishing acoustical concern of FC fans is the prevalent occurrence of low-frequency rumble. FC fans are commonly thought to have 16 Hz, 31.5 Hz, and 63 Hz rumble, particularly when operating to the left of the maximum efficiency point.

Backward inclined (BI) fans and airfoil (AF) fans are generally louder at the blade pass-frequency than a given FC fan selected for the same duty; but BI fans are much more energy efficient at higher pressures and airflow. The blade pass tone generally increases in prominence with increasing fan speed and is typically in a frequency range that is difficult to attenuate. Below the blade pass frequency, these fans generally have lower sound amplitude than FC fans and are often quieter at the high frequencies.

Plenum Fans. In this type of fan, airflow moves into the fan impeller through an inlet bell located in the chamber wall. Airfoil and backward inclined fan impellers are used in a plenum fan configuration. The fan, which has no housing around the fan impeller, discharges directly into the chamber pressurizing the plenum and forcing air through the attached ductwork. These fans produce substantially lower discharge sound power levels if the fan plenum is appropriately sized and acoustically treated with sound absorptive material.

Axial Fans. Axial fans generally have the lowest amplitudes of sound at low frequency of any fan. For this reason they are often used in applications where the higher frequency noise can be managed with attenuation devices. In the useful operating range, the noise from axial fans is a strong function of the inlet airflow symmetry and blade tip speed.

Propeller Fans. Sound from propeller fans generally has a low-frequency dominated spectrum shape, and the blade passage frequency is typically prominent and occurs in the low-frequency bands due to the small number of blades. Propeller fans use blades to radiate noise in the low-frequency bands. High system resistance requires more power, and consequently, fans generate higher sound power levels.

Propeller Fans. Sound from propeller fans generally has a low-frequency dominated spectrum shape, and the blade passage frequency is typically prominent and occurs in the low-frequency bands due to the small number of blades. Propeller fans use blades to radiate noise in the low-frequency bands. High system resistance requires more power, and consequently, fans generate higher sound power levels.

Minimizing Fan Sound. To minimize the sound attenuation required in the air distribution system, proper selection and installation of the fan (or fans) are vitally important. The following factors should be considered:

- Design the air distribution system for minimum airflow resistance. High system resistance requires more power, and consequently, fans generate higher sound power levels.
- Carefully analyze pressure losses. Higher than expected system resistance may result in higher sound power levels than originally estimated.
- Examine the sound power levels of different types of fans. Different fans generate different sound levels and produce different sound spectra. Select a fan (or fans) that will generate the lowest...
possible sound power levels, commensurate with other fan selection requirements.

- Many fans generate tones at the blade passage frequency and its harmonics that may require additional acoustical treatment. The amplitude of these tones can be affected by resonance in the duct system, fan design, and inlet flow distortions caused by poor inlet duct design, or by the operation of an inlet volume control damper. When possible, variable speed control for volume control is preferable to volume control dampers to control fan noise.

- Design duct connections at both the fan inlet and outlet for uniform and straight airflow. Avoid unstable, turbulent, and swirling inlet airflow. Deviation from acceptable practice can severely degrade both the aerodynamic and acoustic performance of any fan and invalidate the manufacturer’s ratings or other performance predictions.

Variable Air Volume (VAV) Systems

General Design Factors. VAV systems can significantly reduce energy cost due to their ability to modulate air capacity. But they can be the source of fan noise that is very difficult to mitigate. To avoid these potential problems, the designer should carefully design the ductwork and the static pressure control systems and select the fan or air handling unit and its air modulation device.

As in other aspects of HVAC design, the duct system should be designed for the lowest practical static pressure loss, especially in the ductwork closest to the fan or air handling unit. High airflow velocity and convoluted duct routing can cause airflow distortions that result in excessive pressure drop and fan instabilities that are responsible for excessive noise, fan stall, or both.

Many VAV noise complaints have been traced to control problems. While most of the problems are associated with improper installation, many are caused by poor design. The designer should specify high-quality fans or air handling units that will operate in their optimum ranges, not at the edge of their operation ranges where low system tolerances can lead to inaccurate fan capacity control. Also, the in-duct static pressure sensors should be placed in duct sections having the lowest possible air turbulence; that is, at least three equivalent duct diameters from any elbow, takeoff, transition, offset, or damper.

VAV noise problems have been traced to improper air balancing. For example, air balance contractors commonly balance an air distribution system by setting all damper positions without considering the possibility of reducing the fan speed. The result is a duct system in which no damper is completely open and the fan is delivering air at a higher static pressure than would otherwise be necessary. If the duct system is balanced with at least one balancing damper wide open, the fan speed could be reduced with a corresponding reduction in fan noise. Lower sound levels will occur if most balancing dampers are wide open or eliminated.

Fan Selection. For constant-volume systems, fans should be selected to operate at maximum efficiency at the fan design airflow rate. However, VAV systems must be selected to operate with efficiency and stability throughout its range of modulation. For example, a fan selected for peak efficiency at full output may aerodynamically stall at an operating point of 50% of full output resulting in significantly increased low frequency noise. Similarly, a fan selected to operate at the 50% output point may be very inefficient at full output, resulting in substantially increased fan noise at all frequencies. In general, a fan selected for a VAV system should be selected for a peak efficiency at an operating point of around 70 to 80% of the maximum required system capacity. This usually means selecting a fan that is one size smaller than that required for peak efficiency at 100% of maximum required system capacity.

Variable Inlet Vanes and Discharge Dampers. Variable inlet vanes vary airflow capacity by changing the inlet airflow to a fan wheel. This type of air modulation varies the total air volume and pressure at the fan while the fan speed remains constant. While, fan pressure and air volume reductions at the fan result in duct system noise reductions by reduced air velocity and pressures in the duct work, there is an associated increase in fan noise caused by the airflow turbulence and flow distortions at the inlet vanes acting as a fan inlet obstruction. Fan manufacturers’ test data have shown that, on airfoil type centrifugal fans, as vanes mounted inside the fan inlet (nested inlet vanes) close, the sound level at the blade passing frequency of the fan increases by 2 to 8 dB, depending on the amount of total air volume restricted. For inlet vanes that are mounted externally the increase is on the order of 2 to 3 dB. Forward curved fan wheels with inlet vanes are about 1 to 2 dB quieter than airfoil fan wheels. In-line axial type fans with inlet vanes generate increased noise levels of 2 to 8 dB in the low frequency octave bands for a 25% to 50% closed vane position.

Discharge dampers are typically located immediately downstream of the supply air fan and reduce airflow and increase pressure drop across the fan while the fan speed remains constant. Because of the air turbulence and flow distortions created by the high-pressure drop across discharge dampers there is a high probability that duct rumble will occur near the damper location. If the dampers are throttled to a very low flow, a stall condition can occur at the fan also resulting in an increase in low-frequency noise.

Variable Pitch Fan Blades for Capacity Control. Variable pitch fan blade controls vary the fan blade angle in order to reduce the overall airflow through the fan. This type of capacity control system problems that can occur with a larger fan operating at less than 100% design capacity most of the time.

Air Modulation Devices. Variable capacity control methods can be divided into three general categories: (1) variable inlet vanes (sometimes called inlet guide vanes) or discharge dampers, which yield a new fan system curve at each vane or damper setting; (2) variable pitch fan blades (usually used on in-line axial fans), which adjust the blade angle for optimum efficiency at varying capacity requirements; and (3) variable speed motor drives where the motor speed is varied by modulation of the power line frequency or by mechanical means such as gears or continuous belt adjustment. While inlet vane and discharge damper volume controls can add noise to a fan system at reduced capacities, variable speed motor drives and variable-pitch fan blade systems are quieter at reduced air output than at full air output.

Variable Inlet Vanes and Discharge Dampers. Variable inlet vanes vary airflow capacity by changing the inlet airflow to a fan wheel. This type of air modulation varies the total air volume and pressure at the fan while the fan speed remains constant. While, fan pressure and air volume reductions at the fan result in duct system noise reductions by reduced air velocity and pressures in the duct work, there is an associated increase in fan noise caused by the airflow turbulence and flow distortions at the inlet vanes acting as a fan inlet obstruction. Fan manufacturers’ test data have shown that, on airfoil type centrifugal fans, as vanes mounted inside the fan inlet (nested inlet vanes) close, the sound level at the blade passing frequency of the fan increases by 2 to 8 dB, depending on the amount of total air volume restricted. For inlet vanes that are mounted externally the increase is on the order of 2 to 3 dB. Forward curved fan wheels with inlet vanes are about 1 to 2 dB quieter than airfoil fan wheels. In-line axial type fans with inlet vanes generate increased noise levels of 2 to 8 dB in the low frequency octave bands for a 25% to 50% closed vane position.

Discharge dampers are typically located immediately downstream of the supply air fan and reduce airflow and increase pressure drop across the fan while the fan speed remains constant. Because of the air turbulence and flow distortions created by the high-pressure drop across discharge dampers there is a high probability that duct rumble will occur near the damper location. If the dampers are throttled to a very low flow, a stall condition can occur at the fan also resulting in an increase in low-frequency noise.

Variable Pitch Fan Blades for Capacity Control. Variable pitch fan blade controls vary the fan blade angle in order to reduce the overall airflow through the fan. This type of capacity control system
is predominantly used in axial type fans. As air volume and pressure are reduced at the fan, the corresponding noise reduction is usually 2 to 5 dB in the 125 through 4000 Hz octave bands for an 80% to 40% air volume reduction.

**Variable-Speed Motor Controlled Fan.** Three types of electronic variable speed control units are used with fans: (1) current source inverter, (2) voltage source inverter, and (3) pulse-width modulation (PWM). The current source inverter and third generation PWM control units are usually the quietest of these controls. In all three controls, the matching of motors to control units and the quality of the motor windings determines the noise output of the motor. The motor typically emits a pure tone whose amplitude depends on the smoothness of the waveform from the line current. The frequency of the motor tone depends on the motor type, windings, and speed. Both the inverter control units and motors should be enclosed in areas, such as mechanical rooms or electrical rooms, where the noise impact on surrounding rooms is minimal. The primary acoustic advantage of a variable speed controlled fan is the reduction of fan speed, which translates into reduced noise where dB reduction is approximately 50log (higher speed/lower speed). Because this speed reduction generally follows the fan system curve, a fan selected at optimum efficiency initially (lowest noise) does not lose that efficiency as the speed is reduced.

The following guidelines should be observed in the use of variable-speed controllers:

1. Select fan vibration isolators on the basis of the lowest reasonable speed of the fan. For example, the lowest rotational speed might be 600 rpm for a 1000 rpm fan in a commercial system.
2. Select a controller with a feature often called "critical frequency jump band." This feature allows a user to program the controller to avoid certain fan or motor speed settings that might excite vibration isolation system or building structure resonance frequencies.
3. Check the intersection of the fan’s various speed curves with the duct system curve, keeping in mind that the system curve does not go to zero static pressure at no flow when selecting a fan that will be controlled by a variable-speed motor controller. (The system curve is asymptotic at the static pressure control setpoint, typically 250 to 370 Pa) An improperly selected fan may be forced to operate in its stall range at slower fan speeds.

**Terminal Units.** Fans and pressure reducing valves in VAV units should use manufacturer published sound data that indicate the sound power levels (1) that are discharged from the low pressure end of the unit and (2) that radiate from the exterior shell of the unit. These sound power levels vary as a function of valve position and fan point of operation. Sound data for VAV units should be obtained according to the procedures specified by ARI Standard 880.

If the VAV unit is located away from critical areas (such as above a storeroom or corridor), the sound radiated from the shell of the unit may be of no concern. If, however, the unit is located above a critical space and separated from the space by a ceiling with little or no sound transmission loss at low frequencies, the sound radiated from the shell may produce sound in the space below that exceeds the desired noise criterion. In this case, it may be necessary to relocate the unit to a noncritical area or to enclose it with a construction having a high transmission loss. In general, fan-powered VAV units should not be placed above or near any room with a required sound criterion rating of less than RC 40(N).

Systems that use VAV units that will not completely shut off are often helpful. If too many units shut off simultaneously, excessive duct system pressure at low flow can occur. This condition can sometimes cause a fan stall, resulting in accompanying roar, rumble, and surge. Using minimum airflow instead of shutoff VAV units help prevents this condition from occurring.

**Rooftop Mounted Air Handlers**

Rooftop air handlers can have unique noise control requirements because these units are often integrated into a light roof construction. Large roof openings are often required for supply and return air duct connections. These ducts run directly from noise-generating rooftop air handlers to the building interior. Generally, the space or distance between the roof-mounted equipment and the closest occupied spaces below the roof is insufficient to apply standard sound control treatments. Rooftop units should be placed above spaces that are not acoustically sensitive and as far as possible from the nearest occupied space. This measure can reduce the amount of sound control treatment necessary.

The four common sound transmission paths associated with rooftop air handlers (Figure 7) are:

1. Airborne through the bottom of the rooftop unit to spaces below
2. Structure-borne from vibrating equipment in the rooftop unit to the building structure
3. Duct-borne through the supply air duct from the air handler
4. Duct-borne through return air duct to the air handler

Airborne paths are associated with casing-radiated sound that passes through the air handler enclosure and roof structure to the spaces below. Airborne sound can either be a result of air handler noise or from other equipment in the rooftop unit. When a rooftop unit is placed over a large opening in the roof structure through which the supply and return air ducts pass, the opening should be divided into two openings sized to accommodate only the supply and return air ducts. These openings should be properly sealed after the installation of the ducts. If a large single opening exists under the rooftop unit, it should be structurally and acoustically sealed around the supply and return air ducts with one or more layers of gypsum board or other similar material. Airborne sound transmission to spaces below a rooftop unit can be greatly reduced. One way is by placing a rooftop unit on a structural support extending above the roof structure and running the supply and return air ducts horizontally along the roof for several duct diameters before the ducts turn to penetrate the roof. The roof deck/ceiling system below the unit can be constructed to adequately attenuate the sound radiated from the bottom of the unit.

Proper vibration isolation can minimize structure-borne sound and vibration from vibrating equipment in a rooftop unit. Special curb mounting bases are available to support and isolate rooftop units. For roofs constructed with open web joists, thin long span slabs, wooden construction, and any unusually light construction, evaluate all equipment with a mass of more than 130 kg to determine the additional deflection of the structure at the mounting points caused by the equipment. Isolator deflection should be a minimum of 15 times the additional deflection. If the required spring isolator deflection exceeds commercially available products, stiffen the supporting structure or change the equipment location.
Ductborne transmission of sound through the supply air duct consists of two components: sound transmitted from the air handler through the supply air duct system to occupied areas and sound transmitted via duct breakout through a section or sections of the supply air duct close to the air handler to occupied areas. Experience has indicated that sound transmission below 250 Hz via duct breakout is often a major acoustical limitation for many rooftop installations. Excessive low-frequency noise associated with fan noise and air turbulence in the region of the discharge section of the fan and the first duct elbow results in duct rumble, which is difficult to attenuate. This problem is often made worse by the presence of a duct with a high aspect ratio at the discharge section of the fan.

Rectangular ducts with duct lagging are often ineffective in reducing duct breakout noise. Using either a single- or dual-wall round duct with a radiused elbow coming off the discharge section of the fan can control duct breakout. If space does not allow for the use of a single duct, the duct can be split into several parallel round ducts. Another method that is effective is the use of an acoustic plenum chamber constructed with a minimum 50 mm thick, dual-wall plenum panel, which is lined with fiberglass and which has a perforated inner liner at the discharge section of the fan. Either round or rectangular ducts can be taken off the plenum as necessary to supply the rest of the air distribution system. Table 2 illustrates twelve possible rooftop discharge duct configurations with their associated low-frequency noise reduction potential (Harold 1986, 1991; Beatty 1987).

</table>
adequately attenuate the sound between the fan inlet and the spaces below the air handler. The sound attenuation through the return air duct can be improved by adding at least one (more if possible) branch division where the return air duct is split into two sections that extend several duct diameters before they terminate into the plenum space above the ceiling. The inside surfaces of all the return air ducts should be lined with a minimum of 25 mm thick duct liner. If conditions permit, duct silencers in the duct branches or an acoustic plenum chamber at the air handler inlet gives better sound conditions.

Aerodynamically Generated Sound in Ducts

Although fans are a major source of sound in HVAC systems, they are not the only sound source. Aerodynamic sound is generated at duct elbows, dampers, branch takeoffs, air modulation units, sound attenuators, and other duct elements. Produced by the interaction of moving air with the structure, the sound power levels in each octave frequency band depend on the duct element geometry and the turbulence of the airflow and the airflow velocity in the vicinity of the duct element. Duct-related aerodynamic noise problems can be avoided by

1. Sizing ductwork or duct configurations so that air velocity is low (see Tables 3 and 4).
2. Avoiding abrupt changes in duct cross-section area.
3. Providing smooth transitions at duct branches, takeoffs, and bends.

### Notes:
1. Branch ducts should have airflow velocities of about 80% of the values listed.
2. Velocities in final runouts to outlets should be 50% of the values or less.
3. Elbows and other fittings can increase airflow noise substantially, depending on the type. Thus, duct airflow velocities should be reduced accordingly.

### Notes:
- The presence of diffusers or grilles can increase sound levels a little or a lot, depending on how many diffusers or grilles are installed and on their design, construction, installation, etc. Thus, allowable outlet or opening airflow velocities should be reduced accordingly.

- Attenuating sound generated at duct fittings with sufficient sound attenuation elements between a fitting and corresponding air-terminal device.

### Duct Velocity

The amplitude of aerodynamically generated sound in ducts is generally proportional to between the fifth and sixth power of the duct airflow velocity in the vicinity of a duct fitting. So reducing duct airflow velocity significantly reduces flow-generated noise. Table 3 (Schaffer 1991) and Table 4 (Egan 1988) recommend the maximum air velocities in duct sections and duct outlets to avoid problems associated with aerodynamically generated sound in ducts.

### Dampers

Depending on its location relative to a duct terminal device, a damper can generate unwanted noise into an occupied area of a building. The noise can be transmitted down the duct to the discharge, or through the ceiling space into the occupied space below.

Volume dampers should not be placed closer than 1.5 m from an air outlet for good design. When a volume control damper is installed close to an air outlet, the acoustic performance of the air outlet must be based on the air volume handled and on the pressure drop across the damper. The sound level produced by the damper is accounted for by adding a quantity to the diffuser sound rating. This quantity is proportional to the pressure ratio, which is the throttled pressure drop across the damper divided by the minimum pressure drop across the damper. Table 5 provides quantities to determine the effect of damper location on diffuser sound ratings.

Balancing dampers, equalizers, and other similar devices should not be placed directly upstream of air devices or open-ended ducts in acoustically critical spaces. They should be located 5 to 10 duct diameters from the termination device with acoustically lined duct joining the damper and duct termination device.

Plenums may be used to keep dampers further away from diffusers. Dampers may be installed at the plenum entrance with linear diffusers installed in the distribution plenum. Further a damper is installed from the outlet, the lower the resultant sound level.

### Air Devices

Manufacturers’ test data should be obtained in accordance with ASHRAE Standards 70 or ARI Standard 890(P) for room air terminal devices such as grilles, registers, diffusers, air handling light fixtures, and air-handling suspension bars. The room duct termination device should be selected to meet the noise criterion required or specified for the room. However, the manufacturer’s sound power rating is obtained with a uniform velocity distribution throughout the diffuser neck or grille collar, which is often not met in practice. If a duct turn precedes the entrance to the diffuser or if a balancing damper is installed immediately before the diffuser, the airflow will be turbulent and the noise generated by the device will be substantially higher than the manufacturer’s data by as much as 12 dB. In some cases, placing an equalizer grid in the neck of the diffuser reduces this turbulence substantially. The equalizer grid can help provide a uniform velocity gradient in the neck of the diffuser so the sound power generated in the field is closer to that listed in the manufacturer’s catalog.

A flexible duct connection between the diffuser and the air supply duct or VAV unit provides a convenient means to align the diffuser with the ceiling grid. A misalignment in this connection that
Sound and Vibration Control

exceeds 1/4 the diffuser neck diameter over a length equal to two times the diffuser neck diameter can cause a significant increase in the diffuser sound power levels relative to the levels provided by the manufacturer. If the diffuser offset is less than 1/8 the length of the connection diameter, no appreciable increase in the sound power level will occur. If the offset is equal to or greater than the neck diffuser diameter over a connection length equal to two times the diffuser neck diameter, the sound power levels associated with the diffuser can increase as much as 12 dB.

At present, diffusers are rated in terms of noise criterion (NC) levels, which include a receiver room sound correction of usually 8 to 10 dB. The ratings may be useful for comparison between and among different diffusers, but are not helpful for design. The designer should request from the diffuser manufacturer the component sound power level data in octave bands, and use the sound power to estimate the effects of the diffusers on the sound level in different spaces.

Chillers and Air Cooled Condensers

All chillers and their associated equipment produce significant amounts of both broadband and tonal noise. The broadband noise is due to flows of both refrigerant and water, while the tonal noise is caused by the rotation of compressors, motors, and fans (in fan-cooled equipment). Chiller noise is usually significant in the octave bands from 250 through 1000 Hz.

Compressors. All compressors, except absorption, produce tonal noise. The acoustical differences among compressors generally relate to their tonal content.

- **Centrifugal compressor** tonal noise is due to the rotation of the impeller and the gears in geared machines. The tonal content is typically not very strong, except at reduced capacities. The centrifugal compressor sound pressure level ($L_p$) typically increases at reduced chiller capacity due to the extra turbulence induced in the refrigerant circuit by the inlet vanes. If, however, capacity is reduced by motor speed control, the resulting compressor $L_p$ values decrease with decreasing capacity.

- **Reciprocating compressor** noise has a drumming quality, caused by the oscillating motion of the pistons. The tonal content is high and the sound level decreases very little with decreasing capacity.

- **Absorption chillers** produce relatively little noise themselves, but the flow of steam in their associated pumps and valves causes significant high-frequency noise. Noise levels increase with decreasing capacity as the valves close. Also, combustion air blowers on direct gas fired units can be noisy.

- **Scroll compressors** have relatively weak tones, and when they are found in capacities less than 260 kW, they may not cause noise-related complaints.

- **Screw compressors** (sometimes called helical rotor or rotary compressors) have very strong tones in the 250 through 2000 Hz octave bands. The rotor-induced tones are amplified by resonances in the oil separation circuit and by efficient sound radiation by the condenser and evaporator shells that are rigidly connected to the compressor via high-pressure piping. Recently, screw compressors have been the sources of chiller noise complaints; therefore, this type of compressor requires the most attention during noise and vibration control design.

**Indoor Water-Cooled Chillers.** The compressor is the dominant noise source in most water-cooled chillers. Any of the five compressor types listed previously can be used, but most water-cooled chillers use a either centrifugal or screw compressors. Factory sound data for indoor chillers is obtained via ARI Standard 575. The standard requires measuring the A-weighted and octave band sound pressure level values at several locations that are 1 m from the chiller and 1.5 m above the floor. Ratings are generally available at operating points of 25%, 50%, and 100% of a chiller’s nominal full capacity. The range of values for typical centrifugal and screw chillers is shown in Figure 8 and Figure 9, respectively.

ARI Standard 575 measurements are usually made in very large rooms with large amounts of sound absorption. The measured levels must be adjusted for each chiller installation to account for the size and surface treatment conditions of the mechanical room. For a
given chiller at a given operating point, a small equipment room, or one with mostly hard surface finishes, has a higher $L_p$ value than a room that is large or has sound-absorbing treatments on its ceiling and walls. Figure 10 shows maximum typical adjustment factors that should be added to the factory provided values based on ARI Standard 575 to estimate the reverberant $L_p$ values in specific installations. The adjustment for each octave band requires knowing the size of an imaginary box that is circumscribed 1 m away from the top and sides of the chiller (the ARI Standard 575 Measurement Surface), the dimensions of the equipment room and the average sound absorption coefficient of the room surfaces. The adjustment in each octave band depends on the ratio of the areas of the equipment room and the imaginary box as well as the average sound absorption of the room finishes. Each curve in Figure 10 is for a different value of the average sound absorption, with the higher curves being for lower values.

**Example 1.** Estimate the reverberant $L_p$ values in a 13.7 m by 12.2 m by 6.1 m tall mechanical equipment room (MER) that houses a 1260 kW centrifugal chiller. The room has a concrete floor and gypsum board walls and ceiling. The chiller dimensions are 1500 mm wide, 2000 mm tall, and 3000 mm long.

**Solution:**

The ARI-575 Measurement Surface area $S_M$ is determined by adding 1 m to the chiller height and 2 m to both its length and width. The floor area is not included in this calculation. The result is a box that has dimensions of 3500 mm wide, 5000 mm long, and 3000 mm tall. The area of this box is approximately 70.7 m$^2$. The area of the equipment room (floor included) $S_{MER}$ is 650 m$^2$. Therefore, the ratio of the areas, $S_M/S_{MER}$, is 650/70.7 = 9.2. Assume that the average absorption coefficient value for room is 0.1 for all octave bands; therefore, refer to Figure 10 for the adjustment factor.

The approximate reverberant $L_p$ values in the last line of the above example can be used along with the sound transmission loss information found elsewhere in this chapter to estimate the transmitted $L_p$ values in rooms adjacent to a chiller room.

Indoor chillers are offered with various types of factory noise reduction options ranging from compressor blankets (2 to 6 dBA reduction) to steel panel enclosures with sound absorbing inner surfaces (up to 18 dBA reduction). The amount of reduction is limited because of the structure-borne transmission of compressor vibration into the frame and heat exchanger shells, which act as soundboards.

Field noise control options include full-size sheet metal housing with specially-treated openings for piping, electrical conduit, and ventilation. Sometimes upgraded building construction is necessary. For more information refer to the section on Mechanical Equipment Room Sound Isolation.

**Outdoor Air-Cooled Chillers and Air-Cooled Condensers.**

Most air-cooled chillers use either reciprocating, scroll, or screw compressors. These chillers are also used as the chiller portion of rooftop packaged units. The dominant noise sources in outdoor air-cooled chillers are the compressors and the condenser fans, which are typically low-cost, high-speed propeller fans. These fans are the only significant noise source.

Factory sound data for outdoor equipment is obtained in accordance with ARI Standard 370, which requires that the A-weighted and octave band Sound Power Level ($L_w$) value of the equipment be determined. The range of ARI Standard 370 $L_w$ values for outdoor chillers in the 70 to 1300 kW range is shown in Figure 11.

Factory-supplied noise reduction options for outdoor equipment include compressor enclosures, oversized condenser fans, and variable-speed condenser fans. Because air-cooled equipment needs a free-flow of cooling air, full enclosures are not feasible; however, strategically placed barriers can help reduce the noise propagation on a selective basis. For more information see the section on Sound Control for Outdoor Equipment.

**Vibration Control.**

Typical chilled water systems include not only compressors and fans but also water pumps. The associated piping and conduit vibration generated by the compressors and pumps can be transmitted to a building structure via the equipment mounts or the attachments of the piping/conduit. Therefore, vibration isolation of a chiller requires essentially floating the entire chiller on resilient-attachment floor mounts and hangers. Refer to the section on Vibration Isolation and Control for more information on chiller vibration control.

If a chiller is to be mounted on an on-grade slab, vibration isolators is not usually required unless an adjacent noise sensitive space shares the common slab. In noise-sensitive applications (e.g., rooftop chillers over occupied spaces), high deflection springs or air mounts will likely be required. However, the potential problem of wave resonance (or surge frequencies) common to all steel spring and rubber pad vibration isolators must be considered. This resonance is of particular concern with a screw chiller because the compressor tones are typically in the same frequency range as the isolator’s wave resonance. If one of the compressor tones coincides with one of the isolator resonances, the compressor tone can readily be transmitted into the building structure causing excessive structure-borne noise in the occupied space near the unit. It is impossible to predict this occurrence in advance, so if it does happen the
solution is to use either another isolator design (with different surge frequencies) or air mounts, which do not exhibit the surge frequency phenomenon.

**DUCT ELEMENT SOUND ATTENUATION**

The duct elements covered in this section include sound ple-
nums, unlined rectangular ducts, acoustically lined rectangular
ducts, unlined round ducts, acoustically lined round ducts, elbows,
acoustically lined round radiused elbows, duct silencers, duct
branch power division, duct end reflection loss, and terminal vol-
ume regulation units. Simplified tabular procedures for obtaining
the sound attenuation associated with these elements are presented
in this section.

**Plenums**

Plenums are often used to smooth the turbulent airflow associ-
ated with air as it leaves the outlet section of a fan and before it
enters the air distribution ducts. These chambers are usually lined
with acoustically absorbent material to reduce fan and other noise.
Plenums are usually large rectangular enclosures with an inlet and
one or more outlets. The transmission loss associated with a plenum
chamber can be expressed as (Beranek 1971, Reynolds and Bledsoe 1991,

\[
TL = -10 \log_{10} \left[ S_{\text{out}} \left( Q \cos \theta \frac{1 - \alpha_A}{S \alpha_A} \right) \right]
\]  

Equation (1) treats a plenum as if it is a large enclosure. Thus,Equation (1) is valid only for the case where the wavelength of
sound is small compared to the characteristic dimensions of the ple-
num. For frequencies that correspond to plane wave propagation in
the duct, the results predicted by Equation (1) are usually not valid.
Plane wave propagation in a duct exists at frequencies below

\[
f_{\text{co}} = \frac{c_o}{2a}
\]  

or

\[
f_{\text{co}} = 0.586 \frac{c_o}{d}
\]

where

\[
f_{\text{co}} = \text{cutoff frequency}, \text{ Hz}
\]

\[
c_o = \text{speed of sound in air}, \text{ m/s}
\]

\[
a = \text{larger cross-section dimension of a rectangular duct}, \text{ m}
\]

\[
d = \text{diameter of a round duct}, \text{ m}
\]

The cutoff frequency \( f_{\text{co}} \) is the frequency above which plane
waves no longer propagate in a duct. At these higher frequencies the
waves that propagate in the duct are referred to as cross or spinning
modes. At frequencies below \( f_{co} \), Equation (1) conserves the energy at frequencies below 1000 Hz. The actual attenuation usually exceeds the values given by Equation (1) by 5 to 10 dB. Equation (1) usually always applies at frequencies of 1000 Hz and higher.

**Example 2.** A plenum is 1.8 m high, 1.2 m wide, and 1.8 m long. The configuration of the plenum is similar to that shown in Figure 12. The inlet and outlet are each 0.9 m wide by 0.6 m high. The horizontal distance between centers of the plenum inlet and outlet is 0.3 m. The vertical distance is 1.2 m. The plenum is lined with 25 mm thick, 48 kg/m\(^3\) density fiberglass insulation board. All of the inside surfaces of the plenum is lined with fiberglass insulation. Determine the transmission loss associated with this plenum. See Table 6 for the values of the absorption coefficients.

**Solution:**

The area of the inlet section, outlet section, and plenum cross-section are

\[
S_{in} = 0.9 \times 0.6 = 0.54 \text{ m}^2
\]

\[
S_{out} = 0.9 \times 0.6 = 0.54 \text{ m}^2
\]

\[
S_{pl} = 1.8 \times 1.2 = 2.16 \text{ m}^2
\]

\[
l = 1.8 \text{ m}; \ r_1 = 1.2 \text{ m}; \ r_2 = 0.3 \text{ m.}
\]

The values of \( r \) and \( \cos \theta \) are

\[
r = \sqrt{1.8^2 + 1.2^2 + 0.3^2} = 2.184 \text{ m}
\]

\[
\cos \theta = 1.8 / 2.184 = 0.824
\]

The total inside surface area of the plenum is

\[
S = 2(1.2 \times 1.8) + 2(1.2 \times 1.8) + 2(1.8 \times 1.8) - 1.1 = 14.4 \text{ m}^2
\]

The value of \( f_{co} \) is

\[
f_{co} = 343 / (2 \times 0.9) = 190 \text{ Hz}
\]

The results are tabulated as follows.

Sound energy attenuated at low frequencies in rectangular ducts may manifest itself as breakout noise elsewhere along the duct. Low-frequency breakout noise should therefore be checked.

**Acoustically Lined Rectangular Sheet Metal Ducts**

Internal duct lining for rectangular sheet metal ducts can be used to attenuate sound in ducts and to thermally insulate ducts. The thickness of duct linings associated with thermal insulation usually varies from 13 to 50 mm. For fiberglass duct lining to be effective for attenuating fan sound, it must have a minimum thickness of 25 mm. The attenuation values shown in Tables 8 and 9 are based on laboratory tests using 3 m lengths of duct, and may be used with confidence for duct lengths at 3 m. For designs incorporating more than 3 m of lined rectangular duct, actual dB/m will be less than shown in Tables 8 and 9 while total attenuated noise will never be below the generated noise level in the duct. The density of the fiberglass lining used in lined rectangular sheet metal ducts usually varies between 24 and 48 kg/m\(^3\).

The **insertion loss** values given in Tables 8 and 9 are the difference in the sound pressure level measured in a reverberation room with sound propagating through an unlined section of rectangular duct minus the corresponding sound pressure level that is measured when the unlined section of rectangular duct is replaced with a similar section of acoustically lined rectangular duct. The attenuation of the unlined duct is subtracted out during the process of calculating the **insertion loss** from measured data.

Insertion loss and attenuation values discussed in this section apply only to rectangular sheet metal ducts made with the lightest gages allowed according to SMACNA duct construction standards.

**Unlined Round Sheet Metal Ducts**

As with lined rectangular ducts, unlined round ducts provide some natural sound attenuation that should be considered when designing a duct system. In contrast to rectangular ducts, round ducts are much more rigid and, therefore, do not resonate or absorb as much sound energy. Because of this, round ducts will only provide about 1/10 the sound attenuation at low frequencies as compared to the sound attenuation associated with rectangular ducts. Table 10 lists sound attenuation values for unlined round circular ducts (Woods 1973, ASHRAE 1987).

**Acoustically Lined Round Sheet Metal Ducts**

The literature has little data for the insertion loss of acoustically lined round ducts. The data that are available are usually manufacturer's product data. Tables 11 and 12 give the insertion loss values for dual-wall round sheet metal ducts with 25 mm and 50 mm acoustical lining, respectively (Reynolds and Bledsoe 1989a). The acoustical lining for the duct is a 12 kg/m\(^2\) density fiberglass blanket, and the fiberglass is covered with an internal liner of perforated galvanized sheet metal that has an open area of...
25%. Because of structure-borne sound that is transmitted through the duct wall, the total sound attenuation of lined round ducts usually does not exceed 40 dB.

Rectangular Sheet Metal Duct Elbows

Table 13 displays insertion loss values for unlined and lined square elbows without turning vanes (Beranek 1960). For lined square elbows, the duct lining must extend at least two duct widths w beyond the elbow. Table 13 applies only where the duct is lined before and after the elbow. Table 14 gives the insertion loss values associated with radius elbows. Table 13 gives the insertion loss values for unlined and lined square elbows with turning vanes. The value of \( f_w (f_w) \) in Table 13 is the center frequency of the octave frequency band times the width of the elbow (Figure 13) and lengths are given in Table 16 (ARI Standard 885). Recommended duct lengths are normally from 1 to 2 m. Care should be taken to keep flexible ducts straight; bends should have as long a radius as possible. While an abrupt bend may provide some additional insertion loss, the airflow-generated noise associated with the airflow in the bend may be unacceptably high. Because of potentially high breakout sound levels associated with flexible ducts, care should be exercised when using flexible ducts above sound-sensitive spaces.

Nonmetallic Insulated Flexible Ducts

Nonmetallic insulated flexible ducts can significantly reduce airborne noise. Insertion loss values for specified duct diameters and lengths are given in Table 16 (ARI Standard 885). Recommended duct lengths are normally from 1 to 2 m. Care should be taken to keep flexible ducts straight; bends should have as long a radius as possible. While an abrupt bend may provide some additional insertion loss, the airflow-generated noise associated with the airflow in the bend may be unacceptably high. Because of potentially high breakout sound levels associated with flexible ducts, care should be exercised when using flexible ducts above sound-sensitive spaces.

### Duct Silencers

Duct silencers are used to attenuate sound that is transmitted through HVAC systems; particularly duct systems. They can add pressure and energy losses. Therefore, when selecting silencers, the following parameters should be considered:

- **Airflow pressure drop**, including system effects for less than ideal flow conditions.
- **Insertion loss**, which is the reduction in sound power level at a given location due solely to the placement of a sound-attenuating device in the transmission path between the sound source and the given location.

Airflow generated noise is created as the air flows into, through, and out of the silencer. In the majority of installations the airflow generated noise is much less than, and does not contribute to, the silenced noise level on the quiet side of the silencer. In general, airflow generated noise should be evaluated if static pressure drops exceed 87 Pa, the noise criteria is below RC-35, or the silencer is located very close to or in the occupied space.
There are three types of HVAC duct silencers: dissipative (with acoustic media), reactive (no media), and active silencers.

- **Dissipative silencers** generally use perforated metal surfaces covering acoustic grade fiberglass to attenuate sound over a broad range of frequencies. Airflow does not significantly affect the insertion loss if pressure drops are under 87 Pa.

- **Reactive silencers** use tuned perforated metal facings covering tuned chambers void of any fibrous material. The outside physical appearance of reactive silencers is similar to its dissipative counterpart. Because of tuning, broadband insertion loss is more difficult to achieve than with dissipative silencers. Longer lengths may be required to achieve similar insertion loss performance as dissipative silencers. Airflow generally increases the insertion loss of reactive silencers.

- **Active duct silencers** reduce noise at lower frequencies by producing inverse sound waves that cancel the unwanted noise. An input microphone measures the noise in the duct and converts it to electrical signals. These signals are processed by a digital computer where exact opposite, mirror-image sound waves of equal amplitude are generated. This secondary noise source destructively interferes with the noise and cancels a significant portion of the unwanted sound. An error microphone measures the residual sound beyond the silencer and provides feedback to adjust the computer model to increase performance. Because the components are mounted outside the airflow, there is no pressure loss or generated noise. Performance is limited, however, by the presence of excessive turbulence in the airflow detected by the microphones. Manufacturers recommend using active silencers where duct velocity is less than 7.6 m/s and where the duct configurations are conducive to smooth evenly distributed airflow.

Data for dissipative and reactive silencers should be obtained from tests in a manner consistent with the procedures outlined in the most current version of ASTM Standard E477. (This standard has not been verified for determining performance of active silencers.) Since insertion loss measurements use a substitution technique, reasonable (±3 dB) insertion loss values can be achieved down to 63 Hz. Airflow generated noise, however, cannot be measured accurately below 100 Hz due to the lack of a standardized means of qualifying the reverberant rooms for sound power measurements at lower frequencies (a function of room size). A recent series round robin tests has shown that airflow generated sound

Fig. 14 Dissipative Duct Silencers
Duct End Reflection Loss

When low frequency plane sound waves interact with openings that discharge into a large room, a significant amount of the sound energy incident on this interface is reflected back into the duct. The sound attenuation values $\Delta L_{Bi}$ associated with duct end reflection losses for ducts terminated in free space are given in Table 18 and for ducts terminated flush with a wall are given in Table 19 (Sandbakken et al. 1981, AMCA Standard 300). Diffusers that terminate in a suspended lay-in acoustic ceiling can be treated as terminating in free space. To use the data given in Table 18 if the duct terminating into a diffuser is rectangular, the duct diameter $D$ is given by

$$D = \sqrt{4A/\pi}$$  (6)

where $A$ is area ($m^2$) of the rectangular duct.

Tables 18 and 19 have some limitations. The tests on which these equations are based were conducted with straight sections of round ducts. These ducts directly terminated into a reverberation chamber with no restriction on the end of the duct or with a round orifice placed over the end of the duct. Diffusers can be either round or rectangular. They usually have a restriction associated with them that may either be a damper, guide vanes to direct airflow, a perforated metal facing, or a combination of these elements. Currently, there is no data that indicate the effects of these elements. It is not known whether or not these elements react similar to the orifices used in the above described tests. As a result, the effects of an orifice placed over the end of a duct are not included in Tables 18 and 19. Equation (6) does yield reasonable results with diffusers that have low aspect ratios (length/width). However, many types of diffusers (particularly...
Sound and Vibration Control

slot diffusers) have high aspect ratios. It is not known whether Tables 18 or 19 can be accurately used with these diffusers. Finally, many diffusers do not have long straight sections (greater than three duct diameters) before they terminate into a room. Many duct sections between a main feed branch and a diffuser are curved or have short, stubby sections. The effects of these configurations on the duct end reflection loss are not known. However, Tables 18 and 19 can be used with reasonable accuracy for many diffuser configurations. However, caution should be exercised and sound from the diffuser may need to be checked if its configuration differs from the test conditions used to derive these tables.

USE OF FIBERGLASS PRODUCTS IN HVAC SYSTEMS

Fiberglass duct liner continues to be a cost-effective solution to noise control in most HVAC air duct systems. However, fiberglass has been banned from or severely limited for use in some institutional, educational, and medical projects. The decisions are based on concerns that the fibers may be carcinogenic and that the products may promote microbial growth. ASHRAE Technical Committee TC 2.6 (Sound and Vibration) conducted an informal review of the available research and studies and concluded the following:

• A review published in ASHRAE (1993) found no clear evidence that any form of manufactured mineral fibers are carcinogenic. The International Agency for Research on Cancer (IARC) has performed research in regard to the carcinogenicity of fiberglass materials and found inadequate evidence to link inhalation of fiberglass wool with cancer in humans (WHO 1986). IARC does indicate there is a possible linkage to cancer from glass wool based on heavy-dosage direct-injection into animals. As a result of this, the U.S. Department of Health & Human Services (USDHHS) has added glasswool to its list of substances “reasonably anticipated” to be a carcinogen. Environment Canada (1994) indicates that studies have failed to show any evidence that fiberglass is carcinogenic and classified the material as “unlikely to be carcinogenic to humans.” In addition, the report indicated fiberglass is not entering the environment in quantities or conditions that may constitute a danger to human life or health.

• Morey and Williams (1991) found that both moisture and dirt are required for microbial growth and that microbial growth can grow on any surface including sheet metal, sound traps, filters, and turning vanes, in addition to duct lining. Microbial growth is not related to one component. Thus, removal of fiberglass duct lining by itself does not eliminate microbial growth. Control of moisture and dirt in duct systems is the best method of reducing potential microbial growth. Duct design for access, proper filtration, humidification, and condensate systems; methods to prevent moisture and dirt accumulation during installation and commissioning; and regular maintenance procedures can reduce the occurrence of microbial growth (ASHRAE Standard 62-1989).

Owners and designers should be warned against removing fiberglass duct lining from any building and must understand the acoustic impact of that decision. Compensating for the removal of fiberglass duct liner may require larger and longer duct runs, larger fans and fan plenums, and the use of alternative noise control devices such as removable, lined duct sections, foil-coated liner, no-fill sound traps, and active noise control, some of which may be less effective and more expensive.

Certain spaces in health care facility such as operating rooms and critical care spaces should follow duct liner guidelines issued by the American Institute of Architects Committee on Architecture (AIA 1992-93). The complete removal of fiberglass duct liner from duct systems in spaces such as theaters, concert halls, recording and TV studios, and educational facilities could result in poor acoustic qualities and may render the spaces unusable.

SOUND RADIATION THROUGH DUCT WALLS

Airflow Generated Duct Rumble

An HVAC fan and its connected ductwork can act as a semi-closed, compressible fluid pumping system where both acoustic and aerodynamic air pressure fluctuations at the fan are transmitted to other locations in the duct system. Air pressure fluctuations can...
be caused by variations in fan, motor or fan belt RPM or by airflow instabilities transmitted to the fan housing or nearby connected ductwork. When the air pressure fluctuations encounter large, flat, unreinforced duct surfaces that have resonance frequencies near or equal to the disturbing frequencies, the duct surfaces will vibrate (Ebbing et al. 1978). This vibration occurs in the stiffness- or resonance-controlled regions of the duct. In typical HVAC duct systems, duct wall vibration can produce sound pressure levels of the order of 65 to 95 dB at frequencies that range from 10 Hz to 100 Hz. This type of duct-generated sound is generally called duct rumble (Figure 16).

Figure 17 shows typical duct configurations that can exist near a centrifugal fan. Fair to bad configurations can result in duct rumble. Good to optimum designs of fan inlet and discharge transitions minimize the potential for duct rumble; however, these designs may not completely eliminate the potential for duct rumble.

Duct rumble can be eliminated or reduced by several methods. One method is to alter the fan, motor, or fan belt speed. This method changes the frequency of the air pressure fluctuations so that they differ from the duct wall resonance frequencies, and duct rumble may not occur or at least will be reduced. Another measure is to apply rigid materials, such as duct reinforcements and drywall, directly to the duct wall to change the wall resonant frequency [Figure 18]. Noise reductions of 5 to 11 dB in the 31.5 Hz and 63 Hz octave frequency bands have been recorded using this treatment.

Mass-loaded materials applied in combination with absorptive materials do not alleviate duct rumble noise into a space unless both materials are completely decoupled from the vibrating duct wall. This means they are significantly separated from the duct and do not touch it. An example of this type of construction, using two layers of drywall, is shown in [Figure 19]. Because the treatment is decoupled from the duct wall, it provides the greatest noise reduction. Mass-loaded materials combined with absorptive materials that are directly attached to the duct wall are not effective in reducing duct rumble [Figure 20]. Mass-loaded flexible material wrapped over an absorptive layer of material on a round duct (which is less prone to low frequency rumble due to the greater inherent stiffness compared to rectangular ducts) can effectively control noise and may be the only one possible solution due to space limitations. This type of treatment is often used on piping.

**Sound Breakout and Breakin from Ducts**

**Breakout** is the sound associated with fan or airflow noise inside a duct that radiates through the duct walls into the surrounding area [Figure 21]. Breakout can be a problem if it is not adequately attenuated before the duct runs over an occupied space (Cummings 1983, Lilly 1987). Sound that is transmitted into a duct from the surrounding area is called **breakin** [Figure 22].

The **transmission loss** characteristics of ducts are presented in this volume in a simpler form than in previous editions of the handbook to make them easier to understand and use. This simplified treatment ignores sound energy attenuation along the duct and can be applied to ducts where the critical length of duct for noise radiation is the first 6 to 9 m.

Breakout Sound Transmission from Ducts. The sound power level associated with sound transmitted through a duct wall and then radiated from the exterior surface of the duct wall is given by

$$L_w(\text{out}) = L_w(\text{in}) + 10 \log (S/A) - TL_{out}$$  \hspace{1cm} (7)

where

- $L_w(\text{out})$ = sound power level of sound radiated from outside surface of duct walls, dB
- $L_w(\text{in})$ = sound power level of sound inside duct, dB
- $S$ = surface area of outside sound-radiating surface of duct, m$^2$
- $A$ = cross-sectional area of inside of duct, m$^2$
- $TL_{out}$ = normalized duct breakout transmission loss (independent of $S$ and $A$), dB

Values for $TL_{out}$ for rectangular ducts are given in Table 20 and for flat-oval ducts are given in Table 22 (Cummings 1983, 1985). The equations for $S$ and $A$ for rectangular ducts are

$$S = 2L(a + b)$$  \hspace{1cm} (8)

$$A = ab$$  \hspace{1cm} (9)

where

- $a$ = larger duct cross-section dimension, m
- $b$ = smaller duct cross-section dimension, m
- $L$ = length of the duct sound radiating surface, m

The equations for $S$ and $A$ for round ducts are

$$S = L\pi d$$  \hspace{1cm} (10)

$$A = \pi d^2/4$$  \hspace{1cm} (11)

where

- $d$ = duct diameter, m
- $L$ = length of duct sound radiating surface, m

Equation (7) assumes no interior sound attenuation along the length of the duct sound radiating surface. Thus, it is valid only for unlined ducts. It is generally valid for duct lengths up to 9 m. $L_w(\text{out})$ must always be equal to or less than $L_w(\text{in})$.

For applications where the duct is exposed, the sound pressure level in an occupied space as a result of duct sound breakout can be obtained from

$$L_p = L_w(\text{out}) - 10 \log (\pi r L)$$  \hspace{1cm} (14)

where

- $L_p$ = sound pressure level at specified point in the space, dB
- $L_w(\text{out})$ = sound power level of sound radiated from outside surface of duct walls given by Equation (7), dB
- $r$ = distance between duct and position at which $L_p$ is being calculated, m
- $L$ = length of duct sound radiating surface, m

Equation (14) does not apply when the duct is in a plenum, concealed behind a suspended ceiling. In such cases, simply subtract the attenuation for ceilings listed in Table 23 instead of 10 log($\pi r L$) and assume the sound field in the room is uniform.

Example 3. A 305 mm by 1220 mm by 4.57 m long rectangular supply duct above a mineral fiber lay-in tile ceiling is constructed of 22 gage (0.853 mm) sheet metal. Given the sound power levels in the duct, what are the sound pressure levels at a listener 1.52 m from the duct?

Solution:

- Ceiling tile Table 23  

The RC level associated with the above $L_p$ values is RC 28 (LFVb).
Example 4. Repeat Example 3 using a round duct of equivalent airflow area: 700 mm in diameter, 22 gage (0.853 mm), 4.57 m long.

Solution:

The RC level associated with the above \( L_p \) values is RC 31(MF).

The use of the round duct results in a slight increase in the RC level and eliminates the low-frequency rumble present in Example 3, but it introduces some mid-frequency roar that can be dealt with by another means. The two spectra are shown in Figure 23.

Examples 3 and 4 demonstrate that a round duct is much more effective in reducing the low-frequency sound transmitted through the duct wall (breakout) into an adjacent space than a rectangular duct.

However, when sound is not transmitted through the duct wall of a round duct, it is transmitted down the duct and may become a problem at some other point. Flexible and rigid fiberglass ducts often come in round configurations and may be referred to as round ducts. These types of round ducts do not have high transmission loss properties because they do not have the mass or stiffness associated with round sheet metal ducts. Whenever duct sound breakout is a concern, fiberglass or flexible round duct should not be used.

Breakin Sound Transmission into Ducts. The sound power level associated with sound that is transmitted into (breakin) a duct through the duct walls from the space outside the duct is given by

\[
L_{w(in)} = L_{w(out)} - TL_{in} - 3
\]  

where

- \( L_{w(in)} \) = sound power level of sound transmitted into duct and then transmitted upstream or downstream of point of entry, dB
- \( L_{w(out)} \) = sound power level of sound incident on outside of duct walls, dB
- \( TL_{in} \) = duct breakin transmission loss, dB

Values for \( TL_{in} \) are given for rectangular ducts in Table 24 for round ducts in Table 25 and for flat-oval ducts in Table 26 (Cummings 1983, 1985).

RECEIVER ROOM SOUND CORRECTION

The sound pressure level at a given location in a room due to a particular sound source is a function of the sound power level and sound radiation characteristics of the sound source, the acoustic properties of the room (surface treatments, furnishings, etc.), the room volume, and the distance between the sound source and the point of observation. Two types of sound sources are typically encountered in HVAC applications: point source and line source. Typical point sources are sound radiated from grilles, registers and diffusers; air-valve and fan-powered air terminal units and fan-coil units located in ceiling plenums; and return-air openings. Line sources are usually associated with sound breakout from air ducts and long slot diffusers.

Note: The values for duct lengths of 6.1 m, but the values may be used for the cross-section shown regardless of length.

For a point source in an enclosed space, classical diffuse-field theory predicts that as the distance between the sound source and point of observation is increased, the sound pressure level initially decreases at the rate of 6 dB per doubling of distance. At some point, the reverberant sound field begins to dominate and the sound pressure level remains at a constant level.

Schultz (1985) and Thompson (1981) found that diffuse-field theory does not apply in real-world rooms with furniture or other sound-scattering objects. Instead, the sound pressure levels decrease at the rate of around 3 dB per every doubling of distance between the sound source and the point of observation. Generally, a reverberant sound field does not exist in small rooms (room volumes less than 420 m³). In large rooms (room volumes greater than 420 m³), reverberant fields usually exist, but usually at distances from the sound sources that are significantly greater than those predicted by diffuse-field theory.

</tbody>
</table>

Values for A are given in Tables 23 and 24. If a normally furnished room has a room volume greater than 420 m³ and the sound source is a single point source, the sound pressure levels associated with the sound source can be obtained from

\[ L_p = L_w + A - B \]  

(16)

where

\[ L_p \]  

sound pressure level at specified distance from source, \( \text{dB} \)

\[ L_w \]  

sound power level of sound source, \( \text{dB} \)

Values for A and B are given in Tables 23 and 24. If a normally furnished room has a room volume greater than 420 m³ and the sound source is a single point source, the sound pressure levels associated with the sound source can be obtained from

\[ L_p = L_w - C - 5 \]  

(17)

Values for C are given in Table 29 Equation (17) can be used for room volumes of up to 420 m³. The accuracy of Equations (16) and (17) is typically within 2 to 5 dB.

Point Sound Sources

Most normally furnished rooms with regular proportions have acoustic characteristics that range from average to medium dead. These usually include carpeted rooms that have sound absorptive ceilings. If a normally furnished room has a room volume less than 420 m³ and the sound source is a single point source, the sound pressure levels associated with the sound source can be obtained from

\[ L_p = L_w + A - B \]  

(16)
Distributed Array of Ceiling Sound Sources

In many office buildings, air supply outlets are located flush with the ceiling of the conditioned space and constitute an array of distributed sound sources in the ceiling. The geometric pattern depends on the floor area served by each outlet, the ceiling height, and the thermal load distribution. In the interior zones of a building where the thermal load requirements are essentially uniform, the air delivery per outlet is usually the same throughout the space; thus, the sound sources tend to have nominally equal sound power levels.

One way to calculate the sound pressure levels in a room associated with such a distributed array is first to use Equation (16) or (17) to calculate the sound pressure levels associated with each individual air outlet at specified locations in the room. Then logarithmically add the sound pressure levels associated with each diffuser at each observation point. This calculation procedure can be very tedious and time consuming for a large number of ceiling air outlets.

For a distributed array of ceiling sound sources (air outlets) of nominally equal sound power, the room sound pressure levels tend to be uniform in the horizontal plane parallel to the ceiling. Although the sound pressure levels will decrease with distance from the ceiling along a vertical axis, the sound pressure levels along any selected horizontal plane are nominally constant. The calculation for a distributed ceiling array can be greatly simplified by using Equation (18) instead of Equation (16) or (17). For this case, it is desirable to use a reference plane of 1.5 m above the floor (the average distance between seated and standing head height). Thus, \( L_{p(1.5)} \) is obtained from the following equation.

\[
L_{p(1.5)} = L_{w(1)} - D
\]

where

\( L_{w(1.5)} \) = sound pressure level 1.5 m above floor, dB

\( L_{w(1)} \) = sound power level of single diffuser in array, dB

Values for \( D \) are given in Table 30.

Nonstandard Rooms

The previous equations assume the acoustic characteristics of a room range from average to medium dead, which is generally true of most rooms. However, some rooms may be acoustically medium live to live (they have little sound absorption). These rooms may be sports or athletic areas, concert halls, or other rooms that are designed to be live; or they may be rooms that are improperly designed from an acoustic standpoint. The previous equations should not be used for acoustically live rooms because they can overestimate the decrease in the sound pressure levels associated with the room sound correction by as much as 10 to 15 dB. When these or other types of nonstandard rooms are encountered, the calculation procedures referred to in Reynolds and Bledsoe (1991) and Reynolds and Bevitt (1994) should be used.

1999 ASHRAE Applications Handbook (SI)

### INDOOR SOUND CRITERIA

HVAC related sound is often the major source of background noise in indoor spaces. Whether an occupant considers the background noise to be acceptable or not generally depends on two factors. First is the perceived loudness of the noise relative to that of normal activities; if it is clearly noticeable then it is likely to be distracting and cause complaint. Second is the quality of the background noise; noise perceived as a rumble, roar, or hiss may result in complaints of annoyance and stress. The spectrum is then said to be unbalanced.

The acoustical design must ensure that HVAC noise is of sufficiently low level and unobtrusive quality so as not to interfere with the occupancy requirements of the space use. If the background noise reduces speech intelligibility, for example, complaints of lost productivity may result. Accordingly, methods of rating HVAC related noise should assess both the relative loudness and quality of the background noise.

#### Sound Rating Methods

Currently, several methods are used to rate indoor sound. They include the traditional A-weighted sound pressure level (dBA) and tangential noise criteria (NC), the more recent room criteria (RC) and balanced noise criteria (NCB), and the new RC Mark II. Each sound rating method was developed based on data for specific applications; hence not all are suitable for the rating of HVAC related noise in the variety of applications encountered. The preferred sound rating methods generally comprise two distinct parts: a family of criterion curves (specifying sound levels by octave bands), and a companion procedure for rating the calculated or measured sound data relative to the criterion curves.

Ideally, HVAC-related background noise should have the following characteristics:

- Balanced contributions from all parts of sound spectrum with no predominant bands of noise
- No audible tones such as a hum or whine
- No fluctuations in level such as a throbbing or pulsing

Unfortunately, no acceptable process easily characterizes the effects of audible tones and level fluctuations. Table 31 summarizes the essential differences, advantages, and disadvantages of the rating methods that characterize HVAC-related background noise.

#### NC Noise Criteria Method

The NC method for rating noise, described in Chapter 7 of the 1997 ASHRAE Handbook—Fundamentals, is widely used and understood. It is a single-number rating that is somewhat sensitive to the relative loudness and speech interference properties of a given noise spectrum. The method consists of a family of criterion curves extending from 63 to 8000 Hz, and a tangency rating procedure. The criterion curves define the limits of octave band spectra that must not be exceeded to meet occupant acceptance in certain spaces. The rating is expressed as NC followed by a number (e.g., NC 40).

The NC method is sensitive to level and has the disadvantage that the tangency method used to determine the rating does not require that the noise spectrum approximate the shape of the NC curves. Thus, many different-sounding noises can have the same numeric rating, but rank differently on the basis of subjective sound quality. With the advent of VAV systems, excessive low frequency noise below the 63 Hz octave band became a serious problem, and the NC rating method does not address this (Ebbing 1992). In many HVAC systems that do not produce excessive low frequency noise, the NC rating correlates relatively well with occupant satisfaction, if sound quality is not a significant concern.

#### RC Room Criteria Method

The RC method consists of a family of criterion curves and a rating procedure (Blazier 1981a,b; ANSI Standard S12.2, ASHRAE
The shape of these curves differs from the NC curves so as to achieve a well-balanced bland-sounding spectrum, and two additional octave bands (16 and 31 Hz) are added to include possible excessive low-frequency noise. This rating procedure assesses background noise in spaces, both on the basis of its effect on speech communication and on subjective sound quality. The rating is expressed as RC followed by a number to show the level of the noise and a letter to indicate the quality, for example, RC 35(N) where N denotes neutral.

**dBA**  
A-weighted sound level

The A-weighted sound level (described in Chapter 7 of the 1997 ASHRAE Handbook—Fundamentals) is a single-number measure of the relative loudness of noise that is used extensively in outdoor environmental noise standards. The rating is expressed as a number followed by dBA, for example, 40 dBA.

A-weighted sound levels can be measured with simple sound level meters. The ratings correlate well with human judgments of relative loudness but take no account of spectral balance or sound quality. Thus many different-sounding spectra can result in the same numeric value, but have quite different subjective qualities.

**NCB**  
Balanced Noise Criteria Method

The NCB method (Beranek 1989) is used to specify or evaluate room noise and includes noise due to occupant activities. The NCB criterion curves (Figure 24) are intended as replacements for the NC curves, and include two additional low frequency octave bands (16 and 31 Hz), and lower permissible noise levels at high frequencies (4000 and 8000 Hz). The NCB rating procedure is based on a speech interference level (SIL) (SIL = average of four sound pressure levels at octave band mid-frequencies of 500, 1000, 2000, and 4000 Hz), and on additional tests for rumble and hiss compliance. The rating is expressed as NCB followed by a number, for example, NCB 40.

The NCB method is better than the NC method in determining whether a noise spectrum has an unbalanced shape sufficient to demand corrective action, and it addresses the issue of low-frequency noise. The rating procedure is, however, more complicated than the familiar tangency method.

**RC Mark II**  
Room Criteria Method

Based on experience and the findings from ASHRAE sponsored research (Broner 1994), the RC method was revised to the RC Mark II method (Blazier 1997). Like its predecessor, the RC Mark II method is intended for rating the sound performance of an HVAC system as a whole. The method can also be used as a diagnostic tool for analyzing noise problems in the field. The RC Mark II method is more complicated to use than the RC method, but spreadsheet macros are available to do the calculations and graphical analysis.

The RC Mark II method has three parts: (1) a family of criterion curves such as shown in Figure 25 (2) a procedure for determining the RC numerical rating and the noise spectral balance (quality), and (3) a procedure for estimation of occupant satisfaction when the spectrum does not have the shape of an RC curve (Quality Assessment Index) (Blazier 1995).

The rating is expressed as RC followed by a number and a letter, for example, RC 35(N). The number is the arithmetic average rounded to the nearest integer of the sound pressure levels in the 500, 1000, and 2000 Hz octave bands (the principal speech frequency region). The letter identifies the perceived character of the sound: (N) for neutral, (LF) for low frequency rumble, (MF) for mid frequency roar, and (HF) for high frequency hiss. There are also two subcategories of the low frequency descriptor: (LFB), denoting a moderate but perceptible degree of sound induced ceiling/wall vibration, and (LFA), denoting a noticeable degree of sound induced vibration.

Each reference curve in Figure 25 identifies the shape of a neutral, bland-sounding spectrum, indexed to a curve number corresponding to the sound level in the 1000 Hz octave-band. The shape of these curves is based on work by Blazier (1981a,b), modified at 16 Hz following research by Broner (1994). Regions A and B denote levels at which sound can induce vibration in light wall and ceiling construction that can potentially cause rattles in light fixtures, furniture, etc. Curve T is the octave-band threshold of hearing as defined by ANSI Standard S12.2.
**Step 2.** Assign a subjective quality by calculating the quality assessment index (QAI) (Blazier 1995). QAI is a measure of the deviation of the shape of the spectrum under evaluation to the shape of the RC reference curve. The procedure requires calculation of energy-averaged spectral deviations from the RC reference curve in each of three frequency groups: low frequency, LF (16–63 Hz), medium frequency, MF (125–500 Hz), and high frequency, HF (1000–4000 Hz). (A simple arithmetic average of these deviations is usually adequate for evaluating HVAC sounds.) The procedure for the LF region is given by Equation (19), and is repeated in the MF and HF regions by substituting the corresponding values at each frequency.

\[
LF = 10 \log\left[\left(10^{0.1\Delta L_{16}} + 10^{0.1\Delta L_{31.5}} + 10^{0.1\Delta L_{40}}\right)/3\right]
\]  

where the \(\Delta L\) terms are the differences between the spectrum being evaluated and the RC reference curve in each frequency band. In this way, three specific spectral deviation factors, expressed in dB with either positive or negative values, are associated with the spectrum being rated. QAI is the range in dB between the highest and lowest values of the spectral deviation factors.

If QAI ≤ 5 dB, the spectrum is assigned a neutral (N) rating. If QAI exceeds 5 dB, the sound quality descriptor of the RC rating is the letter designation of the frequency region of the deviation factor having the highest positive value.

**Example 5.** Figure 25 shows a sound spectrum plotted on an RC Mark II curve plot. The data was processed and is summarized in Table 32. Note that the arithmetic average of the sound levels in the 500, 1000, and 2000 Hz octave bands is 35 dB, so the RC 35 curve is selected as the reference for spectrum quality evaluation.

**Table 32 Example 5 Calculation of RC Mark II Rating**

<table>
<thead>
<tr>
<th>Frequency, Hz</th>
<th>Spectrum levels</th>
<th>Average of 500 to 2000 Hz levels</th>
<th>Levels - RC contour</th>
<th>Quality Assessment Index (QAI)</th>
</tr>
</thead>
<tbody>
<tr>
<td>16 31 63 125 250 500 1000 2000 4000</td>
<td>64 65 64 57 47</td>
<td>40 35 35 30 25</td>
<td>4 5 9 LF MF HF</td>
<td>6.6 4.0 –0.6</td>
</tr>
</tbody>
</table>

The spectral deviation factors in the LF, MF, and HF regions are 6.6, 4.0, and –0.6, giving a QAI of 7.2. The maximum positive deviation...
factor occurs in the LF region, QAI exceeds 5, therefore, the rating of the spectrum is RC 35(LF). An average room occupant should perceive this spectrum as marginally rumble in character.

**Estimating Occupant Satisfaction Using QAI.** The quality assessment index is useful in estimating the probable reaction of an occupant when the system does not produce optimum sound quality. The basis for estimating occupant satisfaction is that changes in sound level of less than 5 dB do not cause subjects to change their ranking of sounds of similar spectral content. However, level changes greater than 5 dB do significantly affect subjective judgments. As noted already, a QAI of 5 dB or less corresponds to a generally acceptable condition, provided that the perceived level of the sound is in a range consistent with the given type of space occupancy as recommended in [Table 34](#). (An exception to this rule occurs when the sound pressure levels in the 16 Hz or 31 Hz octave-bands exceed 65 dB. In such cases, the potential for acoustically-induced vibration in typical light office construction should be considered. If the levels in these bands exceed 75 dB, a significant problem with induced vibration is indicated.)

A QAI that exceeds 5 dB, but is less than or equal to 10 dB, represents a marginal situation in which occupant acceptance is questionable. However, a QAI greater than 10 dB will likely be objectionable to the average occupant. [Table 33](#) lists sound quality descriptors and QAI values and relates them to probable occupant reaction to the noise.

Undoubtedly situations occur in the assessment of HVAC related noise where the numerical part of the RC rating is less than the specified maximum for the space use, but the sound quality descriptor is other than the desirable (N). For example, a maximum of RC 40(N) is specified, but the actual noise environment turns out to be RC 35(MF). Not enough is known in this area to decide which spectrum is preferable.

Even at moderate levels, if the dominant portion of the background noise occurs in the very low-frequency region, Persson-Wayne (1997) observed that some people experience a sense of oppressiveness or depression in the environment. In such situations, the basis for complaint may result from an exposure to that environment for several hours, and may not be noticeable during a short exposure period.

**Guideline Criteria for HVAC-Related Background Sound in Rooms**

[Table 34](#) lists design guidelines for HVAC-related background sound appropriate to various occupancies. Perceived loudness and task interference are factored into the numerical part of the RC rating. Sound quality assumes the preferred design target is a neutral-sounding (N) spectrum, although some spectrum imbalance is likely tolerable in certain limits.

If these levels are used as a basis for contractual requirements, the following additional information must be provided.

1. What sound levels will be measured (specify $L_{eq}$ or $L_{max}$ levels, etc. in each octave frequency band)?
2. Where and how will the sound levels be measured (specify space average over a defined area or specific points, etc.)?
3. What instruments will be used to make the sound measurements (specify ANSI Type 1 or Type 2 sound level meters with octave band filters)?
4. How will the instruments used for the sound measurements be calibrated?
5. How will the sound measurement results be interpreted?

Unless the above five points are clearly stipulated, the specified sound criteria may be unenforceable.

When applying the levels specified in [Table 34](#) as a basis for design, sound from non-HVAC sound sources, such as traffic and office equipment, may be the lower limit for sound levels in a space.

*a The values and ranges are based on judgment and experience, not on quantitative evaluations of human reactions. They represent general limits of acceptability for typical building occupancies. Higher or lower values may be appropriate and should be based on a careful analysis of economics, space use, and user needs.

*b When quality of sound in the space is important, specify criteria in terms of RC(N). If the quality of the sound in the space is of secondary concern, the criteria may be specified in terms of NC or NCB levels of similar magnitude.

*c An experienced acoustical consultant should be retained for guidance on acoustically critical spaces (below RC 30) and for all performing arts spaces.

*d HVAC-related sound criteria for schools, such as those listed in this table, may be too high and impede learning by children in primary grades whose vocabulary is limited. Some educators and others believe that the HVAC-related background sound should not exceed RC 25 (N).

*e RC or NC criteria for these spaces need only be selected for the desired speech and hearing conditions.
OUTDOOR SOUND CRITERIA

Acceptable outdoor sound levels are generally specified by local noise ordinances. In the absence of an ordinance, composite noise rating (CNR) procedures can be used to evaluate acceptability of HVAC and other types of mechanical and electrical equipment noise that intrude into communities (Stevens et al. 1955). Figure 26 shows the set of non-normalized composite noise rating (CNR) curves. The non-normalized composite noise rating is determined by plotting the octave band sound pressure levels associated with an intruding noise on Figure 26. The octave band sound pressure levels should be measured at several representative times at each location of interest in the community. The measurements should span a period long enough to give confidence that the average octave band sound pressure levels of the noise are truly representative. If the daytime and nighttime noise signals are different in contents and levels, separate sound measurements should be taken for the two periods.

The non-normalized composite noise rating associated with a noise equals the highest penetration of any of the octave band sound pressure levels into the curves. If the highest penetration falls between two curves, the non-normalized CNR is the interpolated value between the two curves. The non-normalized CNR must then be normalized or corrected for background noise conditions that exist in the absence of the intruding noise and for the time-of-day, seasonal, noise intermittency, noise characteristics, and previous community-exposure-to-similar-noise factors. The correction for background noise that exists in the absence of the intruding noise can be accomplished in one of two ways. If it is possible to measure the octave band ambient sound pressure levels associated with the ambient or background noise in the absence of any intruding noise source, the levels should be measured and plotted on Figure 27. The zone into which the major portion of the octave band spectrum falls designates the correction to be applied for the background noise. The correction associated with the curve that has a point of tangency that is closest to the octave band ambient sound pressure level curve should be used. It is not necessary to interpolate between curves.

The final correction is associated with time-of-day, seasonal, noise intermittency, noise characteristics, and previous community exposure to similar noise factors. These correction factors are obtained from Table 36. The total correction for these factors is the sum of the corrections associated with each individual factor.

The normalized CNR is calculated by taking the non-normalized CNR obtained from Figure 26 and adding to it the correction number for the background noise obtained from either Figure 27 or Table 35. Once the normalized composite CNR has been calculated, the anticipated community reaction to the intruding noise is obtained from Figure 28. The composite noise rating procedure is generally a reliable method of determining community reaction to outdoor noise from mechanical and electrical equipment. However, it may not be reliable when dealing with certain types of equipment that generate strong pure tones (e.g., high-pressure blowers, diesel generators, gas turbines, etc.). It is strongly advised that an acoustical consultant be consulted when dealing with these types of sound sources.

Example 6. The octave band sound pressure levels associated with a cooling tower are listed below:

<table>
<thead>
<tr>
<th>Octave Band Center Frequency, Hz</th>
<th>63</th>
<th>125</th>
<th>250</th>
<th>500</th>
<th>1000</th>
<th>2000</th>
<th>4000</th>
<th>8000</th>
</tr>
</thead>
<tbody>
<tr>
<td>$L_{eq}$ dB</td>
<td>64</td>
<td>64</td>
<td>62</td>
<td>60</td>
<td>56</td>
<td>53</td>
<td>51</td>
<td>43</td>
</tr>
</tbody>
</table>
The cooling tower runs 24 hours a day. The location at which the sound pressure levels were measured is a business area. Assume there is previous exposure to similar noise and that there are good community relations. Determine the composite noise rating associated with the cooling tower noise, and make some statement relative to the anticipated community reaction to the noise.

**Solution:**

The non-normalized composite noise rating ($\text{CNR}_{nn}$) is obtained by plotting the above octave band sound pressure levels on Figure 26. The resulting plot is shown in Figure 29. An examination of the plot indicates that the $\text{CNR}_{nn}$ is 58.

Because the cooling tower runs 24 hours a day, the normalized composite noise rating ($\text{CNR}_n$) for both daytime and nighttime use must be determined. The background noise correction numbers are obtained from Table 35. The numbers for a business area are

- **Daytime:** $-5$
- **Nighttime:** 0

The correction numbers from Table 36 are:

- **Time-of-day:** 0
- **Intertency:** 0
- **Character of noise:** +5
- **Previous exposure:** 0

Thus, the normalized $\text{CNR}_n$ values are

- **Daytime:** $\text{CNR}_n = 58 - 5 + 0 + 5 + 0 = 58$
- **Nighttime:** $\text{CNR}_n = 58 + 0 + 0 + 5 + 0 = 63$.

An examination of Figure 28 indicates there will be no complaints during the daytime hours; and there will be some sporadic complaints during the nighttime hours.

---

**MECHANICAL EQUIPMENT ROOM SOUND ISOLATION**

Mechanical equipment is inherently noisy. Pumps, chillers, cooling towers, boilers, and fans create noise that is difficult to contain. Noise-sensitive spaces must be isolated from these sources. One of the best precautions is to locate mechanical spaces away from acoustically critical spaces. Space planning early in the design stage is critical for successful new projects. Buffer zones (storage rooms, corridors, or less noise-sensitive spaces) can be placed between mechanical equipment rooms and rooms requiring relatively quiet conditions. Sound transmission through roofs and exterior walls is usually less of a problem, making corner rooms and top-floor spaces reasonably good for housing mechanical equipment.

Construction enclosing a mechanical equipment room should be poured concrete or masonry units with enough surface mass to provide adequate sound transmission loss and inertia to resist low frequency noise often inherent with mechanical equipment. Heavy-duty drywall construction can also be used successfully sometimes. When it can be used, it saves weight on upper floors, but it typically has a lower frequency sound transmission loss than masonry. Walls must be airtight and caulked at the edges to prevent sound leaks. Floors and ceilings should be concrete slabs, except for the ceiling or roof deck above a top-floor mechanical space.

Penetrations of the mechanical equipment room enclosure create potential paths for sound to escape into adjacent spaces. Therefore, wherever ducts, pipes, conduits, and the like penetrate the walls, floor, or ceiling of a mechanical equipment room, the opening must be acoustically treated for adequate noise control. A 13 to 16 mm clear space should be left all around the penetrating element and filled with fibrous material for the full depth of the penetration. Both sides of the penetration should be sealed airtight with a nonharden-
ing resilient sealant (Figure 30).

Doors into mechanical equipment rooms are frequently the weak link in the enclosure. Where noise control is important, they should be as heavy as possible, gasketed around the perimeter, have no grilles or other openings, and be self closing. If such doors lead to sensitive spaces, two doors separated by a 1 to 3 m corridor may be necessary. Mechanical room doors should open out, not in, so that the negative pressure in the room keeps the door sealed against the jamb instead of holding it against the latch.

Penetration of Walls by Ducts

Ducts passing through the mechanical equipment room enclosure pose an additional problem. Sound can be transmitted to either side of the wall via the duct walls. Airborne sound in the mechanical room can be transmitted into the duct (breakin) and enter an adjacent space by reradiating (breakout) from the duct walls, even if the duct contains no grilles, registers, diffusers, or other openings.

Sound levels in ducts close to fans are usually high. Sound can come not only from the fan but also from pulsating duct walls, excessive air turbulence, and air buffeting caused by tight or excessive air turbulence, and air buffeting caused by tight or close fittings. These noise sources can be attenuated by using flexible reducers, flexible ducts, or resilient coupling between sections of ductwork.

Table 36 Correction Numbers for Various Factors

Noise is very low frequency (peak level at 1/1 octave center frequency of 125 Hz or lower) +5
Noise contains tonal components +5
Impulsive sound +5

Mechanical Chases

Mechanical chases and shafts should be acoustically treated the same way as mechanical equipment rooms, especially if they contain noise-producing ductwork, pipes, and equipment such as fans and pumps. The shaft should be closed at the mechanical equipment room, and shaft wall construction must provide sufficient reduction of mechanical noise from the shaft to noise-sensitive areas to obtain acceptable noise levels. Chases should not be allowed to become “speaking tubes” between spaces requiring different acoustical environments. Thus crosstalk through the shaft must be prevented. Any vibrating pipes, ducts, conduits, or equipment should be vibration isolated so that mechanical vibration and structure-borne noise is not transmitted to the shaft walls and into the building.

If mechanical equipment rooms are used as supply or return plenums, all openings into the equipment room may require noise control treatment, especially if any sound critical space is immediately adjacent. This is especially true if the ceiling space just outside the equipment room is used as a return air plenum and the ceiling is acoustical tile. Most acoustical tile ceilings are almost acoustically transparent at low frequencies.

Often supply ducts are run inside a chase that is also used for the return air. It is best to attenuate the supply duct path at the fan rather than let duct breakout noise force the use of additional noise control at the return air inlets to the chase. Care should be used to prevent turbulent noise generation in the supply duct through proper supply duct design. Also the control of return path noise at the fan rather than at the inlet to the chase is best.

Special Wall Construction

When mechanical equipment rooms must be placed adjacent to offices, conference rooms, or other noise-sensitive areas, the
Building construction around the equipment space must reduce the noise enough to satisfy the acoustical requirements for the nearby spaces. Depending on the requirements, walls with high sound transmission loss may need to be considered. The low frequency performance should be carefully considered. Tables 37 and 38 give the transmission loss values for selected wall configurations. Note that the solid concrete data also apply to floors. Also note that the data in the tables are for laboratory tests.

### Floating Floors

Floating floor construction can be used to further reduce sound transmission between the mechanical room and noise-sensitive areas above or below it. Floating floors are composed of two reinforced concrete slabs: the floating or isolated wearing slab and the structural floor slab. The floating slab is designed with a minimum thickness of 90 mm and rests on a stable, long lasting resilient load-bearing material with a 25 to 100 mm separation between the structural and the floating slabs. A 50 mm separation is most common. The edges of the floating slab are isolated from the structure with a resilient material, and the joint between the floating slab and the adjacent curb is resiliently caulked.

The isolation material supporting the floating slab must be resilient, have permanent dynamic and static properties, and safely support both the floating slab and the imposed live load. The performance characteristics of the floating slab should be as follows:

- Have resilient isolation media material with a natural frequency in the range of 7 to 12 Hz with up to 15 Hz being generally acceptable under the load conditions that exist in the building both during and after construction,
- Be tested for load versus deflection and for natural frequency with known aging properties and a history of applications in similar floating floor installations,
- Be tested in service for impact insulation class (IIC) with a recommended minimum value of 68 and sound transmission class (STC) with a recommended minimum value of 73 by an independent testing laboratory, and
- Be designed for the loads imposed on the isolator in service and during construction.

Airborne and structure-borne sound flanking occurs to some degree in all buildings. Thus IIC and STC values should be such that with reasonable flanking, the noise levels produced in the occupied space adjacent to the mechanical room are suitable for the intended use.
Two common methods for constructing floating floors are

1. Individual pads, which are typically of neoprene rubber or pre-compressed fiberglass, are spaced on 300 to 600 mm centers each way and covered with plywood or sheet metal. Low-density sound absorption material can be placed between the pads to increase air damping effect. Tests using this method of construction show an STC value of around 73. Flanking and variations in construction produce either lesser or greater STC values. Reinforced concrete is placed directly on the waterproofed panels and cured; then the equipment is set in place [Figure 31A]. Typically 25 to 50 mm deep air spaces are used. Instead of individual pads, sheets of resilient material designed for this purpose may be used.

2. Isolation mounts, which are typically of neoprene rubber or pre-compressed fiberglass pads or even steel coil springs housed in protective canisters, are cast-in-place on up to 1320 mm centers each way on the structural floor. Concrete is poured over the canisters and the reinforcement steel bars or heavy steel screen mesh; after curing, the entire slab is raised into operating position, the canister access holes are grouted, and the equipment is set in place [Figure 31B]. A concrete bond breaking material such as heavy plastic film is used between slabs. Cast-in-place systems have achieved typical STC values of 73 without absorption materials. Again note that flanking and variations in construction will produce either lesser or greater STC values. Typically 13 to 100 mm deep air spaces are used with lower speed equipment requiring the deeper air space.

With either system, mechanical equipment with vibration isolators can be placed on the floating slab unless the equipment operates at shaft rotation speeds of 0.7 to 1.4 times the resonant frequency of the floating slab. The equipment should be supported on isolators with a maximum resonant frequency of 2 Hz. In case the rotating speed is coincident with the floor resonant frequency, the equipment should be supported with isolators on structural slab extensions that penetrate the floating slab. This type of installation requires careful attention to detail to avoid acoustic flanking associated with improper direct contact between the floating slab and structural penetrations. Floating floors primarily control airborne sound transmission; they are not intended to be used in place of vibration isolators and inertia bases. The actual resonant frequency of the floated slab is determined by both the stiffness of the resilient elements used to support the floated slab and the stiffness of the airspace between the structural and floated slabs.

The floating slab must be designed to operate within the safe bending limits of the concrete. While floating floor tests in laboratories have shown transmission loss ratings exceeding STC of 75; these can only be approached (realized) in field installations where all flanking sound transmission paths or short circuits have been minimized. Table 39 shows improvement of sound transmission loss by floating floor slabs, with or without flanking noise control. Often floating can be controlled by installing the mechanical equipment room wall on the edge of the floating floor slab. Note that sound flanking can occur in high rise curtain wall construction where the exterior wall is lightweight and continuous from floor to floor in the event of an earthquake. Horizontal containment should be provided by a material such as 20 mm thick neoprene pads or other suitable resilient material that would allow a maximum motion of 5 mm of compression in any direction based on the maximum acceleration force used in the building code in that particular area. The resilient pads must bear on suitable building structure or curbs built to the proper capacity.

In seismic zones it is important to contain the floating floor within the structure in the event of an earthquake. Horizontal containment should be provided by a material such as 20 mm thick neoprene pads or other suitable resilient material that would allow a maximum motion of 5 mm of compression in any direction based on the maximum acceleration force used in the building code in that particular area. The resilient pads must bear on suitable building structure or curbs built to the proper capacity.

Buckling of the floor can be of concern, particularly where snubbers are attached to the floating floor around high center of gravity machinery, such as chillers. In those areas additional snubbers such as double acting vertical floor snubbers should be located near the machinery snubber locations or just use of additional concrete reinforcement may be necessary to prevent floor buckling.

**Enclosed Air Cavity**

If acoustically critical spaces are located over a mechanical equipment room, it may be necessary to

</table>
1. Install a floating floor in this space above it, or
2. Form a totally enclosed air cavity between the spaces by installing a dense plaster or gypsum board ceiling, resiliently suspended and acoustically isolated, in the equipment room. Usually sound absorptive batts are placed in the enclosed air cavity to greatly enhance the acoustical performance.

Ideally, such a ceiling can be positioned between building beams, leaving the beam bottoms available for hanging equipment, piping, ducts, and so forth without penetrating the ceiling with hanger rods or other devices. In the case of bar joist construction, it may be easier to resiliently attach the ceiling to the underside of the joists and then support all equipment, ducts, and pipes from the mechanical room floor, wall, column or combination of all surfaces with supports that are properly vibration isolated. This type of ceiling can be difficult to implement especially if the hanging piping and ductwork are already installed. Thus the design, construction schedule, and actual installation must be carefully coordinated.

The same type of sound isolation construction can be used for acoustically critical spaces located below a mechanical equipment room. This room is often encountered with the use of builtup air handling units, chillers, pumps, and cooling towers located on the building penthouse floor level. An acoustically isolated ceiling can be installed above the typical decorative acoustical tile ceiling, and it is often found to be very effective with lighter weight than a floating floor. Such a ceiling can approximate the sound transmission loss performance of a floating floor in the space above. Some extreme sound isolation conditions require both a floating floor and acoustically isolated ceiling in series. If used, the sound isolation ceiling must be designed and installed to minimize flanking, which reduces the sound isolation.

**SOUND TRANSMISSION IN RETURN-AIR SYSTEMS**

The fan return air system provides a sound path (through ducts or through an unducted ceiling plenum) between a fan and occupied rooms. Often a direct opening goes into the mechanical equipment room through the ceiling plenum. This condition can result in high sound levels in adjacent spaces. The high sound levels are caused by the close proximity of the fan and other sound sources in the mechanical equipment room and the low system attenuation between the mechanical equipment room and the adjacent spaces.

Sound in ducted return-air systems is controlled by the fan intake sound power levels. Unducted plenum return air is impacted by the sound power levels of the fan intake and casing-radiated noise components. In certain installations, sound from other equipment in the mechanical equipment room may also radiate through the wall opening and into adjacent spaces. Good design yields room return-air sound levels that are approximately 5 dB below the corresponding supply-air system sound levels.

When sound levels in spaces adjacent to mechanical equipment rooms are too high, noise control measures must be provided. Before specifying modifications, the controlling sound paths between the mechanical equipment room and adjacent spaces must be identified. Ducted return-air systems can be modified using methods applicable to ducted supply systems. Good planning is required with unducted ceiling plenums so that the mechanical equipment room is located away from noise-sensitive spaces.

Unducted plenums may still require several modifications to satisfy design goals. Prefabricated silencers can be effective when installed at the mechanical equipment room wall opening or at the suction side of the fan. Improvements to the ceiling transmission loss are often limited by typical ceiling penetrations and lighting fixtures. Modifications to the mechanical equipment room wall can also be effective for some construction. Adding acoustical absorption in the mechanical equipment room reduces the buildup of reverberant sound energy in this space; however, this typically reduces noise only slightly in the low frequency range in nearby areas.

**SOUND TRANSMISSION THROUGH CEILINGS**

When terminal units, fan-coil units, air-handling units, ducts, or return air openings to mechanical equipment rooms are located in a ceiling plenum above an occupied room, sound transmission through the ceiling system can be high enough to cause excessive noise levels in that room. There are no standard test procedures associated with measuring the direct transmission of sound through ceilings from sources close to the ceiling. As a result, ceiling product manufacturers rarely publish data that can be used in calculations. This problem seems further complicated by the presence of light fixtures, diffusers, grilles, speakers, and so forth, which might be expected to reduce the transmission loss of the ceiling. Experiments have shown, however, that for ceiling panels supported in a T-bar grid system, the leakage between the panels and the grid is the major transmission path; differences among panel types are small and light fixtures, diffusers and the like, have only a localized effect.

To estimate the sound levels in a room associated with sound transmission through the ceiling, the sound power levels in the ceiling plenum must be attenuated by factors that account for the transmission loss of the ceiling and plenum. As well, an adjustment to the measured data must be made to account for the reverberant nature of the room. The procedures given here are based on results found as the result of an ASHRAE research project (Warnock 1998). Proceed as follows:

1. Obtain the octave band radiated sound power levels of the device.
2. Subtract the environmental correction in Table 40.
3. Calculate the surface area of the bottom panel of the source closest to the ceiling tiles.
4. From Table 41 find the adjustment to be subtracted from the sound power values at the three frequencies given there.
5. Select the Ceiling/Plenum attenuations from Table 23 according to the ceiling type in use.
6. Subtract the three sets of values, taking account of sign where necessary, from the sound power values. The result is the average sound pressure level in the room.
7. For practical purposes, the sound field in the room may be assumed to uniform up to distances of about 5 m from the source.

*Sound and Vibration Control* 46.31
Example 7. A terminal unit having an area of 1.3 m$^2$ is to be used above a
equipment to the sound level at any location can be estimated by
sound pressure level spectrum are known, the contribution of the
broadband noise spectrum.
ponents will more likely generate complaints than equipment with a
condition with the equipment not operating determines if the noise
violating local noise codes. The difference in sound levels at the lis-
ment from annoying people outdoors or in nearby building and from
installed, and maintained to prevent sound radiated by the equip-
microscopes, vibration control can be critical, and a vibration spe-
addition, vibration isolation for fume hood exhaust fans is generally
required. However, for some laboratory facilities, particularly those
consist of the following:
1. Use backward inclined or forward curved, rather than radial
blade, fans where conditions permit.
2. Select the fan to operate at a low tip speed and maximum
efficiency.
3. Use prefabricated duct silencers or sections of lined ducts where
conditions permit.

All potential noise control measures should be evaluated for
compliance with applicable codes, safety requirements, and corro-
sion resistance requirements of the specific fume hood system. In
addition, vibration isolation for fume hood exhaust fans is generally
required. However, for some laboratory facilities, particularly those
having highly vibration sensitive instruments such as electron
microscopes, vibration control can be critical, and a vibration spe-
cialist should be consulted.

SOUND CONTROL FOR
OUTDOOR EQUIPMENT

Outdoor mechanical equipment should be carefully selected,
installed, and maintained to prevent sound radiated by the equip-
ment from annoying people outdoors or in nearby building and from
violating local noise codes. The difference in sound levels at the lis-
tening location with the equipment operating and the ambient con-
ditions with the equipment not operating determines if the noise
from the equipment is annoying. Equipment with strong tonal com-
ponents will more likely generate complaints than equipment with a
broadband noise spectrum.

Sound Propagation Outdoors

If the equipment sound power level spectrum and ambient
sound pressure level spectrum are known, the contribution of the
equipment to the sound level at any location can be estimated by
analyzing the sound transmission paths involved. When there are
no intervening barriers, the principal factors outdoors are reflec-
tions from buildings near the equipment and the distance to the
specific location.

The following equation may be used to estimate the sound pres-
sure level of the equipment at a distance from it and at any fre-
quency when given the sound power level:

\[ L_p = L_{10} + 10 \log Q - 20 \log d - 11 \]  \hspace{1cm} (20)

where
\[ L_p = \text{sound pressure level at distance } d \text{ (m) from sound source}, \text{ dB} \]
\[ L_{10} = \text{sound power level of sound source}, \text{ dB} \]
\[ Q = \text{directivity factor associated with the way sound radiates} \]
\[ \text{from sound source (refer to Figure 32)} \]

Equation (20) does not apply where \( d \) is less than twice the max-
imum dimension of the sound source. \( L_p \) may be low by up to 5 dB
where \( d \) is between two and five times the maximum sound source
dimension. Also, if the distance is greater than about 150 m down-
wind, thermal gradients and atmospheric sound absorption need to
be considered.

Sound Barriers

A sound barrier is a solid structure that intercepts the direct
sound path from a sound source to a receiver. It reduces the sound
pressure level within its shadow zone. Figure 33 illustrates the geo-
metrical aspects of an outdoor barrier where no extraneous surfaces
reflect sound into the protected area. Here the barrier is treated as an
intentionally constructed noise control structure. If a sound barrier
is placed between a sound source and receiver location, the sound
pressure level \( L_p \) in Equation (20) is reduce by the insertion loss IL
associated with the barrier. Table 42 gives the insertion loss of an outdoor ideal solid barrier
when

\[ \text{1. No surfaces reflect sound into the shadow zone, and} \]
\[ \text{2. The sound transmission loss of the barrier wall or structure is at} \]
\[ \text{least } 10 \text{ dB greater at all frequencies than the insertion loss} \]
\[ \text{expected of the barrier.} \]}
The path-length difference referred to in Table 42 is given by

\[
\text{Path-length difference} = A + B - D
\]

(21)

where \( A, B, \) and \( D \) are as specified in Figure 33.

The limiting value of about 24 dB is caused by scattering and refraction of sound into the shadow zone formed by the barrier. Practical constructions, size and space restrictions often limit sound barrier performance to 10 to 15 dBA. For large distances outdoors, this scattering and bending of sound waves into the shadow zone reduces the effectiveness of the barrier. At large distances atmospheric conditions can significantly affect the sound path losses by amounts even greater than provided by the barrier with typical differences of 10 dBA observed. For a conservative estimate, the height of the sound source location should be taken as the topmost part of the sound source, and the height of the receiver should be taken as the topmost location of a sound receiver, such as the top of the second-floor windows in a two-floor house or at a height of 1.5 m for a standing person.

**Reflecting Surfaces.** No other surfaces should be located where they can reflect sound around the ends or over the top of the barrier into the barrier shadow zone. Figure 34 shows examples of reflecting surfaces that should be avoided because they can reduce the effectiveness of a barrier wall.

**Width of Barrier.** Each end of the barrier should extend horizontally beyond the line of sight from the outer edge of the source to the outer edge of the receiver position by at least three times the path-length distance. Near the end of the barrier, the barrier effectiveness is reduced because some sound is diffracted over the top of the barrier, some sound is diffracted around the end of the barrier, and some sound is reflected or scattered from various nonflat surfaces along the ground near the end of the barrier. In critical situations, the barrier should completely enclose the sound source to eliminate or reduce the effects of reflecting surfaces.

**Reflection from a Barrier.** A large, flat reflecting surface, such as a barrier wall, may reflect more sound in the opposite direction than if no wall was present. If the wall produces no focusing effect, it may produce only a 2 or 3 dB higher noise level (at most) in the direction of the reflected sound. Acoustical absorption on the barrier surface should be considered to reduce the noise.
DESIGN PROCEDURES

The following design procedures are suggested for managing each of the different sound sources and related sound transmission paths associated with an HVAC system.

1. Determine the design goal for HVAC system noise for each critical area according to its use and construction. Choose desirable RC criterion from Table 34. A balanced sound spectrum is as important as the overall sound level.

2. Relative to equipment such as air inlet and outlet grilles, registers, diffusers, and air terminal and fan coil units that radiate sound directly into a room, select equipment that is quiet enough to meet the desired design goal.

3. If ducted central or roof-mounted mechanical equipment such as air handling units are to be used, complete an initial design and layout of the HVAC system using acoustical treatment such as lined ductwork and duct silencers where appropriate. Consider the return air, exhaust air, and supply paths.

4. Starting at the fan, appropriately add the sound attenuation and sound power levels associated with the central fan(s), fan-powered terminal units (if used), and duct elements between the central fan(s) and the room of interest. Then convert to the corresponding sound pressure levels in the room. For a more complete estimate of resultant sound levels, consider regenerated and self noise from duct silencers and air inlets and outlets due to the airflow itself. Investigate both the supply and return air paths in similar ways. Investigate and control possible duct sound breakout when fans are adjacent to the room of interest or roof-mounted fans are above the room of interest. Be sure to combine the sound contribution from all paths into the occupied space of concern. The following example shows the calculation procedure for supply and return air paths along with duct breakout noise contributions.

5. If the mechanical equipment room is adjacent to the room of interest, determine the sound pressure levels in the room of interest that are associated with sound transmitted through the mechanical equipment room wall. Typical equipment to consider include air handling units, ventilation and exhaust fans, chillers, pumps, electrical transformers, and instrument air compressors. Also consider the vibration isolation requirements for all the equipment along with piping and ductwork.

6. Combine on an energy basis (see the example for sample calculation procedures) the sound pressure levels in the room of interest that are associated with all sound paths between the mechanical equipment room or roof-mounted unit and the room.

7. Determine the corresponding RC level associated with the calculated total sound pressure levels in the room of interest. Take special note of the sound quality indicators for possible rumble, roar, hiss, tones, and perceivable vibration.

8. If the RC level exceeds the design goal, determine the octave frequency bands in which the corresponding sound pressure levels are exceeded and the sound paths that are associated with these octave frequency bands. If resultant noise levels are high enough to cause perceivable vibration, consider both airborne and structure-borne noise.

9. Redesign the system, adding additional sound attenuation to the paths that contribute to the excessive sound pressure levels in the room of interest. If resultant noise levels are high enough to cause perceivable vibration, then major redesign and possibly use of supplemental vibration isolation for the equipment and building systems will often be required.

10. Repeat Steps 4 through 9 until the desired design goal is achieved. Involve the complete design team where major problems are found. Often simple design changes to the building architectural and equipment systems can eliminate potential problems once the problems are identified.

11. Steps 3 through 10 must be repeated for every room that is to be analyzed.

12. Make sure that noise radiated by outdoor equipment such as air cooled chillers and cooling towers will not disturb adjacent properties or interfere with criteria established in Step (1) or any applicable building or zoning ordinances.

Example 8. Individual examples in the preceding sections demonstrate how to calculate equipment and airflow-generated sound power levels and sound attenuation values associated with the elements of HVAC air distribution systems. This example shows how the information can be combined to determine the sound pressure levels associated with a specific HVAC system. Only a summary of the results is shown rather than showing complete calculations for each element.

Air is supplied to the HVAC system in this example by the rooftop unit shown in Figure 35. The receiver room is directly below the unit. The room has the following dimensions: length = 6100 mm, width = 6100 mm; and height = 2750 mm. This example assumes the roof penetrations for the supply and return air ducts are well sealed and there are no other roof penetrations. The supply side of the rooftop unit is ducted to a VAV terminal control unit that serves the room in question. A return air grille conducts air to a common ceiling return air plenum. The return air is then directed to the rooftop unit through a short rectangular return air duct.

The following three sound paths are examined:

Path 1. Fan airborne supply air sound that enters the room from the supply air system through the ceiling diffuser
Path 2. Fan airborne supply air sound that breaks out through the wall of the main supply air duct into the plenum space above the room
Path 3. Fan airborne return air sound that enters the room from the inlet of the return air duct

The sound power levels associated with the supply air and return air sides of the fan in the rooftop unit are specified by the manufacturer as follows:

</tr>
</tbody>
</table>

Solution:

Paths 1 and 2 are associated with the supply air side of the system. Figure 36 shows a layout of the part of the supply air system that is associated with the receiver room. The main duct is a 560 mm diameter, 26 gage (0.551 mm), unlined, round sheet metal duct. The flow volume in the main duct is 3.3 m³/s. The silencer after the radiused elbow is a 560 mm diameter by 1.12 m long, high pressure, circular silencer. The branch junction that occurs 2.44 m from the silencer is a 45° wye. The branch duct between the main duct and the VAV control unit is a 250 mm diameter, unlined, round sheet metal duct. The flow volume in the branch duct is 0.37 m³/s.

The straight section of duct between the VAV control unit and the diffuser is a 250 mm diameter, unlined round sheet metal duct. The diffuser is 380 mm by 380 mm square. Assume a typical distance between the diffuser and a listener in the room is 1.5 m.

1999 ASHRAE Applications Handbook (SI)
With regard to the duct breakout sound associated with the main duct, the length of the duct that runs over the room is 6.1 m. The ceiling of the room is comprised of 6.1 m by 1.22 m by 16 mm lay-in ceiling tiles that have a surface density of 2.9 to 3.4 kg/m². The ceiling has integrated lighting and diffusers.

Path 3 is associated with the return air side of the system. Figure 37 shows a layout of the part of the return air system that is associated with the receiver room. The rectangular return air duct is lined with 50 mm thick, 48 kg/m³ density fiberglass duct liner. For the return air path, assume the typical distance between the inlet of the return air duct and a listener is 3 m.

The calculations associated with this example were conducted with a computer program such as provided in *Algorithms for HVAC Acoustics* (ASHRAE 1991) or other commercially available ones. The analysis associated with each path begins at the rooftop unit (fan) and proceeds progressively through the different elements to the receiver room. The element numbers in the tables correspond to the element numbers contained in brackets in Figures 36 and 37.

The first table is associated with Path 1. The first entry in the table is the manufacturer’s values for supply air fan sound power levels (1). The second entry is the sound attenuation associated with the 560 mm diameter unlined radius elbow (3). Because the next entry is associated with the regenerated sound power levels associated with the elbow (4), the results associated with the elbow attenuation must be tabulated to determine the sound power levels at the exit of the elbow.

These sound power levels and the elbow regenerated sound power levels are then added logarithmically, which is denoted by (Log Sum) in the tables where the value in decibels equals $10\log(10^A + 10^B)$ with $A$ and $B$ being the values in decibels. In a like fashion, the dynamic insertion loss values of the duct silencer (5) and the silencer regenerated sound power levels (6) are included in the table and tabulated.

</table>

Next, the attenuation associated with the 2.44 m section of 560 mm diameter duct (7) and the branch power division (10) associated with sound propagation in the 250 mm diameter branch duct are included in the table. After element 10, the sound power levels that exist in the branch duct after the branch takeoff are calculated so that the regenerated sound power levels (11) in the branch duct associated with the branch takeoff can be logarithmically added to the results.

Next, the sound attenuation values associated with the 1.83 m section of 250 mm diameter unlined duct (12), the terminal volume regulation unit (13), the 610 mm section of 250 mm diameter unlined duct (14), and 250 mm diameter radius elbow (15) are included in the table. The sound power levels that exist at the exit of the elbow are then calculated so that the regenerated sound power levels (16) associated with the elbow can be logarithmically added to the results. The diffuser end reflection loss (17) and the diffuser regenerated sound power levels (18) are appropriately included in the table. The sound power levels that are tabulated after element 18 are the sound power levels that exist at the diffuser in the receiver room. Note that the end reflection from a duct in free space and flush with a suspended acoustical ceiling are assumed to be the same.

The final entry in the table is the “room correction” that converts the sound power levels at the diffuser to their corresponding sound pressure levels at the point of interest in the receiver room. Elements 1 through 7 in Path 2 are the same as Path 1. Elements 8 and 9 are associated with the branch power division (8) and the corresponding regenerated sound power levels (9) associated with sound that propagates down the main duct beyond the duct branch. The next three entries in the table are the sound transmission loss associated with the duct breakout sound (20), the sound transmission loss associated with the ceiling (21), which considers the integrated lighting and diffuser including the return air openings, and the room correction (22), converting the sound power levels at the ceiling to corresponding sound pressure levels in the room. While not specifically considered in this example, noise radiated by a VAV terminal unit can be a significant source. Consult with the manufacturer for both radiated and discharge sound data.

The first element in Path 3 is the manufacturer’s values for return air fan sound power levels (2). The next two elements are the sound attenuation associated with a 810 mm wide, lined square elbow without turning vanes (23) and the regenerated sound power levels associated with the square elbow (24). The final four elements are the insertion loss associated with a 0.810 m by 1.730 m by 2.44 m long rectangular sheet metal duct lined with 50 mm thick, 48 kg/m² fiberglass duct lining (26), the diffuser end reflection loss (27), the transmission loss through the ceiling (21), which considers the integrated lighting and diffuser system including the return air openings, and the room correction (27).
converting the sound power levels at the ceiling to corresponding sound pressure levels in the room.

The total sound pressure levels in the receiver room from the three paths are obtained by logarithmically adding the individual sound pressure levels associated with each path. From the total sound pressure levels for all three paths, the NC value in the room is NC 42, and the RC value is RC 34 (R-H), which is a combination of lower frequency rumble and higher frequency hiss.

If the regenerated noise due to airflow through the ductwork, silencer, and diffuser are not considered, the NC value in the room is NC 42, and the RC value is RC 26 (R-H). While the calculation procedure is simplified, the typically higher-frequency regenerated noise is not accounted for in the overall ratings especially in the RC value, whose numeric magnitude is often set by the higher frequency noise contribution. At a minimum, the self-noise or regenerated noise of the silencers and outlet or inlet devices such as grilles, registers, and diffusers should be considered along with the attenuation provided by the duct elements and dynamic insertion loss of the silencers.

VIBRATION ISOLATION AND CONTROL

Mechanical vibration and vibration-induced noise are often major sources of occupant complaints in modern buildings. Lighter construction in new buildings has made these buildings more susceptible to vibration and vibration-related problems. Increased interest in energy conservation in buildings has resulted in many new buildings being designed with variable air volume systems. This often results in mechanical equipment being located in pent-houses on the roof, in the use of roof-mounted HVAC units, and in mechanical equipment rooms located on intermediate level floors. These trends have resulted in an increase in the number of pieces of mechanical equipment located in a building, and they often have resulted in mechanical equipment being located adjacent to or above occupied areas.

Occupant complaints associated with building vibration typically take one of three forms:
1. The level of vibration perceived by building occupants is of sufficient magnitude to cause concern or alarm.
2. Vibration energy from mechanical equipment, which is transmitted to the building structure, is transmitted to various parts of the building and then is radiated as structure-borne noise.
3. Vibration present in a building may interfere with proper operation of sensitive equipment or instrumentation.

The following sections present basic information to properly select and specify vibration isolators and to analyze and correct field vibration problems. Chapter 7 in the 1997 ASHRAE Handbook—Fundamentals and Reynolds and Bevirt (1994) provide more detailed information.

EQUIPMENT VIBRATION

Vibration can be isolated or reduced to a fraction of the original force with resilient mounts between the equipment and the supporting structure. To determine the excessive forces that must be isolated or that adversely affect the performance or life of the equipment, criteria should be established for equipment vibration. Figures 38 and 39 show the relation between equipment vibration levels and vibration isolators that have a fixed vibration isolation efficiency. In this case, the magnitude of transmission to the building is a function of the magnitude of the vibration force.

VIBRATION CRITERIA

Vibration criteria can be specified relative to three areas: (1) human response to vibration, (2) vibration levels associated with potential damage to sensitive equipment in a building, and (3) vibration severity of a vibrating machine. Figure 40 and
spans, equipment operating speeds, equipment power, damping, and other factors have been considered in the vibration isolator selection guide in Table 45.

By specifying isolator deflection rather than isolation efficiency, transmissibility, or other theoretical parameters, a designer can compensate for floor stiffness and building resonances by selecting isolators that provide minimum vibration transmission and that have more deflection than the supporting floor. To apply the information from Table 45, base type, isolator type, and minimum deflection columns are added to the equipment schedule. These isolator specifications are then incorporated into mechanical specifications for the project.

The minimum deflections listed in Table 45 are based on the experience of acoustical and mechanical consultants and vibration control manufacturers. Recommended isolator type, base type, and minimum static deflection are reasonable and safe recommendations for 70% to 80% of HVAC equipment installations. The selections are based on concrete equipment room floors 100 to 300 mm thick with typical floor stiffness. The type of equipment, proximity to noise-sensitive areas, and the type of building construction may alter these choices.

**Base Types:**
A. No base, isolators attached directly to equipment (Note 27)
B. Structural steel rails or base (Notes 28 and 29)
C. Concrete inertia base (Note 30)
D. Curb-mounted base (Note 31)

**Isolator Types:**
1. Pad, rubber, or glass fiber (Notes 20 and 21)
2. Rubber floor isolator or hanger (Notes 20 and 25)
3. Spring floor isolator or hanger (Notes 22, 23, and 25)
4. Restrained spring isolator (Notes 22 and 24)
5. Thrust restraint (Note 26)
The notes in this section are keyed to the numbers listed in the column titled “Reference Notes” and to other reference numbers throughout the table. While the guide is conservative, cases may arise where vibration transmission to the building is still excessive. If the problem persists after all short circuits have been eliminated, it can almost always be corrected by increasing isolator deflection, using lower-frequency air springs, changing operating speed, reducing vibratory output by additional balancing or, as a last resort, changing floor frequency by stiffening or adding more mass.

**Note 1.** Isolator deflections shown are based on a floor stiffness that can be reasonably expected for each floor span and class of equipment.

**Note 2.** For large equipment capable of generating substantial vibratory forces and structure-borne noise, increase isolator deflection, if necessary, so isolator stiffness is at least 0.10 times the floor stiffness.

**Note 3.** For noisy equipment adjoining or near noise-sensitive areas, see the text section on Mechanical Equipment Room Sound Isolation.

**Note 4.** Certain designs cannot be installed directly on individual isolators (Type A), and the equipment manufacturer or a vibration specialist should be consulted on the need for supplemental support (Base Type).

**Note 5.** Wind load conditions must be considered. Restrains can be achieved with restrained spring isolators (Type 4), supplemental bracings, or limit stops.

**Note 6.** Certain types of equipment require a curb-mounted base (Type D). Airborne noise must be considered.

**Note 7.** See the text section on Resilient Pipe Hangers and Supports for hanger locations adjoining equipment and in equipment rooms.

**Note 8.** To avoid isolator resonance problems, select isolator deflection so that resonant frequency is 40% or less of the lowest operating speed of equipment.

**Note 9.** To limit undesirable movement, thrust restraints (Type 5) are required for all ceiling-suspended and floor-mounted units operating at 50 mm and more total static pressure.

**Note 10.** Pumps over 55 kW may require extra mass and restraining devices.

### Isolation for Specific Equipment

**Note 12. Refrigeration Machines:** Large centrifugal, hermetic, and reciprocating refrigeration machines generate very high noise levels, and special attention is required when such equipment is installed in upper stories or near noise-sensitive areas. If such equipment is to be located near extremely noise-sensitive areas, confer with an acoustical consultant.

**Note 13. Compressors:** The two basic reciprocating compressors are (1) single- and double-cylinder vertical, horizontal or L-head, which are usually air compressors; and (2) Y, W, and multihed or multicylinder air and refrigeration compressors. Single- and double-cylinder compressors generate high vibratory forces requiring large inertia bases (Type C) and are generally not suitable for upper-story locations. If such equipment must be installed in upper stories or on grade locations near noise-sensitive areas, unbalanced forces should be obtained from the equipment manufacturer, and a vibration specialist should be consulted for design of the isolation system.

**Note 14. Compressors:** When using Y, W, and multihed and multicylinder compressors, obtain the magnitude of unbalanced forces from the equipment manufacturer so that the necessity for an inertia base can be evaluated.

**Note 15. Compressors:** Base-mounted compressors through 4 kW and horizontal tank-type air compressors through 8 kW can be installed directly on spring isolators (Type 3) with structural bases (Type B) if required, and compressors 10 to 75 kW on spring isolated (Type 3) with inertia bases (Type C) with a mass of one to two times the compressor mass.

**Note 16. Pumps:** Concrete inertia bases (Type C) are preferred for all flexible-coupled pumps and are desirable for most close-coupled pumps, although steel bases (Type B) can be used. Close-coupled pumps should not be installed directly on individual isolators (Type A) because the impeller usually overhangs the motor support base, causing the rear mounting to be in tension. The primary requirements for Type C bases are strength and shape to accommodate base elbow supports. Mass is not usually a factor, except for pumps over 55 kW where extra mass helps limit excess movement due to starting torque and forces. Concrete bases (Type C) should be designed for a thickness of one-tenth the longest dimension with minimum thickness as follows:

- (1) for up to 20 kW, 150 mm; (2) for 30 to 55 kW, 200 mm; and (3) for 75 kW and higher, 300 mm.

**Note 17. Packaged Rooftop Air-Conditioning Equipment:** This equipment is usually on light structures that are susceptible to sound and vibration transmission. The noise problem is further compounded by curbed-mounted equipment, which requires large roof openings for supply and return air.

The table shows Type D vibration isolator selections for all spans up to 6 m, but extreme care must be taken for equipment located on spans of over 6 m, especially when construction is open web joists or thin low-density slabs. The recommended procedure is to determine the additional deflection caused by equipment in the roof. If additional roof deflection is 6 mm or under, the isolator can be selected for 15 times the additional roof deflection. If additional roof deflection is over 6 mm, supplemental stiffening should be installed or the unit should be relocated.

For units, especially large units, capable of generating high noise levels, consider (1) mounting the unit on a platform above the roof deck to provide an air gap (buffer zone) and (2) locating the unit away from the roof penetration, thus permitting acoustical treatment of ducts before they enter the building.

Some rooftop equipment has compressors, fans, and other equipment isolated internally. This isolation is not always reliable because of internal short circuiting, inadequate static deflection, or panel resonances. It is recommended that rooftop equipment be isolated externally, as if internal isolation were not used.

**Note 18. Cooling Towers:** These are normally isolated with restrained spring isolators (Type 4) directly under the tower or tower dunnage. Occasionally, high deflection isolators are proposed for use directly under the motor-fan assembly, but this arrangement must be used with extreme caution.

**Note 19. Fans and Air-Handling Equipment:** The following should be considered in selecting isolation systems for fans and air-handling equipment:

- Fans with wheel diameters of 560 mm and under and all fans operating at speeds to 300 rpm do not generate large vibratory forces. For fans operating under 300 rpm, select isolator deflection so that the isolator natural frequency is 40% or less of the fan speed. For example, for a fan operating at 275 rpm, an isolator natural frequency of 110 rpm (1.8 Hz) or lower is required (0.4 x 275 = 110 rpm). A 75-mm deflection isolator (Type 3) can provide this isolation.

- Flexible duct connectors should be installed at the intake and discharge of all fans and air-handling equipment to reduce vibration transmission to air ducts.

Inertia bases (Type C) are recommended for all Class 2 and 3 fans and air-handling equipment because extra mass permits the use of stiffer springs, which limit movement.

Thrust restraints (Type 5) that incorporate the same deflection as isolators should be used for all fan heads, all suspended fans, and all base-mounted and suspended air-handling equipment operating at 500 Pa and over total static pressure.

### Vibration Isolators:

#### Materials, Types, and Configurations

Notes 20 through 31 are useful for evaluating commercially available isolators for HVAC equipment. The isolator selected for a particular application depends on the required deflection, but life, cost, and suitability must also be considered.
Rubber isolators are available in pad (Type 1) and molded (Type 2) configurations. Pads are used in single or multiple layers. Molded isolators come in a range of 30 to 70 durometer (a measure of stiffness). Material in excess of 70 durometer is usually ineffective as an isolator. Isolators are designed for up to 13-mm deflection, but are used where 8-mm or less deflection is required. Solid rubber and composite fabric and rubber pads are also available. They provide high load capacities with small deflection and are used as noise barriers under columns and for pipe supports. These pad types work well only when they are properly loaded and the weight load is evenly distributed over the entire pad surface. Metal loading plates can be used for this purpose.

Precompressed glass fiber isolation pads (Type 1) constitute inorganic inert material and are available in various sizes in thicknesses of 25 to 100 mm, and in capacities of up to 3.4 MPa. Their manufacturing process assures long life and a constant natural frequency of 7 to 15 Hz over the entire recommended load range. Pads are covered with an elastomeric coating to increase damping and to protect the glass fiber. Glass fiber pads are most often used for the isolation of concrete foundations and floating floor construction.

Steel springs are the most popular and versatile isolators for HVAC applications because they are available for almost any deflection and have a virtually unlimited life. All spring isolators should have a rubber acoustical barrier to reduce transmission of high-frequency vibration and noise that can migrate down the steel spring coil. They should be corrosion-protected if installed outdoors or in a corrosive environment. The basic types include:

1. **Open spring isolators (Type 3)** consist of a top and bottom load plate with an adjustment bolt for leveling. Springs should be designed with a horizontal stiffness at least 100% of the vertical stiffness to assure stability, 50% travel beyond rated load and safe solid stresses.

2. **Restrained spring isolators (Type 4)** have hold-down bolts to limit vertical movement. They are used with (a) equipment with large variations in mass (boilers, refrigeration machines) to restrict movement and prevent strain on piping when water is removed, and (b) outdoor equipment, such as cooling towers, to prevent excessive movement because of wind load. Spring criteria should be the same as for open spring isolators, and restraints should have adequate clearance so that they are activated only when a temporary restraint is needed.

3. **Housed spring isolators** consist of two telescoping housings separated by a resilient material. Depending on design and installation, housed spring isolators can bind and short circuit. Their use should be avoided.

Air springs can be designed for any frequency but are economical only in applications with natural frequencies of 1.33 Hz or less (150-mm or greater deflection). Their use is advantageous in that they do not transmit high-frequency noise and are often used to replace high deflection springs on problem jobs. Constant air supply is required, and there should be an air dryer in the air supply.

Isolation hangers (Types 2 and 3) are used for suspended pipe and equipment and have rubber, springs, or a combination of spring and rubber elements. Criteria should be the same as for open spring isolators. To avoid short circuiting, hangers should be designed for 20 to 35° angular hanger rod misalignment. Swivel or traveler arrangements may be necessary for connections to piping systems subject to large thermal movements.

Thrust restraints (Type 5) are similar to spring hangers or isolators and are installed in pairs to resist the thrust caused by air pressure.

Direct isolation (Type A) is used when equipment is unitary and rigid and does not require additional support. Direct isolation can be used with large chillers, packaged air-handling units, and air-cooled condensers. If there is any doubt that the equipment can be supported directly on isolators, use structural bases (Type B) or inertia bases (Type C), or consult the equipment manufacturer.
The following approach is suggested to develop isolator selections for specific applications:

1. Use Table 45 for floors specifically designed to accommodate mechanical equipment.
2. Use recommendations for the 6 m span column for equipment on ground-supported slabs adjacent to noise-sensitive areas.
3. For roofs and floors constructed with open web joists, thin long span slabs, wooden construction, and any unusual light construction, evaluate all equipment with a mass of more than 140 kg to determine the additional deflection of the structure caused by the equipment. Isolator deflection should be 15 times the additional deflection or the deflection shown in Table 45, whichever is greater. If the required spring isolator deflection exceeds commercially available products, consider air springs, stiffen the supporting structure, or change the equipment location.
4. When mechanical equipment is adjacent to noise-sensitive areas, isolate mechanical equipment room noise.

**ISOLATION OF VIBRATION AND NOISE IN PIPING SYSTEMS**

All piping has mechanical vibration generated by the equipment and impeller-generated and flow-induced vibration and noise, which is transmitted by the pipe wall and the water column. In addition, equipment installed on vibration isolators exhibits some motion or movement from pressure thrusts during operation. Vibration isolators have even greater movement during start-up and shutdown, when the equipment goes through the isolators’ resonant frequency. The piping system must be flexible enough to (1) reduce vibration transmission along the connected piping, (2) permit equipment movement without reducing the performance of vibration isolators, and (3) accommodate equipment movement or thermal movement of the piping at connections without imposing undue strain on the connections and equipment.

Flow noise in piping can be minimized by sizing pipe so that the velocity is 1.2 m/s maximum for pipe 50 mm and smaller and using a pressure drop limitation of 400 Pa per metre of pipe length with a maximum velocity of 3 m/s for larger pipe sizes. Flow noise and vibration can be reintroduced by turbulence, sharp pressure drops, and entrained air. Care should be taken to avoid these conditions.

**Resilient Pipe Hangers and Supports**

Resilient pipe hangers and supports are necessary to prevent vibration and noise transmission from the piping to the building structure and to provide flexibility in the piping.
**Suspended Piping.** Isolation hangers described in the vibration isolation section should be used for all piping in equipment rooms or for 15 m from vibrating equipment, whichever is greater. To avoid reducing the effectiveness of equipment isolators, at least the first three hangers from the equipment should provide the same deflection as the equipment isolators, with a maximum limitation of 50 mm deflection; the remaining hangers should be spring or combination spring and rubber with 20 mm deflection.

Good practice requires the first two hangers adjacent to the equipment to be the positioning or precompressed type, to prevent load transfer to the equipment flanges when the piping is filled. The positioning hanger aids in installing large pipe, and many engineers specify this type for all isolated pipe hangers for piping 200 mm and over.

While isolation hangers are not often specified for branch piping or piping beyond the equipment room for economic reasons, they should be used for all piping over 50 mm in diameter and for any piping suspended below or near noise-sensitive areas. Hangers adjacent to noise-sensitive areas should be the spring and rubber combination Type 3.

**Floor Supported Piping.** Floor supports for piping in equipment rooms and adjacent to isolated equipment should use vibration isolators as described in the vibration isolation section. They should be selected according to the guidelines for hangers. The first two adjacent floor supports should be the restrained spring type, with a blocking feature that prevents load transfer to equipment flanges as the piping is filled or drained. Where pipe is subjected to large thermal movement, a slide plate (PTFE, graphite, or steel) should be installed on top of the isolator, and a thermal barrier should be used when rubber products are installed directly beneath steam or hot water lines.

**Riser Supports, Anchors, and Guides.** Many piping systems have anchors and guides, especially in the risers, to permit expansion joints, bends, or pipe loops to function properly. Anchors and guides eliminate or limit (guide) pipe movement, but must be rigidly attached to the structure; this is inconsistent with the resiliency required for effective isolation. The engineer should try to locate the pipe shafts, anchors, and guides in noncritical areas, such as next to elevator shafts, stairwells, and toilets, rather than adjoining noise-sensitive areas. Where concern about vibration transmission exists, some type of vibration isolation support or acoustical support is required for the pipe support, anchors, and guides.

Because anchors or guides must be rigidly attached to the structure, the isolator cannot deflect in the sense previously discussed, and the primary interest is to create an acoustical barrier. Such acoustical barriers can be provided by heavy-duty rubber and duck and rubber pads that can accommodate large loads with minimal deflection. Figure 43 shows some arrangements for resilient anchors and guides. Similar resilient-type supports can be used for the pipe.

Resilient supports for pipe, anchors, and guides can attenuate noise transmission, but they do not provide the resiliency required to isolate vibration. Vibration must be controlled in an anchor guide by designing flexible pipe connectors and resilient isolation hangers or supports.

Completely spring-isolated risers that eliminate the anchors and guides have been used successfully in many instances and give effective vibration and acoustical isolation. In this type of isolation, the springs are sized to accommodate thermal growth as well as to guide and support the pipe. Such systems require careful engineering to accommodate the movements encountered not only in the riser but also in the branch takeoff to avoid overstressing the piping.

**Piping Penetrations.** Most HVAC systems have many points at which piping must penetrate floors, walls, and ceilings. If such penetrations are not properly treated, they provide a path for airborne noise, which can destroy the acoustical integrity of the occupied space. Seal the openings in the pipe sleeves between noisy areas, such as equipment rooms, and occupied spaces with an acoustical barrier such as fibrous material and caulking or with engineered pipe penetration seals as shown in Figure 43.

**Flexible Pipe Connectors**

Flexible pipe connectors (1) provide piping flexibility to permit isolators to function properly, (2) protect equipment from strain from misalignment and expansion or contraction of piping, and (3)
Hose Connectors

Limitations should be strictly adhered to. Manufacturers' recommendations on restraint, pressure, and temperature should be limited to 80 mm and smaller pipe diameter. The fittings should be the mechanically expanded type to minimize the possibility of pressure thrust blowout. Flanged types are available in larger pipe sizes. Table 46 lists recommended lengths.

Expansion Joint or Arched-Type Connectors

Expansion joint or arched-type connectors have one or more convolutions or arches and can accommodate all modes of axial, lateral, and angular movement and misalignment. These connectors are available in flanged rubber and PTFE (Teflon) construction. PTFE expansion joints and couplings are similar in construction to rubber expansion joints with reinforcing metal rings. When made of rubber, they are commonly called expansion joints, spool joints, or spherical connectors, and in PTFE, as couplings or expansion joints.

Rubber expansion joints or spool joints are available in two basic types: (1) handwrapped with wire and fabric reinforcing, and (2) molded with fabric and wire or with high-strength fabric only (instead of metal) for reinforcing. The handmade joint is available in a variety of materials and lengths for special applications. Rubber spherical connectors are molded with high-strength fabric or tire cord reinforcing instead of metal. Their distinguishing characteristic is a large radius arch. The shape and construction of some designs permit use without control assemblies in systems operating to 1 MPa. Where thrust restraints are not built in, they must be used as described for rubber hose joints.

In evaluating these devices, temperature, pressure, and service conditions must be considered as well as the ability of each device to attenuate vibration and noise. Metal hose connections can accommodate misalignment and attenuate mechanical vibration transmitted through the pipe wall but do little to attenuate noise. This type of connector has superior resistance to long-term temperature effects.

Rubber hose, expansion joints, and spherical connectors attenuate vibration and impeller-generated noise transmitted through the pipe wall. Because the rubber expansion joint and spherical connector walls are flexible, they have the ability to grow volumetrically and attenuate noise and vibration at blade passage frequencies. This feature is particularly desirable for uninsulated piping, such as condenser water and domestic water, which may run adjacent to noise-sensitive areas. However, high pressure has a detrimental effect on the ability of the connector to attenuate vibration and noise.

Because none of the flexible pipe connectors control flow or velocity noise or completely isolate vibration and noise transmission to the piping, resilient pipe hangers and supports should be used; these are shown in Note 25, Table 45 and are described in the Resilient Pipe Hangers and Supports section.

bBased on recommendations of Rubber Expansion Division, Fluid Sealing Association.

attenuate noise and vibration transmission along the piping. [Figure 44] Connectors are available in two configurations: (1) hose type, a straight or slightly corrugated wall construction of either rubber or metal; and (2) the arched or expansion joint type, a short length connector with one or more large radius arches, of rubber, Teflon, or metal. Metal expansion joints are seldom used for vibration and sound isolation in HVAC work, and their use is not recommended. All flexible connectors require end restraint to counteract the pressure thrust, which is (1) added to the connector, (2) incorporated by its design, (3) added to the piping (anchoring), or (4) built in by the stiffness of the system. Connector extension caused by pressure thrust on isolated equipment should also be considered when flexible connectors are used. Overextension will cause failure. Manufacturers' recommendations on restraint, pressure, and temperature limitations should be strictly adhered to.

Hose Connectors

Hose connectors accommodate lateral movement perpendicular to the length and have very limited or no axial movement capability. Rubber hose connectors can be of molded or handwrapped construction with wire reinforcing. They are available with metal-threaded end fittings or integral rubber flanges. Threaded fittings should be limited to 80 mm and smaller pipe diameter. The fittings should be the mechanically expanded type to minimize the possibility of pressure thrust blowout. Flanged types are available in larger pipe sizes. Table 46 lists recommended lengths.

Metal hose is constructed with a corrugated inner core and a braided cover, which helps attain a pressure rating and provides end restraints that eliminate the need for supplemental control assemblies. Short lengths of metal hose or corrugated metal bellows, or pump connectors, are available without braid and have built-in control assemblies. Metal hose is used to control misalignment and vibration rather than noise and is used primarily where temperature or the pressure of flow media precludes the use of other material. Table 46 provides recommended lengths.

Flexible Pipe Connectors

Flexible pipe connectors attenuate noise and vibration transmission along the piping. They are available with handwrapped or integral rubber flanges. Threaded fittings should be limited to 80 mm and smaller pipe diameter. The fittings should be the mechanically expanded type to minimize the possibility of pressure thrust blowout. Flanged types are available in larger pipe sizes. Table 46 lists recommended lengths.

aLive length is end-to-end length for integral flanged rubber hose and is end-to-end less total fitting length for all other types.
bBased on recommendations of Rubber Expansion Division, Fluid Sealing Association.

Metal hose is constructed with a corrugated inner core and a braided cover, which helps attain a pressure rating and provides end restraints that eliminate the need for supplemental control assemblies. Short lengths of metal hose or corrugated metal bellows, or pump connectors, are available without braid and have built-in control assemblies. Metal hose is used to control misalignment and vibration rather than noise and is used primarily where temperature or the pressure of flow media precludes the use of other material. Table 46 provides recommended lengths.

Expansion Joint or Arched-Type Connectors

Expansion joint or arched-type connectors have one or more convolutions or arches and can accommodate all modes of axial, lateral, and angular movement and misalignment. These connectors are available in flanged rubber and PTFE (Teflon) construction. PTFE expansion joints and couplings are similar in construction to rubber expansion joints with reinforcing metal rings. When made of rubber, they are commonly called expansion joints, spool joints, or spherical connectors, and in PTFE, as couplings or expansion joints.

Rubber expansion joints or spool joints are available in two basic types: (1) handwrapped with wire and fabric reinforcing, and (2) molded with fabric and wire or with high-strength fabric only (instead of metal) for reinforcing. The handmade joint is available in a variety of materials and lengths for special applications. Rubber spherical connectors are molded with high-strength fabric or tire cord reinforcing instead of metal. Their distinguishing characteristic is a large radius arch. The shape and construction of some designs permit use without control assemblies in systems operating to 1 MPa. Where thrust restraints are not built in, they must be used as described for rubber hose joints.

In evaluating these devices, temperature, pressure, and service conditions must be considered as well as the ability of each device to attenuate vibration and noise. Metal hose connections can accommodate misalignment and attenuate mechanical vibration transmitted through the pipe wall but do little to attenuate noise. This type of connector has superior resistance to long-term temperature effects.

Rubber hose, expansion joints, and spherical connectors attenuate vibration and impeller-generated noise transmitted through the pipe wall. Because the rubber expansion joint and spherical connector walls are flexible, they have the ability to grow volumetrically and attenuate noise and vibration at blade passage frequencies. This feature is particularly desirable for uninsulated piping, such as condenser water and domestic water, which may run adjacent to noise-sensitive areas. However, high pressure has a detrimental effect on the ability of the connector to attenuate vibration and noise.

Because none of the flexible pipe connectors control flow or velocity noise or completely isolate vibration and noise transmission to the piping, resilient pipe hangers and supports should be used; these are shown in Note 25, Table 45 and are described in the Resilient Pipe Hangers and Supports section.

ISOLATING DUCT VIBRATION

Flexible canvas and rubber duct connections should be used at fan intake and discharge. However, they are not completely effective since they become rigid under pressure and allow the vibrating fan to pull on the duct wall. To maintain a slack position of the flexible duct connections, thrust restraints (see note 26, Table 45) should be used on all equipment.

While vibration transmission from ducts isolated by flexible connectors is not a common problem, flow pulsations in the duct can cause vibration in the duct walls, which can be transmitted through rigid hangers. Spring or combination spring and rubber hangers should be used on ducts suspended below or near a noise-sensitive area. These hangers are especially recommended for large ducts with a velocity above 7.5 m/s and for all size ducts when duct static pressure is 500 Pa and over.
SEISMIC PROTECTION

Seismic restraint requirements are specified by applicable building codes that define the design forces to be resisted by the mechanical system, depending on the building location and occupancy, location of the system in the building, and whether it is used for life safety. Where required, seismic protection of resiliently mounted equipment poses a unique problem, because resiliently mounted systems are much more susceptible to earthquake damage due to overturning forces and to resonances inherent in vibration isolators.

As a deficiency in seismic restraint design or anchorage would not become apparent until an earthquake occurs, with possible catastrophic consequences, the adequacy of the restraints and anchorage to resist design forces must be verified before the event. This verification should be either by equipment tests, calculations, or dynamic analysis, depending on the item; with calculations or dynamic analysis performed under the direction of a professional engineer. These items are often supplied as a package by the vibration isolation vendor.

The restraints for floor-mounted equipment should have adequate clearances so that they are not engaged during normal operation of the equipment. Contact surfaces should be protected with resilient pads to limit shock during an earthquake, and restraints should be sufficiently strong to resist forces in any direction. The integrity of these devices can be verified by a comprehensive analysis but is more frequently verified by laboratory tests.

Calculations or dynamic analysis should have an engineer’s seal to verify that input forces are obtained in accordance with code or specification requirements. The anchorage calculations should also be made by a professional engineer in accordance with accepted standards. Chapter 53, Seismic and Wind Restraint Design, has more information on this topic.

VIBRATION INVESTIGATIONS

Theoretically, a vibration isolation system can be selected to isolate vibration forces of extreme magnitude. However, isolators should not be used to mask a condition that should be corrected before it damages the equipment and its operation. High transmitted vibration levels can indicate a faulty equipment operating condition before it damages the equipment and its operation. High transmitted vibration forces of extreme magnitude. However, isolators should not be used to mask a condition that should be corrected before the event is over. Therefore, the need for troubleshooting should be avoided by carefully designing, installing, and testing the system as soon as it is operational and before the building is occupied.

DETERMINING PROBLEM SOURCE

The system or equipment that is the source of the problem can often be determined without instrumentation. Vibrations and noise levels are usually well above the sensory level of perception and are readily felt or heard. A simple and accurate method of determining the problem source is to turn individual pieces of equipment on and off until the vibration or noise is eliminated. Since the source of the problem is often more than one piece of equipment or the interaction of two or more systems, it is good practice to double check by shutting off the system and operating the equipment individually. Reynolds and Bevirt (1994) provides information relative to the measurement and assessment of sound and vibration in buildings.

DETERMINING PROBLEM TYPE

The next step is to determine if the problem is one of noise or vibration.

1. If vibration is perceptible, vibration transmission is usually the major cause of the problem. The possibility that lightweight wall or ceiling panels are excited by airborne noise should be considered. If vibration is not perceptible, the problem may still be one of vibration transmission causing structure-borne noise, which can be checked by following the procedure below.

2. If a sound level meter is available, check C-weighted and overall readings. If the difference is greater than 6 dB, or if the slope of the curve is greater than 5 to 6 dB per octave in the low frequencies, vibration is probably the cause.

3. If the affected area is remote from the source equipment, no problem is apparent in intermediary spaces, and noise does not appear to be coming from the duct system or diffusers, structure-borne noise is the probable cause.

Noise Problems

Noise problems are more complex than vibration problems and usually require the services of an acoustical engineer or consultant. If the affected area adjoins the room where the source equipment is located, structure-borne noise must be considered as part of the problem, and the vibration isolation should be checked. A simple but reasonably effective test is to have one person listen in the affected area while another shouts loudly in the equipment room. If the voice cannot be heard, the problem is likely one of structure-borne noise. If the voice can be heard, check for openings in the wall or floor separating the areas. If no such openings exist, the structure separating the areas does not provide adequate transmission loss. In such situations, refer to the Mechanical Equipment Room Sound Isolation section of this chapter for possible solutions.

If ductborne sound, i.e. noise from grilles or diffusers or duct breakout noise, is the problem, measure the sound pressure levels and compare them with the design goal RC curves. Where the measured curve differs from the design goal RC curve, the potential noise source(s) can be identified. Once the noise sources have been identified, the engineer can determine whether sufficient attenuation has been provided by analyzing each sound source using the procedures presented in this chapter.

If the sound source is a fan, pump, or similar rotating equipment, determine if it is operating at the most efficient part of its operating curve. Excessive vibration and noise can occur if a fan or pump is trying to move too little or too much air or water. In this respect,
check that vanes, dampers, and valves are in the correct operating position and that the system has been properly balanced.

**Vibration Problems**

Vibration and structure-borne noise problems can occur from:

- Equipment operating with excessive levels of vibration, usually caused by unbalance
- Lack of vibration isolators
- Improperly selected or installed vibration isolators that do not provide the required isolator deflection
- Flanking transmission paths such as rigid pipe connections or obstructions under the base of vibration-isolated equipment
- Floor flexibility
- Resonances in equipment, the vibration isolation, or the building structure

Most field-encountered problems are the result of improperly selected or installed isolators and flanking paths of transmission, which can be simply evaluated and corrected. Floor flexibility and resonance problems are sometimes encountered and usually require analysis by experts. However, the information provided below will identify such problems. If the equipment lacks vibration isolators, isolators recommended in Table 43 can be added by using structural brackets without altering connected ducts or piping.

**Testing Vibration Isolation**. Improperly functioning vibration isolation is the cause of most field-encountered problems and can be evaluated and corrected by the following procedures.

1. Ensure that the system is free-floating by bouncing the base, which should cause the equipment to move up and down freely and easily. On floor-mounted equipment, check that there are no obstructions between the base and the floor that would short-circuit the isolation system. This check is best accomplished by passing a rod under the equipment. A small obstruction might permit the base to rock, giving the impression that it is free-floating when it is not. On suspended equipment, make sure that rods are not touching the hanger box. Rigid connections such as pipes and ducts can prevent equipment from floating freely, prohibit isolators from functioning properly, and provide flanking paths for the transmission of vibration.

2. Determine if the isolator deflection is as specified or required, changing it if necessary, as recommended in Table 45. A common problem is inadequate deflection caused by underloaded isolators. Overloaded isolators are not generally a problem as long as the system is free floating and there is space between the spring coils.

With the most spring isolators, determine the spring deflection by measuring the operating height and comparing it to the free height information available from the manufacturer. Once the actual isolator deflection is known, determine its adequacy by comparing it with the recommended deflection in Table 45.

If the natural frequency of the isolator is 25% or less than the disturbing frequency (usually considered the operating speed of the equipment), the isolators should be amply efficient except for heavy equipment installed on extremely long span floors or very flexible floors. If a transmission problem exists, it may be caused by (1) excessively rough equipment operation, (2) the system not being free floating or flanking path transmission, or (3) a resonance or floor stiffness problem, as described below.

While it is easy to determine the natural frequency of spring isolators by height measurements, such measurements are difficult with pad and rubber isolators and are not accurate in determining their natural frequencies. Although such isolators can theoretically provide natural frequencies as low as 4 Hz, they actually provide higher natural frequencies and generally do not provide the desired isolation efficiencies for upper floor equipment locations.

Generally, vibration isolation efficiency cannot be determined in field installations by field vibration measurements. However, vibration measurements can be made on vibrating equipment, on equipment supports, on floors supporting vibration-isolated equipment, and on floors in adjacent areas to determine if vibration criteria specified in Table 43 or in Figures 40 and 41 have been achieved in field installations.

**Floor Flexibility Problems**. Floor flexibility is not a problem with most equipment and structures; however, such problems can occur with heavy equipment installed on long span floors or on thin slabs and with rooftop equipment installed on light structures with open web joist construction. If floor flexibility is suspected, the isolators should be one-tenth or less as stiff as the floor to eliminate the problem. Floor stiffness can be determined by calculating the additional deflection in the floor caused by a specific piece of equipment.

For example, if a 5000 kg piece of equipment causes floor deflection of an additional 2.5 mm, floor stiffness is 19.6 MN/m (2 Gg/m), and an isolator combined stiffness of 1.96 MN/m or less must be used. Note that the floor stiffness or spring rate, not the total floor deflection, is determined. In this example, the total floor deflection might be 25 mm, but if the problem equipment causes 2.5 mm of that deflection, 2.5 mm is the important figure, and floor stiffness k is 19.6 MN/m.

**Resonance Problems**. These problems occur when the operating speed of the equipment is the same as or close to the resonant frequency of (1) an equipment component such as a fan shaft or bearing support pedestal, (2) the vibration isolation, or (3) the resonant frequency of the floor or other building component, such as a wall. Vibration resonances can cause excessive equipment vibration levels, as well as objectionable and possibly destructive vibration transmission in a building. These conditions must always be identified and corrected.

When vibrating mechanical equipment is mounted on vibration isolators on a flexible floor, there are two resonance frequencies that must be considered. The lower frequency is associated with and primarily controlled by the stiffness (and consequently the static deflection) of the vibration isolators. This frequency is generally significantly less than the operating speed (or frequency) of the mechanical equipment and is generally not a problem. The higher resonant frequency is associated with and primarily controlled by the stiffness of the floor. This resonant frequency is usually not affected by increasing or decreasing the static deflection of the mechanical equipment vibration isolators. Sometimes when the floor on which mechanical equipment is located is flexible (occurs with some long-span floors and with roofs supporting rooftop packaged units) the operating speed of the mechanical equipment can coincide with the higher resonant frequency. When this occurs, changing the static deflection of the vibration isolators will not solve the problem.

**Vibration Isolation Resonance**. Always characterized by excessive equipment vibration, vibration isolation resonance usually results in objectionable transmission to the structure. However, transmission might not occur if the equipment is on-grade or on a stiff floor. Vibration isolation resonance can be measured with instrumentation or, more simply, by determining the isolator natural frequency as described in the section Testing Vibration Isolation and comparing this figure to the operating speed of the equipment.

When vibration isolation resonance exists, the isolator natural frequency must be changed using the following guidelines:

1. If the equipment is installed on pad or rubber isolators, isolators with the deflection recommended in Table 45 should be installed.
2. If the equipment is installed on spring isolators and there is objectionable vibration or noise transmission to the structure, determine if the isolator is providing maximum deflection. For
example, an improperly selected or installed nominal 50 mm deflection isolator could be providing only 3 mm deflection, which would be in resonance with equipment operating at 500 rpm. If this is the case, the isolators should be replaced with ones having enough capacity to provide 50 mm deflection. Since there was no transmission problem with the resonant isolators, it is not necessary to use greater deflection isolators than can be conveniently installed.

3. If the equipment is installed on spring isolators and there is objectionable noise or vibration transmission, replace the isolators with spring isolators with the deflection recommended in Table 45.

**Building Resonances.** These problems occur when some part of the structure has a resonant frequency the same as the disturbing frequency or the operating speed of some of the equipment. These problems can exist even if the isolator deflections recommended in Table 45 are used. The resulting objectionable noise or vibration should be evaluated and corrected. Often, the resonant problem is in the floor on which the equipment is installed, but it can also occur in a remotely located floor, wall, or other building component. If a noise or vibration problem has a remote source which cannot be associated with piping or ducts, resonance must be suspected.

Building resonance problems can be resolved by the following:

1. Reduce the vibration force by balancing the equipment. This is not a practical solution for a true resonant problem; however, it is viable when the disturbing frequency equals the floor natural frequency, as evidenced by the equal displacement of the floor and the equipment, especially when the equipment is operating with excessive vibration.

2. Change the isolator resonant frequency by increasing or decreasing the static deflection of the isolator. Only small changes are necessary to “detune” the system. Generally, increasing the deflections is preferred. If the initial deflection is 25 mm, a 50 or 75 mm deflection isolator should be installed. However, if the initial isolator deflection is 100 mm, it may be more practical and economical to replace it with a 75 or 50 mm deflection isolator.

3. Change the structure stiffness or the structure resonant frequency. A change in structure stiffness changes the structure resonant frequency. The greater the stiffness, the higher the resonant frequency. However, the structure resonant frequency can also be changed by increasing or decreasing the floor deflection without changing the floor stiffness. While this approach is not recommended, it may be the only solution in certain cases.

4. Change the disturbing frequency by changing the equipment operating speed. This is practical only for belt-driven equipment, or equipment driven by variable frequency drives.

THIS chapter covers the fundamentals of water treatment and some of the common problems associated with water in heating and air-conditioning equipment.

WATER CHARACTERISTICS

Chemical Characteristics

When rain falls, it dissolves carbon dioxide and oxygen in the atmosphere. The carbon dioxide mixes with the water to form carbonic acid (H$_2$CO$_3$). When carbonic acid contacts soil that contains limestone (CaCO$_3$), it dissolves the calcium to form calcium carbonate. Calcium carbonate in water used in heating or air-conditioning applications can eventually become scale, which can increase energy costs, maintenance time, equipment shutdowns, and could eventually lead to equipment replacement.

The following paragraphs discuss typical chemical and physical properties of water used for HVAC applications.

Alkalinity is a measure of the capacity of a water to neutralize strong acids. In natural waters, the alkalinity almost always consists of bicarbonate, although some carbonate may also be present. Borate, hydroxide, phosphate, and other constituents, if present, are included in the alkalinity measurement in treated waters. Alkalinity also contributes to scale formation.

Alkalinity is measured using two different end-point indicators. The phenolphthalein alkalinity (P alkalinity) measures the strong alkali present; the methyl orange alkalinity (M alkalinity), or total alkalinity, measures all of the alkalinity present in the water. Note that the total alkalinity includes the phenolphthalein alkalinity. For most natural waters, in which the concentration of phosphates, borates, and other noncarbonated alkaline materials is small, the actual chemical species present can be estimated from the two alkalinity measurements (Table 1).

Alkalinity or acidity is often confused with pH. Such confusion may be avoided by keeping in mind that the pH is a measure of hydrogen ion concentration expressed as the logarithm of its reciprocal.

Chlorides have no effect on scale formation but do contribute to corrosion because of their conductivity and because the small size of the chloride ion permits the continuous flow of corrosion current when surface films are porous. The amount of chlorides in the water is a useful measuring tool in evaporative systems. Virtually all other constituents in the water increase or decrease when common treatment chemicals are added or because of chemical changes that take place in normal operation. With few exceptions, only evaporation affects chloride concentration, so the ratio of chlorides in a water sample from an operating system to those of the makeup water provides a measure of how much the water has been concentrated. (Note: Chloride levels will change if the system is continuously chlorinated.)

Dissolved solids consist of salts and other materials that combine with water as a solution. They can affect the formation of corrosion and scale. Low-solids waters are generally corrosive because they have less tendency to deposit protective scale. If a high-solids water is nonscaling, it tends to produce more intensive corrosion because of its high conductivity. Dissolved solids are often referred to as total dissolved solids (TDS).

Conductivity or specific conductance measures the ability of a water to conduct electricity. Conductivity increases with the total dissolved solids. Specific conductance can be used to estimate total dissolved solids.

Silica can form particularly hard-to-remove deposits if allowed to concentrate. Fortunately, silicate deposition is less likely than other deposits.

Soluble iron in water can originate from metal corrosion in water systems or as a contaminant in the makeup water supply. The iron can form heat-insulating deposits by precipitation as iron hydroxide or iron phosphate (if a phosphate-based water treatment product is used or if phosphate is present in the makeup water).

Sulfates also contribute to scale formation in high-calcium waters. Calcium sulfate scale, however, forms only at much higher concentrations than the more common calcium carbonate scale. High sulfates also contribute to increased corrosion because of their high conductivity.

Suspended solids include both organic and inorganic solids suspended in water (particularly unpurified water from surface sources or those that have been circulating in open equipment). Organic matter in surface supplies may be colloidal. Naturally occurring compounds such as lignins and tannins are often colloidal. At high velocities, hard suspended particles can abrade equipment. Settled suspended matter of all types can contribute to concentration cell corrosion.

Turbidity can be interpreted as a lack of clearness or brilliance in a water. It should not be confused with color. A water may be dark in color but still clear and not turbid. Turbidity is due to suspended matter in a finely divided state. Clay, silt, organic matter, microscopic organisms, and similar materials are contributing causes of turbidity. Although suspended matter and turbidity are closely related, they are not synonymous. Suspended matter is the quantity of material in a water that can be removed by filtration. The turbidity of water used in HVAC systems should be as low as possible. This is particularly true of boiler feedwater. The turbidity can concentrate in the boiler and may settle out as sludge or mud and lead to deposition. It can also cause increased boiler blowdown, plugging, overheating, priming, and foaming.

Biological Characteristics

Bacteria, algae, and fungi can be present in water systems, and their growth can cause operating, maintenance, and health problems.
Microorganism growth is affected by temperature, food sources, and water availability. Biological growth can occur in most water systems below 65°C. Problems caused by biological materials range from green algae growth in cooling towers to slime formation from bacteria in secluded and dark areas. The result can be plugging of equipment where flow is essential. Dead algae are often characterized by foul odors and mud-like deposits, which are often high in silica from the cell walls of the diatoms. These problems can be eliminated, or at least reduced to reasonable levels, by mechanical or chemical treatment.

CORROSION CONTROL

Corrosion is the destruction of a metal or alloy by chemical or electrochemical reaction with its environment. In most instances, this reaction is electrochemical in nature, much like that in an electric battery. For corrosion to occur, a corrosion cell consisting of an anode, a cathode, an electrolyte, and an electrical connection must exist. Metal ions dissolve into the electrolyte (water) at the anode. Electrically charged particles (electrons) are left behind. These electrons flow through the metal to other points (cathodes) where electron-consuming reactions occur. The result of this activity is the loss of metal and often the formation of a deposit.

Types of Corrosion

Corrosion can often be characterized as general, localized or pitting, galvanic, caustic cracking, corrosion fatigue, erosion corrosion, and microbiological corrosion.

General corrosion is uniformly distributed over the metal surface. The considerable amount of iron oxide produced by generalized corrosion contributes to fouling.

Localized or pitting corrosion exists when only small areas of the metal corrode. Pitting is the most serious form of corrosion because the action is concentrated in a small area. Pitting may perforate the metal in a short time.

Galvanic corrosion can occur when two different metals are in contact. The more active (less noble) metal corrodes rapidly. Common examples of galvanic corrosion in water systems are steel and brass, aluminum and steel, zinc and steel, and zinc and brass. If galvanic corrosion occurs, the metal named first corrodes.

Corrosion fatigue may occur by one of two mechanisms. In the first mechanism, cyclic stresses (for example, those created by rapid heating and cooling) are concentrated at points where corrosion has roughened or pitted the metal surface. In the second type, cracks often originate where metal surfaces are covered by a dense protective oxide film, and cracking occurs from the action of applied cyclic stresses.

Caustic cracking occurs when metal is stressed, water has a high caustic content, a trace of silica is present, and a mechanism of concentration occurs.

Stress corrosion cracking can occur in alloys exposed to a characteristic corrosive environment and subject to tensile stress. The stress may be either applied, residual (from processing), or a combination. The resulting crack formation is generally intergranular.

Erosion corrosion occurs as a result of flow or impact that physically removes the protective metal oxide surface. This type of corrosion usually takes place due to altered flow patterns or a flow rate that is above design.

Microbiologically influenced corrosion occurs when bacteria secrete corrosive acids on the metal surface. Often bacteria commingle with dirt and silt that protect the bacteria from biocides.

Factors That Contribute to Corrosion

Moisture. Corrosion does not occur in dry environments. However, some moisture is present as water vapor in most environments. In pure oxygen, almost no iron corrosion occurs at relative humidities up to 99%. However, when contaminants such as sulfur dioxide or solid particles of charcoal are present, corrosion can proceed at relative humidities of 50% or more. The corrosion reaction proceeds on surfaces of exposed metals such as iron and unalloyed steel as long as the metal remains wet. Many alloys develop protective corrosion-product films or oxide coatings and are thus unaffected by moisture.

Oxygen. In electrolytes consisting of water solutions of salts or acids, the presence of dissolved oxygen accelerates the corrosion rate of ferrous metals by depolarizing the cathodic areas through reaction with hydrogen generated at the cathode. In many systems, such as boilers or water heaters, most of the dissolved oxygen and other dissolved gases are removed from the water by deaeration to reduce the potential for corrosion.

Solutions. In ferrous materials such as iron and steel, mineral acids accelerate the corrosion rate, whereas alkalies decrease it. The likelihood of cathodic polarization, which slows down corrosion, decreases as the concentration of hydrogen ions (i.e., the acidity of the environment) increases. Relative acidity or alkalinity of a solution is defined as pH; a neutral solution has a pH of 7. The corrosivity of most salt solutions depend on their pH. Because alkaline solutions are generally less corrosive to ferrous systems, it is practical in many closed water systems to minimize corrosion by adding alkali or alkaline salt to raise the pH to 9 or higher.

Differential Solute Concentration. For the corrosion reaction to proceed, a potential difference between anode and cathode areas is required. This potential difference can be established between different locations on a metal surface because of differences in solute concentration in the environment at these locations. Corrosion caused by such conditions is called concentration cell corrosion. These cells can be metal ions or oxygen concentration cells.

In the metal ion cell, the metal surface in contact with the higher concentration of dissolved metal ion becomes the cathodic area, and the surface in contact with the lower concentration becomes the anode. The metal ions involved may be a constituent of the environment or may come from the corroding surface itself. The concentration differences may be caused by the sweeping away of the dissolved metal ions at one location and not at another.

In an oxygen concentration cell, the surface area in contact with the surface environment of higher oxygen concentration becomes the cathodic area, and the surface in contact with the surface environment of lower oxygen concentration becomes the anode. Crevices or foreign deposits on the metal surface can create conditions that contribute to corrosion. The anodic area, where corrosion proceeds, is in the crevice or under the deposit. Although there are manifestations of concentration cell corrosion, crevice corrosion and deposit attack are sometimes referred to as separate forms of corrosion.

Galvanic or Dissimilar Metal Corrosion. Another factor that can accelerate the corrosion process is the difference in potential of dissimilar metals coupled together and immersed in an electrolyte. The following factors control the severity of corrosion resulting from such dissimilar metal coupling:

- Relative differences in position (potential) in the galvanic series, with reference to a standard electrode. The greater the difference, the greater the force of the reaction. The galvanic series for metals in flowing aerated seawater is shown in Table 2.
- Relative area relationship between anode and cathode areas. Because the amount of current flow and, therefore, total metal loss is determined by the potential difference and resistance of the circuits, a small anodic area corrodes more rapidly; it is penetrated at a greater rate than a large anodic area.
- Polarization of either the cathodic or anodic area. Polarization can reduce the potential difference and thus reduce the rate of attack of the anode.
- The mineral content of water. As mineral content increases, the resulting higher electrical conductivity increases the rate of galvanic corrosion.
Temperature can affect the nature of the corrosion protective layer of scale. One example is calcium carbonate scale in water treatment systems. An increase in temperature may increase the corrosion rate, but only to a point. Oxygen solubility decreases as temperature increases and, in an open system, may approach zero as water boils. Beyond a critical temperature level, the corrosion rate may decrease due to a decrease in oxygen solubility. However, in a closed system, where oxygen cannot escape, the corrosion rate may continue to increase with an increase in temperature.

For those alloys, such as stainless steel, that depend on oxygen in the environment for maintaining a protective oxide film, the reduction in oxygen content due to an increase in temperature can accelerate the corrosion rate by preventing oxide film formation.

Temperature can affect corrosion potential by causing a salt dissolving in the environment to precipitate on the metal surface as a protective layer of scale. One example is calcium carbonate scale in hard waters. Temperature can also affect the nature of the corrosion product, which may be relatively stable and protective in certain temperature ranges and unstable and nonprotective in others. An example of this is zinc in distilled water; the corrosion product is nonprotective from 60 to 80°C but reasonably protective at other temperatures.

**Pressure.** Where dissolved gases such as oxygen and carbon dioxide affect the corrosion rate, pressure on the system may increase their solubility and thus increase corrosion. Similarly, a vacuum on the system reduces the solubility of the dissolved gas, thus reducing corrosion. In a heated system, pressure may rise with temperature. It is difficult and impractical to control system corrosion by pressure control alone.

**Flow Velocity.** The effect of flow velocity on the corrosion rate of systems depends on several factors, including

- Amount of oxygen in the water
- Type of metal (iron and steel are most susceptible)
- Flow rate

In metal systems where corrosion products retard corrosion by acting as a physical barrier, high flow velocities may cause the removal of those protective barriers and increase the potential for corrosion. A turbulent environment may cause uneven attack, from both erosion and corrosion. This corrosion is called erosion corrosion. It is commonly found in piping with sharp bends where the flow velocity is high. Copper and softer metals are more susceptible to this type of attack.

**Preventive and Protective Measures**

**Materials Selection.** Any piece of heating or air-conditioning equipment can be made of metals that are virtually corrosion-proof under normal and typical operating conditions. However, economics usually dictate material choices. When selecting construction materials the following factors should be considered:

- Corrosion resistance of the metal in the operating environment
- Corrosion products that may be formed and their effects on equipment operation
- Ease of construction using a particular material
- Design and fabrication limitations on corrosion potential
- Economics of construction, operation, and maintenance during the projected life of the equipment; i.e., expenses may be minimized in the long run by paying more for a corrosion-resistant material and avoiding regular maintenance.
- Use of dissimilar metals should be avoided. Where dissimilar materials are used, insulating gaskets and/or organic coatings must be used to prevent galvanic corrosion.
- Compatibility of chemical additives with materials in the system

**Protective Coatings.** The operating environment has a significant role in the selection of protective coatings. Even with a coating suited for that environment, the protective material depends on the adhesion of the coating to the base material, which itself depends on the surface preparation and application technique.

**Maintenance.** Defects in a coating are difficult to prevent. These defects can be either flaws introduced into the coating during application or mechanical damage sustained after application. In order to maintain corrosion protection, defects must be repaired.

**Cycles of Concentration.** Some corrosion control may be achieved by optimizing the cycles of concentration (the degree to which soluble mineral solids in the makeup water have increased in the circulating water due to evaporation). Generally, adjustment of the blowdown rate and pH to produce a slightly scale-forming condition (see section on Scale Control) will result in an optimum condition between excess corrosion and excess scale.

**Chemical Methods.** Chemical protective film-forming chemical inhibitors reduce or stop corrosion by interfering with the corrosion mechanism. Inhibitors usually affect either the anode or the cathode.
White Rust on Galvanized Steel Cooling Towers

**General**

Mainly Cathodic Corrosion Inhibitors

Anodic Corrosion Inhibitors

- Phosphonate
- Zinc
- Silicate

**Mainly Cathodic Corrosion Inhibitors**

- Bicarbonate
- Polyphosphate
- Zinc
- Polysilicate

**General**

- Soluble oils
- Other organics, such as azole or carboxylate

### Table 3 Typical Corrosion Inhibitors

<table>
<thead>
<tr>
<th>Anodic Corrosion Inhibitors</th>

<th>Nitrite</th>
<th>Orthophosphate</th>
<th>Silicate</th>
</tr>
</thead>
</table>

**Anodic corrosion inhibitors** establish a protective film on the anode. Though these inhibitors can be effective, they can be dangerous—if insufficient anodic inhibitor is present, the entire corrosion potential occurs at the unprotected anode sites. This causes severe localized (or pitting) attack.

**Cathodic corrosion inhibitors** form a protective film on the cathode. These inhibitors reduce the corrosion rate in direct proportion to the reduction of the cathodic area.

**General corrosion inhibitors** protect by forming a film on all metal surfaces whether anodic or cathodic.

Table 3 lists typical corrosion inhibitors. The most important factor in an effective corrosion inhibition program is the consistent control of both the corrosion inhibition chemicals and the key water characteristics. No program will work without controlling these factors.

**Cathodic Protection.** Sacrificial anodes reduce galvanic attack by providing a metal (usually zinc, but sometimes magnesium) that is higher on the galvanic series than either of the two metals that are coupled together. The sacrificial anode thereby becomes anodic to both metals and supplies electrons to these cathodic surfaces. Proper design and placement of these anodes are important. When properly used, they can reduce loss of steel from the tube sheet of exchangers using copper tubes. Sacrificial anodes have helped supplement chemical programs in many cooling water and process exchangers using copper tubes. Sacrificial anodes have helped supplement chemical programs in many cooling water and process systems.

Impressed-current protection is a similar corrosion control technique that reverses the corrosion cell’s normal current flow by impressing a stronger current of opposite polarity. Direct current is applied to an anode—inert (platinum, graphite) or expendable (aluminum, cast iron)—reversing the galvanic flow and converting the steel from a corroding anode to a protective cathode. The method is very effective in protecting essential equipment such as elevated water storage tanks, steel tanks, or softeners.

**White Rust on Galvanized Steel Cooling Towers**

White rust is a zinc corrosion product that forms on galvanized surfaces. It appears as a white, waxy or fluffy deposit composed of loosely adhering zinc carbonate. The loose crystal structure allows rapid corrosion of galvanized steel, as evidenced by white rust, which is highly soluble in the system water to that in the makeup water.

Before chromates in cooling tower water were banned, the common treatment system consisted of chromates for corrosion control and sulfuric acid for scale control. This control method generally has been replaced by alkaline treatment involving scale inhibitors at a higher pH. Alkaline water chemistry is naturally less corrosive to steel and copper, but create an environment where white rust on galvanized steel can occur. Also, some scale prevention programs soften the water to reduce hardness, rather than use acid to reduce alkalinity. The resulting soft water is corrosive to galvanized steel.

**Prevention.** White rust can be prevented by promoting the formation of a nonporous surface layer of basic zinc carbonate. This barrier layer is formed during a process called passivation and normally protects the galvanized steel for many years. Passivation is best accomplished by controlling pH during initial operation of the cooling tower. Control of the cooling water pH in the range of 7 to 8 for 45 to 60 days usually allows passivation of galvanized surfaces to occur. In addition to pH control, operation with moderate hardness levels of 100 to 300 ppm as CaCO₃ and alkalinity levels of 100 to 300 ppm as CaCO₃ will promote passivation. Where pH control is not possible, certain phosphate-based inhibitors may help protect galvanized steel. A water treatment company should be consulted for specific formulations.

**SCALE CONTROL**

Scale is a dense coating of predominantly inorganic material formed from the precipitation of water-soluble constituents. Some common scales are:

- Calcium carbonate
- Calcium phosphate
- Magnesium salts
- Silica

The following principal factors determine whether or not a water is scale forming:

- Temperature
- Alkalinity or acidity (pH)
- Amount of scale-forming material present
- Influence of other dissolved materials, which may or may not be scale-forming

As any of these factors changes, scaling tendencies also change. Most salts become more soluble as temperature increases. However, some salts, such as calcium carbonate, become less soluble as temperature increases. Therefore, they often cause deposits at higher temperatures.

A change in pH or alkalinity can greatly affect scale formation. For example, as pH or alkalinity increases, calcium carbonate—the most common scale constituent in cooling systems—decreases in solubility and deposits on surfaces. Some materials, such as silica (SiO₂), are less soluble at lower alkalinities. When the amount of scale-forming material dissolved in water exceeds its saturation point, scale may result. In addition, other dissolved solids may influence scale-forming tendencies. In general, a higher level of scale-forming dissolved solids results in a greater chance for scale formation. Indices such as the Langier Saturation Index (Langier 1936) and the Ryznar Stability Index (Ryznar 1944) can be useful tools to predict the calcium carbonate scaling tendency of water. These indices are calculated using the pH, alkalinity, calcium hardness, temperature, and total dissolved solids of the water, and indicate whether the water will favor precipitating or dissolving of calcium carbonate.

Methods used to control scale formation include

- Limit the concentration of scale-forming minerals by controlling cycles of concentration or by removing the minerals before they enter the system (see the section on External Treatments later in this section). Cycles of concentration is the ratio of makeup rate to the sum of blowdown and drift rates. The cycles of concentration can be monitored by calculating the ratio of chloride ion, which is highly soluble, in the system water to that in the makeup water.
- Make mechanical changes in the system to reduce the chances for scale formation. Increased water flow and exchangers with larger surface areas are examples.
- Feed acid to keep the common scale forming minerals (such as calcium carbonate) dissolved.
• Treat with chemicals designed to prevent scale. Chemical scale inhibitors work by the following mechanisms:

  1. **Threshold inhibition chemicals** prevent scale formation by keeping the scale forming minerals in solution and not allowing a deposit to form. Threshold inhibitors include organic phosphates, polyphosphates, and polymeric compounds.

  2. **Scale conditioners** modify the crystal structure of scale, creating a bulky, transportable sludge instead of a hard deposit. Scale conditioners include lignins, tannins, and polymeric compounds.

**Nonchemical Methods**

Equipment based on magnetic, electromagnetic, or electrostatic technology has been used for scale control in boiler water, cooling water, and other process applications.

**Magnetic systems** are designed to cause scale-forming minerals to precipitate in a low-temperature area away from heat exchanger surfaces, thus producing nonadherent particles (e.g., aragonite form of calcium carbonate versus the hard, adherent calcite form). The precipitated particles can then be removed by blowdown, mechanical means, or physical flushing. The effectiveness of a magnetic system can be diminished by a low ratio of dissolved calcium to silica, by the presence of excessive iron in the water, or if it is installed in close proximity to high-voltage power lines.

The objective of **electrostatics** is to prevent scale-forming reactions by imposing a surface charge on dissolved ions that causes them to repel.

Results of side-by-side comparative tests with conventional water treatment have been mixed. A Federal Technology Alert report regarding these technologies (DOE 1998) stresses that success of the application depends largely on the experience of the installer. The report includes a discussion of the potential benefits achieved and the necessary precautions to consider when applying these systems.

**External Treatments**

Minerals may also be removed by various external pretreatment methods such as reverse osmosis and ion exchange. Zeolite softening, demineralization, and dealkalization are examples of ion exchange processes.

**BIological GROWTH CONTROL**

Biological growth (algae, bacteria, and fungi) can interfere with a cooling operation due to fouling or corrosion, and may present a health hazard if present in aerosols produced by the equipment. Heating equipment operates above normal biological limits and therefore has fewer microbial problems. When considering biological growth in a cooling system, it is important to distinguish between free-living planktonic organisms and sessile (attached) organisms. Sessile organisms cause the majority of the problems, though they may have entered and multiplied as planktonic organisms.

Biological fouling can be caused by a wide variety of organisms that produce biofilm and slime masses. Slimes can be formed by bacteria, algae, yeasts, or molds and frequently consist of a mixture of these organisms combined with organic and inorganic debris. Organisms such as barnacles and mussels may cause fouling when river, estuarine, or sea water is used. Biological fouling can significantly reduce the efficiency of cooling by reducing heat transfer, increasing back pressure on recirculation pumps, disrupting flow patterns over cooling media, plugging heat exchangers, and blocking distribution systems. In extreme cases the additional mass of slime has caused the cooling media to collapse.

Microorganisms can dramatically enhance, accelerate or, in some cases, initiate localized corrosion (pitting). Microorganisms can influence localized corrosion directly by their metabolism or indirectly by the deposits they form. Indirect influence may not be mediated by simply killing the microorganisms; deposit removal is usually necessary, while direct influence can be substantially mediated by inhibiting microorganism metabolism.

Algae use energy from the sun to convert bicarbonate or carbon dioxide into biomass. Masses of algae can block piping, distribution holes, and nozzles. A distribution deck cover, which drastically reduces the sunlight reaching the algae, is one of the most cost-effective control devices for a cooling tower. Biocides are also used to assist in the control of algae.

Algae can also provide nutrients for other microorganisms in the cooling system, increasing the biomass in the water. Bacteria can grow in systems even when nutrient levels are relatively low. Yeasts and fungi are much slower growing than bacteria and find it difficult to compete in bulk waters for the available food. Fungi do thrive in partially wetted and high humidity areas such as the cooling media. Wood-destroying species of fungi can be a major concern for wooden cooling towers as the fungi consume the cellulose and/or lignin in the wood, reducing its structural integrity.

Most waters contain organisms capable of producing biological slime, but optimal conditions for growth are poorly understood. Equipment near nutrient sources or that has process leaks acting as a food source is particularly susceptible to slime formation. Even a thin layer of biofilm significantly reduces heat transfer rates in exchangers.

**Control Measures**

Eliminating sunlight from wetted surfaces such as distribution troughs, cooling media, and sumps significantly reduces algae growth. Eliminating deadlegs and low flow areas in the piping and the cooling loop reduces biological growth in those areas. Careful selection of materials of construction can remove nutrient sources and environmental niches for growth. Maintaining a high quality makeup water supply with low bacteria counts also helps minimize biological growth. Equipment should also be designed with adequate access for inspection, sampling, and manual cleaning.

Sometimes the effective control of slime and algae requires a combination of mechanical and chemical treatments. For example, when a system already contains a considerable accumulation of slime, a preliminary mechanical cleaning makes the subsequent application of a biocidal chemical more effective in killing the growth and more effective in preventing further growth. A build-up of scale deposits, corrosion product, and sediment in a cooling system also reduces the effectiveness of chemical biocides. Routine manual cleaning of cooling towers, including the use of high level chlorination and a biodispersant (surfactant), helps control Legionella bacteria as well as other microorganisms.

**Microbiocides.** Chemical biocides used to control biological growth in cooling systems fall into two broad categories: oxidizing and nonoxidizing biocides.

**Oxidizing biocides** (chlorine, chlorine-yielding compounds, bromine, bromochlorodimethylhydantoin (BCDMH, or BCD), ozone, iodine, and chlorine dioxide) are among the most effective microbiocidal chemicals. However, they are not always appropriate for control in cooling systems with a high organic loading. In air washers, the odor may become offensive; in wooden cooling towers, excessive concentrations of oxidizing biocides can cause delignification; and overdosing of oxidizing biocides may cause corrosion of metallic components. In systems large enough to justify the cost of equipment to control feeding of oxidizing biocides accurately, the application may be safe and economical. The most effective use of oxidizing biocides is to maintain a constant low level residual in the system. However, if halogen-based oxidizing biocides are fed intermittently (slug dosed), a pH near 7 is advantageous because, at this neutral pH, halogens are present as the hypohalous acid (HOR, where R represents the halogen) form over the hypohalous ion (OR−) form. The effectiveness of this shock feeding is enhanced due to the faster killing action of hypohalous acid over that of hypohalous ion. The residual
biocide concentration should be tested, using a field test kit, on a routine basis. Most halogenation programs can benefit from the use of dispersants or surfactants (chlorine helpers) to break up microbiological masses.

Chlorine has been the oxidizing biocide of choice for many years, either as chlorine gas or in the liquid form as sodium hypochlorite. Other forms of chlorine, such as powders or pellets, are also available. Use of chlorine gas is declining due to the health and safety concerns involved in handling this material and in part due to environmental pressures concerning the formation of chloramines and trihalomethane.

Bromine is produced either by the reaction of sodium hypochlorite with sodium bromide on site, or by release from pellets. Bromine has certain advantages over chlorine: it is less volatile, and bromamines break down more rapidly than chloramines in the environment. Also, when slug feeding bromide in high pH systems, hypobromous acid may have an advantage because its dissociation constant is lower than that of chlorine. This effect is less important when biocides are fed continuously.

Ozone has several advantages compared to chlorine: it does not produce chloramines or trihalomethane, it breaks down to nontoxic compounds rapidly in the environment, it controls biofilm better, and it requires significantly less chemical handling. The use of ozone-generating equipment in an enclosed space however, requires care be taken to protect operators from the toxic gas. Also, research by ASHRAE has shown that ozone is only marginally effective as a scale and corrosion inhibitor (Gan et al. 1996, Nass zadani and Chao 1996).

Water conditions should be reviewed to determine the need for scale and corrosion inhibitors and then, as with all oxidizing biocides, inhibitor chemicals should be carefully selected to ensure compatibility. To maximize the biocidal performance of the ozone, the injection equipment should be designed to provide adequate contact of the ozone with the circulating water. In larger systems, care should be taken to ensure that the ozone is not depleted before the water has circulated through the entire system.

Iodine is provided in pelletized form, often from a rechargeable cartridge. Iodine is a relatively expensive chemical for use on cooling towers and is probably only suitable for use on smaller systems.

Nonoxidizing Biocides. When selecting a nonoxidizing microbiocide, the pH of the circulating water and the chemical compatibility with the corrosion and/or scale inhibitor product must be considered. The following list, while not exhaustive, identifies some of these products:

- Quaternary ammonium compounds
- Methylene bis(thiocyanate) (MBT)
- Isothiazolones
- Thidiazine thioune
- Dithiocarbamates
- Decyl thiouthanamine (DTEA)
- Glutaraldehyde
- Dodecylguanidine
- Benzoic acid
- Tetrakis(hydroxymethyl)phosphonium sulfate (THPS)
- Dibromo-nitriopropionamide (DBNPA)
- Bromo-nitropropane-diol
- Bromo-nitrostyrene (BNS)
- Proprietary blends

The manner in which nonoxidizing biocides are fed is important. Sometimes the continuous feeding of low dosages is neither effective nor economical. Slug feeding large concentrations to achieve a toxic level of the chemical in the water for a sufficient time to kill the organisms present can show better results. Water blowdown rate and biocide hydrolysis (chemical degradation) rate affect the required dosage. The hydrolysis rate of the biocide is affected by the type of biocide, along with the temperature and pH of the system water. Dosage rates are proportional to system volume; dosage concentrations should be sufficient to ensure that the contact time of the biocide is long enough to obtain a high kill rate of microorganisms before the minimum inhibitory concentration of the biocide is reached. The period between nonoxidizing biocide additions should be based on the system half life, with sequential additions timed to prevent regrowth of bacteria in the water.

Handling Microbiocides. All microbiocides must be handled with care to ensure personal safety. In the United States, cooling water microbiocides are approved and regulated through the EPA and, by law, must be handled in accordance with labeled instructions. Maintenance staff handling the biocides should read the material safety data sheets and be provided with all the appropriate safety equipment to handle the substance. Automatic feed systems should be used that minimize and eliminate the handling of biocides by maintenance personnel.

Other Biocides. Ultraviolet irradiation deactivates the microorganisms as the water passes through a quartz tube. The intensity of the light and thorough contact with the water are critical in obtaining a satisfactory kill of microorganisms. Suspended solids in the water or deposits on the quartz tube significantly reduce the effectiveness of this treatment method. Therefore, a filter is often installed upstream of the lamp to minimize these problems. Because the ultraviolet light leaves no residual material in the water, sessile organisms and organisms that do not pass the light source are not affected by the ultraviolet treatment. Ultraviolet irradiation may be effective on humidifiers and air washers where the application of biocidal chemicals is unacceptable and where 100% of the recirculating water passes the lamp. Ultraviolet irradiation is less effective where all the microorganisms cannot be exposed to the treatment, such as in cooling towers. Ultraviolet lamps require replacement after approximately every 8000 h of operation.

Metallic ions, namely copper and silver, effectively control microbial populations under very specific circumstances. Either singularly or in combination, copper and silver ions are released into the water via electrochemical means to generate 1 to 2 ppm of copper and/or 0.5 to 1.0 ppm of silver. The ions assist in the control of bacterial populations in the presence of a free chlorine residual of at least 0.2 ppm. Copper, in particular, effectively controls algae. Liu et. al. (1994) reported control of Legionella pneumophila bacteria in a hospital hot water supply using copper-silver ionization. In this case, Legionella colonization decreased significantly when copper and silver concentrations exceeded 0.4 and 0.04 ppm, respectively. Also, residual disinfection prevented Legionella colonization for two months after the copper-silver unit was inactivated.

Significant limitations exist in the use of copper and silver ion for cooling systems. Many states are restricting the discharge of these ions to surface waters, and if the pH of the system water rises above 7.8, the efficacy of the treatment is significantly reduced. Systems that have steel or aluminum heat exchangers should not be treated by this method, as the potential for the deposition of the copper ion and subsequent galvanic corrosion is significant.

Legionnaires’ Disease

Like other living things, Legionella pneumophila, the bacterium that causes Legionnaires’ disease (legionellosis), requires moisture for survival. Legionella bacteria are widely distributed in natural water systems and are present in many drinking water supplies. Potable hot water systems between 27 and 50°C, cooling towers, certain types of humidifiers, evaporative condensers, whirlpools and spas, and the various components of air conditioners are considered to be amplifiers. These bacteria are killed in a matter of minutes when exposed to temperatures above 60°C.

Legionellosis can be acquired by inhalation of Legionella organisms in aerosols. Aerosols can be produced by cooling towers, evaporative condensers, decorative fountains, showers, and mists. It has been reported that the aerosol from cooling towers
can be transmitted over a distance of up to 3 km. If air inlet ducts of nearby air conditioners draw the aerosol from contaminated cooling towers into the building, the air distribution system itself can transmit the disease. When an outbreak of Legionnaires’ disease occurs, cooling towers are often the suspected source. However, other water systems may produce an aerosol and should not be neglected. Amplification of *Legionella* within protozoans has been demonstrated, and *Legionella* bacteria are thought to be protected from biocides while growing intracellularly. Amplification of *Legionella* bacteria in biofilm and slime masses has been shown by a number of researchers. Microbial control programs should consider the effectiveness of the products against slimes as part of the *Legionella* control program.

**Humidifiers.** Units that generate a water aerosol for humidity control can become amplifiers of bacteria if their reservoirs are poorly maintained. Manufacturers’ recommendations on cleaning and maintenance should be followed closely. Steam humidifiers should not pose a bacterial problem because the steam does not contain bacteria.

**Whirlpools and Spas.** These units pose a potential hazard to users if not properly maintained. The complexity of some units makes cleaning difficult, so a firm that specializes in cleaning these devices may need to be hired. Manufacturers’ instructions should be followed carefully.

**Decorative Fountains.** If these systems become contaminated, *Legionella* may multiply and pose a hazard to those nearby. The recirculating water should be kept clean and clear with proper filtration. Continuous chlorination or use of another biocide with EPA approval for decorative fountains is recommended. Indoor decorative fountains with ponds containing fish and other aquatic life cannot be chlorinated or treated; steps should be taken to ensure that water does not become airborne via sprays or cascading waterfalls.

**Roof Ponds.** These are used to lower the roof temperature and thus the demand on the air conditioning. If contaminated, such ponds can pose a risk to the staff and general public. Roof ponds should be monitored and treated in the same manner as recirculating cooling water systems (see the section on Selection of Water Treatment).

**Safety Showers.** Safety showers are mandated for safety, but they are used infrequently. Standing reservoirs of nonsterile water at room temperature should be avoided. A preventative maintenance program that includes flushing is suggested.

**Vegetable Misters or Sprays.** Although an older-style ultrasonic mist machine has been implicated in at least one case of this disease, once-through cool-water sprayers, (directly connected to a cold, potable water line with no reservoir) do not appear to be a problem.

**Machine Shop Cooling.** Water used in machining operations may be mixed with oil or other ingredients to improve cooling and cutting efficiency. It is typically stored in holding tanks that are subject to bacterial contamination, including by *Legionella*. Bacterial activity should be monitored and controlled.

**Ice-Making Machines.** While *Legionella* bacteria are not likely to amplify in this cold environment, bacterial amplification can occur prior to freezing the water. Graman et al. (1997) described a case in which *Legionella* were presumed to have been transmitted by aspiration of ice or ice water from an ice machine.

**Prevention and Control.** The *Legionella* count required to cause illness has not been firmly established because many factors are involved, including (1) virulence and number of *Legionella* in the air, (2) rate at which the aerosol dries, (3) wind direction, and (4) susceptibility to the disease of the person breathing the air. The organism is often found in sites not associated with an outbreak of the disease. It has been shown that it is feasible to operate cooling systems with *Legionella* bacteria below the limit of detection and that the only method to prove that a system is operating at these levels is to specifically test for *Legionella* bacteria, rather than to infer from total bacteria count measurements.

Periodic monitoring of circulating water for total bacteria count and *Legionella* count can be accomplished using culture methods. However, routine culturing of samples from building water systems may not yield an accurate prediction of the risk of *Legionella* transmission. Monitoring system cleanliness and using a microbial control agent that has proven efficacy or is generally regarded as effective in controlling *Legionella* populations are also important. Other measures to decrease risk include optimizing cooling tower design to minimize drift, eliminating deadlegs or low flow areas, selecting materials that do not promote the growth of *Legionella*, and locating the tower so that drift is not injected into the air handlers. The *Legionellosis Position Statement*, an ASHRAE Position Paper (1998) has further information on this topic.

**SUSPENDED SOLIDS AND DEPOSITION CONTROL**

**Mechanical Filtration**

Strainers, filters, and separators may be used to reduce suspended solids to an acceptable low level. Generally, if the screen is 200 mesh, with an aperture of 74 µm, it is called a strainer; if it is finer than 200 mesh, it is called a filter.

**Strainers.** A strainer is a closed vessel with a cleanable screen designed to remove and retain foreign particles down to 25 µm diameter from various flowing fluids. Strainers extract material that is not wanted in the fluid, and allow saving the extracted product if it is valuable. Strainers are available as single-basket or duplex units, manual or automatic cleaning units, and may be made of cast iron, bronze, stainless steel, copper-nickel alloys, or plastic. Magnetic inserts are available where microscopic iron or steel particles are present in the fluid.

**Cartridge Filters.** These are typically used as final filters to remove nearly all suspended particles from about 100 µm down to 1 µm or less. Cartridge filters are typically disposable (i.e., once plugged, they must be replaced). The frequency of replacement, and thus the economical feasibility of their use, depends on the concentration of suspended solids in the fluid, the size of the smallest particles to be removed, and the removal efficiency of the cartridge filter selected.

In general, cartridge filters are favored in systems where contamination levels are less than 0.01% by mass (< 100 ppm). They are available in many different materials of construction and configurations. Filter media materials include yarns, felts, papers, nonwoven materials, resin-bonded fabric, woven wire cloths, sintered metal, and ceramic structures. The standard configuration is a cylinder with an overall length of approximately 250 mm, an outside diameter of approximately 65 to 70 mm, and an inside diameter of about 25 to 40 mm, where the filtered fluid collects in the perforated internal core. Overall lengths from 0.1 to 1 m are readily available.

Cartridges made of yarns, resin-bonded, or melt-blown fibers normally have a structure that increases in density towards the center. These depth-type filters capture particles throughout the total media thickness. Thin media, such as pleated paper (membrane types), have a narrow pore size distribution design to capture particles at or near the surface of the filter. Surface-type filters can normally handle higher flow rates and provide higher removal efficiency than equivalent depth filters. Cartridge filters are rated according to manufacturers’ guidelines. Surface-type filters have an absolute rating, while depth-type filters have a nominal rating that reflects their general classification function. Higher efficiency meltblown depth filters are available with absolute ratings as needed.

**Sand Filters.** A downflow filter is used to remove suspended solids from a water stream. The degree of suspended solids removal depends on the combinations and grades of the medium being used in the vessel. During the filtration mode, water enters the top of the filter vessel. After passing through a flow impingement plate, it enters the quiescent (calm) freeboard area above the medium.
In multimedia downflow vessels, various grain sizes and types of media are used to filter the water. This design increases the suspended solids holding capacity of the system, which in turn increases the backwashing interval. Multimedia vessels might also be used for low suspended solids applications, where chemical additives are required. In the multimedia vessel, the fluid enters the top layer of anthracite media, which has an effective size of 1 mm. This relatively coarse layer removes the larger suspended particles, a substantial portion of the smaller particles, and small quantities of free oil. Flow continues down through the next layer of fine garnet material, which has an effective size of 0.3 mm. A more finely divided range of suspended solids is removed in this polishing layer. The fluid continues into the final layer, a coarse garnet material that has an effective size of 2 mm. Contained in this layer is the header/lateral assembly that collects the filtered water.

When the vessel has retained enough suspended solids to develop a substantial pressure drop, the unit must be backwashed either manually or automatically by reversing the direction of flow. This operation removes the accumulated solids out through the top of the vessel.

Centrifugal-Gravity Separators. In this type of separator, liquids/solids enter the unit tangentially, which sets up a circular flow. Liquids/solids are drawn through tangential slots and accelerated into the separation chamber. Centrifugal action tosses the particles heavier than the liquid to the perimeter of the separation chamber. Solids gently drop along the perimeter and into the separator’s quiescent collection chamber. Solids-free liquid is drawn into the separator’s vortex (low-pressure area) and up through the separator’s outlet. Solids are either purged periodically or continuously bled from the separator by either a manual or automatic valve system.

Bag Type Filters. These filters are composed of a bag of mesh or felt supported by a removable perforated metal basket, placed in a closed housing with an inlet and outlet. The housing is a welded, tubular pressure vessel with a hinged cover on top for access to the bag and basket. Housings are made of carbon or stainless steel. The inlet can be in the cover, in the side (above the bag), or in the bottom (and internally piped to the bag). The side inlet is the simplest type. In any case, the liquid enters the top of the bag. The outlet is located at the bottom of the side (below the bag). Pipe connections can be threaded or flanged. Single-basket housings can handle up to 14 L/s, multibaskets up to 220 L/s.

The support basket is usually of 304 stainless steel perforated with 3 mm holes. (Heavy wire mesh baskets also exist.) The baskets can be lined with fine wire mesh and used by themselves as strainers, without adding a filter bag. Some manufacturers offer a second, inner basket (and bag) that fits inside the primary basket. This provides for two-stage filtering: first a coarse filtering stage, then a finer one. The benefits are longer service time and possible elimination of a second housing to accomplish the same function.

The filter bags are made of many materials (cotton, nylon, polypropylene, and polyester) with a range of ratings from 0.01 mm to 0.85 mm. Most common are felted materials because of their depth-filtering quality, which provides high dirt-loading capability, and their fine pores. Mesh bags are generally coarser, but are reusable and, therefore, less costly. The bags have a metal ring sewn into their opening; this holds the bag open and seats it on top of the basket rim.

In operation, the liquid enters the bag from above, flows out through the basket, and exits the housing cleaned of particulate down to the desired size. The contaminant is trapped inside the bag, making it easy to remove without spilling any downstream.

Special Methods. Localized areas frequently can be protected by special methods. Thus, pump-packing glands or mechanical shaft seals can be protected from fresh water makeup or by circulating water from the pump casing through a cyclone separator or filter, then into the lubricating chamber.

In smaller equipment, a good dirt-control measure is to install backflush connections and shutoff valves on all condensers and heat exchangers so that accumulated settled dirt can be removed by backflushing with makeup water or detergent solutions. These connections can also be used for acid cleaning to remove calcium carbonate scale.

In specifying filtration systems, third-party testing by a qualified university or private test agency should be requested. The test report documentation should include a description of methods, piping diagrams, performance data, and certification.

Filters described in this section may also be used where industrial process cooling water is involved. For this type of service, consultation with the filtration equipment manufacturer is essential to ensure proper application.

**START-UP AND SHUTDOWN OF COOLING TOWER SYSTEMS**

The following guidelines are for start-up (or recommissioning) and shutdown of cooling tower systems:

**Start-Up and Recommissioning for Drained Systems**

- Clean all debris, such as leaves and dirt from the cooling tower.
- Close building air intakes in the area of the cooling tower to prevent entrainment of biocide and biological aerosols in the building air handling systems.
- Fill the system with water. While operating the condensing water pump(s) and prior to operating the cooling tower fans, execute one of the following two biocidal treatment programs:
  1. Resume treatment with the biocide that had been used prior to shutdown. Use the services of the water treatment supplier. Maintain the maximum recommended biocide residual (for the specific biocide) for a period sufficient to bring the system under good biological control (residual and time varies with the biocide).
  2. Treat the system with sodium hypochlorite at a level of 4 to 5 ppm free chlorine residual at a pH of 7.0 to 7.6. The residual level of free chlorine must be held at 4 to 5 ppm for 6 h. Commercially available test kits can be used to measure the residual of free chlorine.
- Once one of the two biocidal treatment programs has been successfully completed, turn on the fan and put the system in service. The standard water treatment program (including biocidal treatment) should be resumed at this time.

**Start-Up and Recommissioning for Undrained (Stagnant) Systems**

- Remove accessible solid debris from bulk water storage vessel.
- Close building air intakes in the area of the cooling tower to prevent entrainment of biocide and biological aerosols in the building air handlers.
- Perform one of the two biocide pretreatment procedures (described in the section on Start-Up for Drained Systems) directly to the bulk water storage vessel (cooling tower sump, drain-down tank, etc.). Do not circulate stagnant bulk cooling water over cooling tower fill or operate cooling tower fans during pretreatment.
- Stagnant cooling water may be circulated with condenser water pumps if tower fill is bypassed. Otherwise, add approved biocide directly to the bulk water source and mix with manual or side-stream flow methods. Take care to prevent the creation of aerosol spray from the stagnant cooling water from any point in the cooling water system.
- When one of the two biocidal pretreatments has been successfully completed, the cooling water should be circulated over the tower fill. If biocide residual is maintained at a satisfactory level for at least 6 h, the cooling tower fans may then be operated safely.
Water Treatment

Shutdown

When the system is to be shut down for an extended period, the entire system (cooling tower, system piping, heat exchangers, etc.) should be flushed and drained using the following procedure:

- Add a dispersant and biocide to the system and recirculate for 12 to 24 h. Confer with a water treatment consultant for suitable chemicals and dosage levels.
- Shut down pumps and completely drain all water distribution piping and headers, as well as the cooling loop. Remove water and debris from dead heads and low areas in the piping, which may not have completely drained.
- Rinse silt and debris from the sump. Pay special attention to corners and crevices. Add a mild solution of detergent and disinfectant to the sump and rinse. If the sump does not completely drain, pump out the remaining water and residue.
- If the equipment cannot be completely drained and is exposed to cold temperatures, freeze protection may be required.

SELECTION OF WATER TREATMENT

As discussed in the previous sections, many methods are available to prevent or correct water-caused problems. The selection of the proper water treatment method, and the chemicals and equipment necessary to apply that method, depends on many factors. The chemical characteristics of the water, which change with the operation of the equipment, are important. Other factors contributing to the selection of proper water treatment are

- Economics
- Chemistry and cycles of concentration control using a conductivity controller
- Dynamics of the operating system
- Design of major components (e.g., the cooling tower or boiler)
- Number of operators available
- Training and qualifications of personnel
- Preventive maintenance program

Once-Through Systems

Economics is an overriding concern in treating water for once-through systems (in which a very large volume of water passes through the system only once). Protection can be obtained with relatively little treatment per unit mass of water because the water does not change significantly in composition while passing through equipment. However, the quantity of water to be treated is usually large that any treatment other than simple filtration or the addition of a few parts per million of a polyphosphate, silicate, or other inexpensive chemical may not be practical or affordable. Intermittent treatment with polyelectrolytes can help maintain clean conditions when the cooling water is sediment-laden. In such systems, it is generally less expensive to invest more in corrosion-resistant construction materials than to attempt to treat the water.

Open Recirculating Systems

In an open recirculating system with chemical treatment, more chemical must be present because the water composition changes significantly by evaporation. Corrosive and scaling constituents are concentrated. However, treatment chemicals also concentrate by evaporation; therefore, after the initial dosage, only moderate dosages maintain the higher level of treatment needed. The selection of a water treatment program for an open recirculating system depends on the following major factors:

- Economics
- Water quality
- Performance criteria (e.g., corrosion rate, bacteria count, etc.)
- System metallurgy
- Available staffing
- Automation capabilities
- Environmental requirements

- Water treatment supplier (some technologies are superior to others in terms of economics, ease of use, safety, and impact on the environment)

An open recirculating system is typically treated with a scale inhibitor, corrosion inhibitor, oxidizing biocide, nonoxidizing biocide, and possibly a dispersant. The exact treatment program depends on the previously mentioned conditions.

A water treatment control scheme for a cooling tower might include

- Chemistry and cycles of concentration control using a conductivity controller
- Alkalinity control using automatic injection of sulfuric acid based on pH
- Scale control using contacting water meters, proportional feed, or trace control technology
- Oxidizing biocide control using an ORP (oxidation-reduction potential) controller
- Nonoxidizing biocide control using timers and pump systems

Air Washers and Sprayed Coil Units

A water treatment program for an air washer or a sprayed coil unit is usually complex and depends on the purpose and function of the system. Some systems, such as sprayed coils in office buildings, are used primarily to control the temperature and humidity. Other systems are intended to remove dust, oil vapor, and other airborne contaminants from an airstream. Unless the water is properly treated, the fouling characteristics of the contaminants removed from the air can cause operating problems.

Scale control is important in air washers or sprayed coils providing humidification. The minerals in the water may become concentrated (by evaporation) enough to cause problems. Inhibitor/dispersant treatment commonly used in cooling towers are often used in air washers to control scale formation and corrosion.

Suitable dispersants and surfactants are often needed to control oil and dust removed from the airstream. The type of dispersant depends on the nature of the contaminant and the degree of contamination. For maximum operating efficiency, dispersants should produce minimal amounts of foam.

Control of slime and bacterial growth is also necessary in the treatment of air washers and sprayed coils. The potential for biological growth is enhanced, especially if the water contains contaminants that are nutrients for the microorganisms. Due to variations in conditions and applications of air-washing installations and the possibility of toxicity problems, individual treatment options should be discussed with water treatment experts before a program is chosen. All microbiocides applied in air washers must have specific regulatory approval.

Ice Machines

Lime scale formation, cloudy or "milky" ice, objectionable taste and odor, and sediment are the most frequently encountered water problems in ice machines. Lime scale formation is probably the most serious problem because it interferes with the harvest cycle by forming on the freezing surfaces, preventing the smooth release of ice from the surface to the harvest bin.

Scale is caused by dissolved minerals in the water. Water freezes in a pure state and dissolved minerals concentrate in the unfrozen water, and some eventually deposit on the machine’s freezing surfaces as scale. As shown in Table 4, the probability of scale formation in an ice machine varies directly with the concentrations of carbonate and bicarbonate in the water circulating in the machine.

Dirty or scaled-up ice makers should be thoroughly cleaned before the water treatment program is started. Water distributor holes should be cleared, and all loose sediment and other material should be flushed from the system. Existing scale can be removed by circulating an acid solution through the system.
Closed Recirculating Systems

- Silicates
- Molybdate
- Buffered nitrite

System size
- Makeup rate
- Operating conditions
- System metallurgy

In a closed recirculating system, water composition remains fairly constant with very little loss of either water or treatment chemical. Closed systems are often defined as those requiring less than 5% makeup per year. The need for water treatment in such systems (i.e., water heating, chilled water, combined cooling and heat-tems that are converted to secondary water heating during winter and primary low-temperature water heating, both of which usually operate in the range of 60 to 120°C, require sufficient inhibitors to control corrosion to less than 125 µm per year. Ethylene glycol or propylene glycol may be used as antifreeze in secondary hot water systems. Such glycols are available commercially, with inhibitors such as sodium nitrite, potassium phosphate, and organic inhibitors for nonferrous metals added by the manufacturer. These require no further treatment, but softened water should be used for all filling and makeup requirements. Samples should be checked periodically to ensure that the inhibitor has not been depleted. Analytical services are available from the glycol manufacturers and others for this purpose.

Secondary and Low-Temperature. Closed, chilled-water systems that are converted to secondary water heating during winter and primary low-temperature water heating, both of which usually operate in the range of 60 to 120°C, require sufficient inhibitors to control corrosion to less than 125 µm per year. Ethylene glycol or propylene glycol may be used as antifreeze in secondary hot water systems. Such glycols are available commercially, with inhibitors such as sodium nitrite, potassium phosphate, and organic inhibitors for nonferrous metals added by the manufacturer. These require no further treatment, but softened water should be used for all filling and makeup requirements. Samples should be checked periodically to ensure that the inhibitor has not been depleted. Analytical services are available from the glycol manufacturers and others for this purpose.

Environment- and High-Temperature. Environment-temperature water heating systems (120 to 175°C) and high-temperature, high-pressure hot water systems (above 175°C) require careful consideration of treatment for corrosion and deposit control. Makeup water for such systems should be demineralized or softened to prevent scale deposits. For corrosion control, oxygen scavengers such as sodium sulfite can be added to remove dissolved oxygen.

Electrode boilers are sometimes used to supply low- or high-temperature hot water. Such systems use heat generated due to the electrical resistance of the water between electrodes. The conductivity of the recirculating water must be in a specific range depending on the voltage used. Treatment of this type of system for corrosion and deposit control varies. In some cases oil-based corrosion inhibitors that do not contribute to the conductivity of the recirculating water are used.

Brine Systems

Systems containing brine, a strong solution of sodium chloride or calcium chloride, must be treated to control corrosion and deposits. Sodium nitrite at a minimum 3000 ppm in calcium brines or 4000 ppm in sodium brines, and a pH between 7.0 and 8.5 should provide adequate protection. Organic inhibitors are available that may provide adequate protection where nitrites cannot be used. Molybdates should not be used with calcium brines because insoluble calcium molybdate will precipitate.

Boiler Systems

Many treatment methods are available for steam-producing boilers; the method selected depends on

- Makeup water quality
- Makeup water quantity (or percentage condensate return)
- Pretreatment equipment
- Boiler operating conditions
- Steam purity requirements
- Economics

Pretreatment for makeup water could consist of

- Water softeners (for removal of calcium and magnesium hardness)
• Deaerators (for removal of dissolved gases; especially oxygen and carbon dioxide)
• Dealkalizers (to remove alkalinity in systems with high makeup rates and high alkalinity makeup water)
• Demineralizers (to remove almost all the hardness, alkalinity, and solids, depending on the application)
• Reverse osmosis (can remove up to 99% of minerals and dissolved solids from the water leaving almost pure H₂O)

Contaminants that are not removed mechanically by pretreatment equipment must be treated chemically. Once in the feedwater, dissolved gases, hardness, and dissolved minerals must be treated to prevent deposition and corrosion. ASME (1994) and ABMA (1982) have published recommended water chemistry limits for boiler water.

Treatment of the boiler water is often determined by the end use of the steam. Treatment regimens may include reduction of alkalinity; hardness removal; silica removal; oxygen reduction; and the feed of scale and corrosion inhibitors, oxygen scavengers, condensate treatment chemicals, and antifoams. These regimens are described in the following paragraphs.

Prevention of Scale. After the feedwater is pretreated, scale is controlled with phosphates, acrylates, polymers, chelates, and coagulation programs. Chelates, polymers, and acrylates work by binding the hardness, thereby preventing precipitation and scale formation. Phosphates and coagulation programs work in combination with sludge conditioners (tannins, lignins, starches, and synthetic polymers) to produce a softened precipitate that is removed by blowdown of the boiler.

Prevention of Corrosion and Oxygen Pitting. While boilers can corrode as the result of low boiler water pH or misuse of certain chemicals, corrosion is primarily caused by oxygen. After mechanical deaeration, boiler feedwater must be treated chemically. Effective deaeration removes most of the dissolved oxygen. (Most properly operating deaerators can remove oxygen down to 0.007 mg/kg and deaerating heaters can remove oxygen down to 0.04 mg/kg.) Oxygen scavengers such as catalyzed sodium sulfite and proprietary organic oxygen scavengers should then be fed to react with the residual oxygen in feedwater after deaeration. Oxygen scavengers will not only provide added protection to the boiler but to the steam and condensate system as well. Oxygen at levels as low as 0.005 mg/kg can cause oxygen pitting in the steam and condensate system if not chemically reduced by oxygen scavengers.

Most of the corrosion damage to boilers and associated equipment occurs during idle periods. The corrosion is caused by the exposure of wet metal to oxygen in the air or water. For this reason, special precautions must be taken to prevent corrosion while boilers are out of service.

Wet Boiler Lay-Up. This is a method of storing boilers full of water so that they can be returned to service. It involves adding extra chemicals (usually something to increase alkalinity, an oxygen scavenger, and a dispersant) to the boiler water. The water level is raised in the idle boiler to eliminate air spaces, and the boiler is kept completely full of treated water. Superheaters require special protection. Nitrogen gas can also be used on airtight boilers to maintain a positive pressure on the boiler, thereby preventing oxygen in-leakage.

Dry Boiler Lay-Up. This method of lay-up is usually for longer boiler outages. It involves draining, cleaning, and drying the boiler. A material that absorbs moisture, such as hydrated lime or silica gel, is placed in trays inside the boiler. The boiler is then sealed carefully to keep out air. Periodic inspection and replacement of the drying chemical are required during long storage periods.

Steam and Condensate Systems

Two problems associated with steam and condensate systems include general corrosion and pitting corrosion. In order to prevent condensate corrosion, the systems must be protected from acidic conditions, which lead to general corrosion, and oxygen, which leads to pitting corrosion. Protection can be by mechanical or chemical means or a combination of both. The following methods are commonly used for condensate system protection.

Protection from General Corrosion

Mechanical Protection. Reduce alkalinity from boiler feedwater to minimize the amount of carbon dioxide in the system. Carbon dioxide reacts with water (condensate) and forms carbonic acid that will corrode condensate system metal. Alkalinity can be reduced by dealkalization, demineralization, and reverse osmosis. Note: In many cases mechanical reduction of alkalinity is not needed due to low alkalinity makeup water and/or feedwater.

Chemical Protection. Use volatile amines, such as morpholine, diethylamino ethanol (DEAE), and cyclohexylamine, to neutralize carbonic acid and keep the condensate pH between 8.0 and 9.0.

Protection from Oxygen Corrosion

Mechanical Protection. Reduce oxygen from all boiler feedwater to prevent oxygen carryover to the steam and condensate system (via mechanical methods and chemical oxygen scavengers).

Chemical Protection. Feed filmogenic amines, such as octadecylamine, to the steam to form a thin, hydrophobic film on the condensate system surfaces.

Chemical Protection. Feed a volatile oxygen scavenger to the steam to scavenge the oxygen.

The need for chemical treatment can be reduced by designing and maintaining tight return systems so that the condensate is returned to the boiler and less makeup is required in the boiler feedwater. The greater the amount of makeup, the more the system requires increased chemical treatment.

TERMINOLOGY

The following terms are commonly used in the water treatment industry as they pertain to corrosion, scale formation and fouling.

Alkalinity. The sum of bicarbonate, carbonate, and hydroxide ions in water. Other ions, such as borate, phosphate, or silicate, can also contribute to alkalinity.

Anion. A negatively charged ion of an electrolyte that migrates toward the anode influenced by an electric potential gradient.

Anode. The electrode of an electrolytic cell at which oxidation occurs.

Biological deposits. Water-formed deposits of biological organisms or the products of their life processes, such as barnacles, algae, or slimes.

Cathode. The electrode of an electrolytic cell at which reduction occurs.

Cation. A positively charged ion of an electrolyte that migrates toward the cathode influenced by an electric potential gradient.

Corrosion. The deterioration of a material, usually a metal, by reaction with its environment.

Corrosivity. The capacity of an environment or environmental factor to bring about destruction of a specific metal by the process of corrosion.

Electrolyte. A solution through which an electric current can flow.

Filtration. Process of passing a liquid through a porous material in such a manner as to remove suspended matter from the liquid.

Galvanic corrosion. Corrosion resulting from the contact of two dissimilar metals in an electrolyte or from the contact of two similar metals in an electrolyte of nonuniform concentration.

Hardness. The sum of the calcium and magnesium ions in water; usually expressed in ppm as CaCO₃.

Inhibitor. A chemical substance that reduces the rate of corrosion, scale formation, fouling, or slime production.

Ion. An electrically charged atom or group of atoms.
Passivity. The tendency of a metal to become inactive in a given environment.

pH. The logarithm of the reciprocal of the hydrogen ion concentration of a solution. pH values below 7 are increasingly acidic; those above 7 are increasingly alkaline.

Polarization. The deviation from the open circuit potential of an electrode resulting from the passage of current.

ppm. Parts per million by mass. In water, ppm are essentially the same as milligrams per liter (mg/L); 10,000 ppm (mg/L) = 1%.

Scale. 1. The formation at high temperature of thick corrosion product layers on a metal surface. 2. The precipitation of water-insoluble constituents on a surface.

Sludge. A sedimentary water-formed deposit, either of biological origin or suspended particles from the air.

Tuberculation. The formation over a surface of scattered, knob-like mounds of localized corrosion products.

Water-formed deposit. Any accumulation of insoluble material derived from water or formed by the reaction with water on surfaces in contact with it.

### SERVICE WATER HEATING

| System Planning | 48.1 |
| Water Heating Equipment | 48.1 |
| Distribution | 48.3 |
| Terminal Hot Water Usage Devices | 48.6 |
| Water Heating Terminology | 48.6 |
| Design Considerations | 48.7 |
| Water Quality, Scale, and Corrosion | 48.7 |
| Safety Devices for Hot Water Supplies | 48.8 |
| Special Concerns | 48.8 |

A SERVICE water heating system has (1) a heat energy source, (2) heat transfer equipment, (3) a distribution system, and (4) terminal hot water usage devices.

**Heat energy sources** may be (1) fuel combustion, (2) electrical conversion, (3) solar energy, and/or (4) recovered waste heat from such sources as flue gases, ventilation and air-conditioning systems, refrigeration cycles, and process waste discharge.

**Heat transfer equipment** is either of the direct or indirect type. For direct equipment, heat is derived from combustion of fuel or direct conversion of electrical energy into heat and is applied within the water heating equipment. For indirect heat transfer equipment, heat energy is developed from remote heat sources, such as boilers, solar energy collection, cogeneration, refrigeration, or waste heat, and is then transferred to the water in a separate piece of equipment. Storage tanks may be part of or associated with either type of heat transfer equipment.

**Distribution systems** transport the hot water produced by the water heating equipment to terminal hot water usage devices. The water consumed must be replenished from the building water service main. For locations where constant supply temperatures are desired, circulation piping or a means of heat maintenance must be provided.

**Terminal hot water usage devices** are plumbing fixtures and equipment requiring hot water that may have periods of irregular flow, constant flow, and no flow. These patterns and their related water usage vary with different buildings, process applications, and personal preference.

In this chapter, it is assumed that an adequate supply of service water is available. If this is not the case, alternate strategies such as water accumulation, pressure control, and flow restoration should be considered.

### SYSTEM PLANNING

Flow rate and temperature are the primary factors to be determined in the hydraulic and thermal design of a water heating and piping system. Operating pressures, time of delivery, and water quality are also factors to consider. Separate procedures are used to select water heating equipment and to design the piping system.

Water heating equipment, storage facilities, and piping should (1) have sufficient capacity to provide the required hot water while minimizing the waste of energy or water and (2) allow economical system installation, maintenance, and operation.

Water heating equipment types and designs are based on (1) the energy source, (2) the application of the developed energy to heating the water, and (3) the control method used to deliver the necessary hot water at the required temperature under varying water demand conditions. Application of water heating equipment within the overall design of the hot water system is based on (1) location of the equipment within the system, (2) related temperature requirements, and (3) the volume of water to be used.

### ENERGY SOURCES

The choice among available energy sources is interrelated with the choices among equipment types and locations. These decisions should be made only after evaluating purchase, installation, operating, and maintenance costs. A life-cycle analysis is highly recommended.

In making energy conservation choices, current editions of the following energy conservation guides should be consulted: the ANSI/ASHRAE/IES Standard 90 series or the sections on Service Water Heating of ANSI/ASHRAE/IESNA Standard 100 (see also the section on Design Considerations in this chapter).

### WATER HEATING EQUIPMENT

#### Gas-Fired or Oil-Fired

Residential water heating equipment is usually the automatic storage type. For industrial and commercial applications, commonly used types of heaters are (1) automatic storage, (2) circulating tank, (3) instantaneous, and (4) hot water supply boilers.

Installation guidelines for gas-fired water heaters can be found in the National Fuel Gas Code, NFPA Standard 54 (ANSI Z223.1). This code also covers the sizing and installation of venting equipment and controls. Installation guidelines for oil-fired water heaters can be found in NFPA Standard 31, Installation of Oil-Burning Equipment (ANSI Z95.1).

Automatic storage water heaters incorporate the burner(s), storage tank, outer jacket, insulation, and controls in a single unit. Circulating tank water heaters are classified in two types: (1) automatic, in which the thermostat is located in the water heater, and (2) nonautomatic, in which the thermostat is located within an associated storage tank.

Automatic instantaneous water heaters are produced in two distinctly different types. Tank-type instantaneous heaters have an input-to-storage capacity ratio of 4.4 kW per litre or more and a thermostat to control energy input to the heater. Water-tube type instantaneous heaters have minimal water storage capacity. They usually have a flow switch that controls the burner. They may have a modulating fuel valve that varies fuel flow as water flow changes.

Hot water supply boilers are capable of providing service hot water. They are typically installed with separate storage tanks and applied as an alternative to circulating tank water heaters.

Direct vent models are available in nearly all types of water heating equipment. They are to be install indoors, but are not vented...
via a conventional chimney or gas vent, nor do they use ambient air for combustion. They must be installed with the means for venting (typically horizontal) and the means for supplying combustion air from outside the building that is supplied or specified by the equipment manufacturer.

**Electric**

Electric water heaters are generally of the automatic storage type, consisting of a tank with one or more immersion heating elements. The heating elements consist of resistance wire embedded in refractories having good heat conduction properties and electrical insulating values. Heating elements are fitted into a threaded or flanged mounting for insertion into a tank. Thermostats controlling heating elements may be of the immersion or surface-mounted type.

**Residential storage tank water heaters** range up to 450 L with input up to 12 kW. They have a primary resistance heating element near the bottom and often a secondary element located in the upper portion of the tank. Each element is controlled by its own thermostat. In dual element heaters, the thermostats are usually interlocked so that the lower heating element cannot operate if the top element is operating. Thus, only one heating element operates at a time to limit the current draw.

**Commercial storage tank water heaters** are available in many combinations of element quantity, wattage, voltage, and storage capacity. Storage tanks may be horizontal or vertical. Compact, low-volume models are used in point-of-use applications to reduce hot water piping length. Location of the water heater near the point of use makes recirculation loops unnecessary.

**Instantaneous electric water heaters** are sometimes used in lavatory, hot tub, whirlpool bath, and swimming pool applications. The smaller sizes are commonly used as boosters for dishwasher final rinse applications.

**Heat pump water heaters (HPWHs)** use a vapor-compression refrigeration cycle to extract energy from an air or water source to heat water. Most HPWHs are air-to-water units. As the HPWH collects heat, it provides a potentially useful cooling effect and dehumidifies the air. HPWHs typically have a maximum output temperature of 60°C. Where a higher delivery temperature is required, a conventional storage-type or booster water heater downstream of the heat pump storage tank should be used. HPWH functions most efficiently where the inlet water temperature is low and the entering air is warm and humid. Systems should be sized to allow high HPWH run time. The effect of HPWH cooling output on the building’s energy balance should be considered. Cooling output should be directed to provide occupant comfort and avoid interfering with temperature-sensitive equipment (EPRI 1990).

**Demand controlled water heating** can significantly reduce the cost of heating water electrically. Demand controllers operate on the principle that a building’s peak electrical demand exists for a short period, during which heated water can be supplied from storage rather than hot water recovery. Shifting the use of electricity for service water heating from peak demand periods allows water heating at the lowest electric energy cost in many electric rate schedules. The building electrical load must be detected and compared with peak demand data. When the load is below peak demand, the control device allows the water heater to operate. Some controllers can program deferred loads in steps as capacity is available. The priority sequence may involve each of several tanks of elements in (1) a water heater, (2) multiple water heaters, or (3) water heating and other equipment having a deferrable load, such as pool heating and snow melting. When load controllers are used, hot water storage must be used.

**Instantaneous and hot water supply boilers** as described in the section on Gas-Fired or Oil-Fired water heating equipment are also available with electric heating elements.

**Electric off-peak storage water heating** is a water heating equipment load management strategy whereby electrical demand to a water heating system is time-controlled, primarily in relation to the building or utility electrical load profile. This approach may require an increase in tank storage capacity and/or stored water temperature to accommodate water use during peak periods.

Sizing recommendations in this chapter apply only to water heating without demand or off-peak control. When demand control devices are used, the storage and recovery rate may need to be increased to supply all the hot water needed during the peak period and during the ensuing recovery period. Manian and Chackeris (1974) include a detailed discussion on load-restricted, storage system design.

**Indirect**

In indirect water heating, the heating medium is steam, hot water, or another fluid that has been heated in a separate generator or boiler. The water heater extracts heat through an external or internal heat exchanger.

When the heating medium is at a higher pressure than the service water, the service water may be contaminated by leakage of the heating medium through a damaged heat transfer surface. In the United States, some national, state, and local codes require double-wall, vented tubing in indirect water heaters to reduce the possibility of cross-contamination. When the heating medium is at a lower pressure than the service water, other jurisdictions allow single-wall tubing heaters because any leak would be into the heating medium.

If the heating medium is steam, high rates of condensation occur, particularly when a sudden demand causes an inflow of cold water. The steam pipe and condensate return pipes should be of ample size. Condensate should drain by gravity, without lifts, to a vented condensate receiver located below the level of the heater. Otherwise, water hammer, reduced capacity, or heater damage may result. The condensate may be cooled by preheating the cold water supply to the heater.

Corrosion is minimized on the heating medium side of the heat exchanger because no makeup water, and hence no oxygen, is brought into that system. The metal temperature of the service water side of the heat exchanger is usually less than that in direct-fired water heaters. This minimizes scale formation from hard water.

**Storage water heaters** are designed for service conditions where hot water requirements are not constant, i.e., where a large volume of heated water is held in storage for periods of peak load. The amount of storage required depends on the nature of the load and the recovery capacity of the water heater. An individual tank or several tanks joined by a manifold may be used to provide the required storage.

**External storage water heaters** are designed for connection to a separate tank. The boiler water circulates through the heater shell, while service water from the storage tank circulates through the tubes and back to the tank. Circulating pumps are usually installed in both the boiler water piping circuit and the circuits.
Service Water Heating

between the heat exchanger and the storage tank. Steam can also be used as the heating medium in a similar scheme.

**Instantaneous indirect water heaters (tankless coils)** are best used for a steady, continuous supply of hot water. In these units, the water is heated as it flows through the tubes. Because the heating medium flows through a shell, the ratio of hot water volume to heating medium volume is small. As a result, variable flow of the service water causes uncertain temperature control unless a thermostatic mixing valve is used to maintain the hot water supply to the plumbing fixtures at a more uniform temperature.

Some indirect instantaneous water heaters are located inside a boiler. The boiler is provided with a special opening through which the coil can be inserted. While the coil can be placed in the steam space above the water line of a steam boiler, it is usually placed below the water line. The water heater transfers heat from the boiler water to the service water. The gross output of the boiler must be sufficient to serve all loads.

**Semi-Instantaneous**

These water heaters have limited storage to meet the average momentary surges of hot water demand. They usually consist of a heating element and control assembly devised for close control of the temperature of the leaving hot water.

**Circulating Tank**

These water heaters are instantaneous or semi-instantaneous types used with a separate storage tank and a circulating pump. The storage acts as a flywheel to accommodate variations in the demand for hot water.

**Blending Injection**

These water heaters inject steam or hot water directly into the process or volume of water to be heated. This is often associated with point-of-use applications, e.g., certain types of commercial laundry, food, and process equipment. **Caution:** Cross-contamination of potable water is possible.

**Solar**

The availability of solar energy at the building site, the efficiency and cost of solar collectors, and the availability and cost of other fuels determine whether solar energy collection units should be used as a primary heat energy source. Solar energy equipment can also be included to supplement other energy sources and conserve fuel or electrical energy.

The basic elements of a solar water heater include solar collectors, a storage tank, piping, controls, and a transfer medium. The system may use natural convection or forced circulation. Auxiliary heat energy sources may be added, if needed.

Collector design must allow operation in below-freezing conditions, where applicable. Antifreeze solutions in a separate collector piping circuit arrangement are often used, as are systems that allow water to drain back to heated areas when low temperatures occur. Uniform flow distribution in the collector or bank of collectors and stratification in the storage tank are important for good system performance.

The application of solar water heaters depends on (1) auxiliary energy requirements; (2) collector orientation; (3) temperature of the cold water; (4) general site, climatic, and solar conditions; (5) installation requirements; (6) area of collectors; and (7) amount of storage. **Chapter 32** Solar Energy Use, has more detailed design information.

**Waste Heat Use**

Waste heat recovery can reduce energy cost and the energy requirement of the building heating and service water heating equipment. Waste heat can be recovered from equipment or processes by using appropriate heat exchangers in the hot gaseous or liquid streams. Heat recovered is frequently used to preheat the water entering the service water heater. Refrigeration heat reclaim uses refrigerant-to-water heat exchangers connected to the refrigeration circuit between the compressor and condenser of a host refrigeration or air-conditioning system to extract heat. Water is heated only when the host is operating at the same time there is a call for water heating. A conventional water heater is typically required to augment the output of the heat reclaim and to provide hot water during periods when the host system is not in operation.

**Refrigeration Heat Reclaim**

These systems heat water with heat that would otherwise be rejected through a refrigeration condenser. Because many simple systems reclaim only superheat energy from the refrigerant, they are often called desuperheaters. However, some units are also designed to provide partial or full condensing. The refrigeration heat reclaim heat exchanger is generally of vented, double-wall construction to isolate potable water from refrigerant. Some heat reclaim devices are designed for use with multiple refrigerant circuits. Controls are required to limit high water temperature, prevent low condenser pressure, and provide for freeze protection. Refrigeration systems with higher run time and lower efficiency provide more heat reclaim potential. Most systems are designed with a preheat water storage tank connected in series with a conventional water heater (EPRI 1992). In all installations, care must be taken to prevent the inappropriate venting of refrigerants.

**Combination Heating**

A combo system is an integrated appliance that provides both space heating and domestic hot water. A space heating coil and a space cooling coil are often included with the air handler to provide year-round comfort. Combo systems also can use other types of heat exchangers for space heating, such as baseboard convectors or floor heating coils. A method of testing combo systems is contained in the ASHRAE Standard 124. The test procedures allow the calculation of a Combined Annual Efficiency (CAE), as well as space-heating and water-heating efficiency factors. Subherwal (1986), Pietsch and Talbert (1989), Talbert et al. (1992), Kweller (1992), and Pietsch et al. (1994) provide additional design information on these heaters.

**DISTRIBUTION**

**Piping Material**

Traditional piping materials have included galvanized steel used with galvanized cast iron or galvanized malleable iron screwed fittings. Copper piping and copper tube types K, L, or M have been used with brass, bronze, or wrought copper solder fittings. Legislation or plumbing code changes have banned the use of lead in solder or pipe-jointing compounds in potable water piping because of possible lead contamination of the water supply. See the current ASHRAE Standard 90 series for pipe insulation requirements.

Today, most potable water supplies require treatment before distribution; this may cause the water to become more corrosive. Therefore, depending on the water supply, traditional galvanized steel piping or copper tube may no longer be satisfactory, due to accelerated corrosion. Galvanized steel piping is particularly susceptible to corrosion (1) when hot water is between 60 and 80°C and (2) where repairs have been made using copper tube without a non-metallic coupling.

Before selecting any water piping material or system, consult the local code authority. The local water supply authority should also be consulted about any history of water aggressiveness causing failures of any particular material.

Alternate piping materials that may be considered are (1) stainless steel tube and (2) various plastic piping and tubes. Particular...
Pipe Sizing

Sizing of hot water supply pipes involves the same principles as sizing of cold water supply pipes (see chapter 33 of the 1997 ASHRAE Handbook—Fundamentals). The water distribution system must be correctly sized for the total hot water system to function properly. Hot water demand varies with the type of establishment, usage, occupancy, and time of day. The piping system should be capable of meeting peak demand at an acceptable pressure loss.

Supply Piping

Table 1, Figures 23 and 24 and manufacturers’ specifications for fixtures and appliances can be used to determine hot water demands. These demands, together with procedures given in chapter 33 of the 1997 ASHRAE Handbook—Fundamentals, are used to size the mains, branches, and risers.

Allowance for pressure drop through the heater should not be overlooked when sizing hot water distribution systems, particularly where instantaneous water heaters are used and where the available pressure is low.

Pressure Differential

Sizing of both cold and hot water piping requires that the pressure differential at the point of use of blended hot and cold water be kept to a minimum. This required minimum differential is particularly important for tubs and showers, since sudden changes in flow at fixtures cause discomfort and a possible scalding hazard. Pressure-compensating devices are available.

Return Piping

Return piping is commonly provided for hot water supply supplies in which it is desirable to have hot water available continuously at the fixtures. This includes cases where the hot water piping exceeds 30 m.

The water circulation pump may be controlled by a thermostat (in the return line) set to start and stop the pump over an acceptable temperature range. This thermostat can significantly reduce both heat loss and pumping energy in some applications. An automatic time switch or other control should turn the water circulation off when hot water is not required. Because hot water is corrosive, circulating pumps should be made of corrosion-resistant material.

For small installations, a simplified pump sizing method is to allow 3 mL/s for every fixture unit in the system, or to allow 30 mL/s for each 20 or 25 mm riser; 60 mL/s for each 32 or 40 mm riser; and 130 mL/s for each riser 55 mm or larger.

Werden and Spielvogel (1969) and Dunn et al. (1959) cover heat loss calculations for large systems. For larger installations, piping heat losses become significant. A quick method to size the pump and return for larger systems is as follows:

1. Determine the total length of all hot water supply and return piping.
2. Choose an appropriate value for piping heat loss from Table 2 or other engineering data (usually supplied by insulation companies, etc.). Multiply this value by the total length of piping involved.

Table 2 Heat Loss of Pipe at 60°C Inlet, 21°C Ambient

A rough estimation can be made by multiplying the total length of covered pipe by 30 W/m or uninsulated pipe by 60 W/m. Table 2 gives actual heat losses in pipes at a service water temperature of 60°C and ambient temperature of 21°C. The values of 30 or 60 W/m are only recommended for ease in calculation.

3. Determine pump capacity as follows:

\[
Q_p = \frac{q}{\rho c_p \Delta t}
\]

where

\[
Q_p = \text{pump capacity, L/s}
\]

\[
q = \text{heat loss, W}
\]

\[
\rho = \text{density of water} = 0.99 \text{ kg/L (50°C)}
\]

\[
c_p = \text{specific heat of water} = 4180 \text{ J/(kg·k)}
\]

\[
\Delta t = \text{allowable temperature drop, K}
\]

For a 10 K allowable temperature drop,

\[
Q_p(\text{L/s}) = \frac{q}{0.99 \times 4180 \times 10} = \frac{q}{41400} \quad (2)
\]

Caution: This calculation assumes that a 10 K temperature drop is acceptable at the last fixture.

4. Select a pump to provide the required flow rate, and obtain from the pump curves the pressure created at this flow.
5. Check that the pressure does not exceed the allowable friction loss per metre of pipe.
6. Determine the required flow in each circulating loop, and size the hot water return pipe based on this flow and the allowable friction loss.

Where multiple risers or horizontal loops are used, balancing valves with means of testing are recommended in the return lines. A swing-type check valve should be placed in each return to prevent entry of cold water or reversal of flow, particularly during periods of high hot water demand.

Three common methods of arranging circulation lines are shown in Figure 2. Although the diagrams apply to multistory buildings, arrangements (A) and (B) are also used in residential designs. In circulation systems, air venting, pressure drops through the heaters and storage tanks, balancing, and line losses should be considered. In Figures 2A and 2B, air is vented by connecting the circulating line below the top fixture supply. With this arrangement, air is eliminated from the system each time the top fixture is opened. Generally, for small installations, a NPS 15 or 20 mm hot water return is ample.

All storage tanks and piping on recirculating systems should be insulated as recommended by the ASHRAE Standard 90 series and Standard 100.

Heat Traced, Nonreturn Piping

In this system, the fixtures can be as remote as in the return piping. The hot water supply piping is heat traced with electric resistance heating cable preinstalled under the pipe insulation. Electrical energy input is self-regulated by the cable’s construction to maintain the required water temperature at the fixtures. No return piping system or circulation pump is required.

Special Piping—Commercial Dishwashers

An adequate flow rate and pressure must be maintained for automatic dishwashers in commercial kitchens. To reduce operating difficulties, piping for automatic dishwashers should be installed according to the following recommendations:

1. The cold water feed line to the water heater should be no smaller than NPS 25.
2. The supply line that carries 82°C water from the water heater to the dishwasher should not be smaller than NPS 20.
3. No auxiliary feed lines should connect to the 82°C supply line.
4. A return line should be installed if the source of 82°C water is more than 1.5 m from the dishwasher.
5. Forced circulation by a pump should be used if the water heater is installed on the same level as the dishwasher, if the length of return piping is more than 18 m, or if the water lines are trapped.

6. If a circulating pump is used, it is generally installed in the return line. It may be controlled by (a) the dishwasher wash switch, (b) a manual switch located near the dishwasher, or (c) an immersion or strap-on thermostat located in the return line.
7. A pressure-reducing valve should be installed in the low-temperature supply line to a booster water heater, but external to a recirculating loop. It should be adjusted, with the water flowing, to the value stated by the washer manufacturer (typically 140 kPa).
8. A check valve should be installed in the return circulating line.
9. If a check valve type of water meter or a backflow prevention device is installed in the cold water line ahead of the heater, it is necessary to install a properly sized diaphragm-type expansion tank between the water meter or prevention device and the heater.
10. National Sanitation Foundation (NSF) standards require the installation of a NPS 8 IPS connection for a pressure gage mounted adjacent to the supply side of the control valve. They also require a water line strainer ahead of any electrically operated control valve.
11. NSF standards do not allow copper water lines that are not under constant pressure, except for the line downstream of the solenoid valve on the rinse line to the cabinet.

Water Pressure—Commercial Kitchens

Proper flow pressure must be maintained to achieve efficient dishwashing. NSF standards for dishwasher water flow pressure are 100 kPa (gage) minimum, 170 kPa (gage) maximum, and 140 kPa (gage) ideal. Flow pressure is the line pressure measured when water is flowing through the rinse arms of the dishwasher.

Low flow pressure can be caused by undersized water piping, stoppage in piping, or excess pressure drop through heaters. Low water pressure causes an inadequate rinse, resulting in poor drying and sanitizing of the dishes. If flow pressure in the supply line to the dishwasher is below 100 kPa (gage), a booster pump or other means should be installed to provide supply water at 140 kPa (gage).

A flow pressure in excess of 170 kPa (gage) causes atomization of the 82°C rinse water, resulting in an excessive temperature drop. The temperature drop between the rinse nozzle and the dishes can be as much as 8 K. A pressure regulator should be installed in the supply water line adjacent to the dishwasher and external to the return circulating loop (if used). The regulator should be set to maintain a pressure of 140 kPa (gage).
Two-Temperature Service

Where multiple temperature requirements are met by a single system, the system temperature is determined by the maximum temperature needed. Where the bulk of the hot water is needed at the higher temperature, lower temperatures can be obtained by mixing hot and cold water. Automatic mixing valves reduce the temperature of the hot water available at certain outlets to prevent injury or damage. Applicable codes should be consulted for mixing valve requirements.

For mixing valve requirements.

Where predominant use is at a lower temperature, the common design heats all water to the lower temperature and then uses a separate booster heater to further heat the water for the higher temperature service. This method offers better protection against scalding.

![Fig. 4 Two-Temperature Service with Mixing Valve](image1)

![Fig. 5 Two-Temperature Service with Primary Heater and Booster Heater in Series](image2)

![Fig. 6 Two-Temperature Service with Separate Heater for Each Service](image3)

A third method uses separate heaters for the higher temperature service. It is common practice to cross-connect the two heaters, so that one heater can serve the complete installation temporarily while the other is valved off for maintenance. Each heater should be sized for the total load unless hot water consumption can be reduced during maintenance periods.

Manifolding

Where one heater does not have sufficient capacity, two or more water heaters may be installed in parallel. If blending is needed in such an installation, a single mixing valve of adequate capacity should be used. It is difficult to obtain even flow through parallel mixing valves.

Heaters installed in parallel should have similar specifications, i.e., have the same input and storage capacity, with inlet and outlet piping arranged so that an equal flow is received from each heater under all demand conditions.

An easy way to get balanced, parallel flow is to use reverse/return piping. The unit having its inlet closest to the cold water supply is piped so that its outlet will be farthest from the hot water supply line. Quite often this results in a hot water supply line that reverses direction (see dotted line) to bring it back to the first unit in line; hence the name reverse/return.

TERMINAL HOT WATER USAGE DEVICES

Details on the vast number of devices using service hot water are beyond the scope of this chapter. Nonetheless, they are important to a successful overall design. Consult the manufacturer’s literature for information on required flow rates, temperature limits, and/or other operating factors for specific items.

WATER HEATING TERMINOLOGY

The following terms apply to water heaters and water heating:

- **Recovery efficiency.** Heat absorbed by the water divided by the heat input to the heating unit during the period that water temperature is raised from inlet temperature to final temperature.
- **Recovery rate.** The amount of hot water that a residential water heater can continually produce, usually reported as flow rate in litres per hour that can be maintained for a specified temperature rise through the water heater.
- **Thermal efficiency.** Heat in the water flowing from the heater outlet divided by the heat input of the heating unit over a specific period of steady-state conditions.
- **Energy factor.** Is the delivered efficiency of a water heater when operated as specified in DOE test procedures (10 CFR Part 430).
- **First hour rating.** An indicator of the amount of hot water a residential water heater can supply. This rating is used by the Federal Trade Commission (FTC) for comparative purposes.
- **Standby loss.** As applied to a tank type water heater (under test conditions with no water flow), the average hourly energy consumption divided by the average hourly heat energy contained in the stored water, expressed as a percent per hour. This can be converted to the average watts energy consumption required to maintain any water-air temperature difference by multiplying the percent by the temperature difference, $1.15 \text{ kW·h/(m}^2\text{ K)}$ (a nominal specific heat for water), the tank capacity, and then dividing by 100.
- **Hot water distribution efficiency.** Heat contained in the water at points of use divided by the heat delivered at the heater outlet at a given flow.
- **Heater/system efficiency.** Heat contained in the water at points of use divided by the heat input to the heating unit at a given flow rate (thermal efficiency times distribution efficiency).
- **Overall system efficiency.** Heat energy in the water delivered at points of use divided by the total energy supplied to the heater for any selected period.
Service Water Heating

**System standby loss.** The amount of heat lost from the water heating system and the auxiliary power consumed during periods of nonuse of service hot water.

**DESIGN CONSIDERATIONS**
Hot water system design should consider the following:

- Water heaters of different sizes and insulation may have different standby losses, recovery efficiency, thermal efficiency, or energy factors.
- A distribution system should be properly designed, sized, and insulated to deliver adequate water quantities at temperatures satisfactory for the uses served. This reduces standby loss and improves hot water distribution efficiency.
- Heat traps between recirculation mains and infrequently used branch lines reduce convection losses to these lines and improve heater/system efficiency.
- Controlling circulating pumps to operate only as needed to maintain proper temperature at the end of the main reduces losses on return lines.
- Provision for shutdown of circulators during building vacancy reduces standby losses.

**WATER QUALITY, SCALE, AND CORROSION**
A complete water analysis and an understanding of system requirements are needed to protect water heating systems from scale and corrosion. Analysis shows whether water is hard or soft. Hard water, unless treated, will cause scaling or liming of heat transfer and water storage surfaces; soft water may aggravate corrosion problems and anode consumption (Talbert 1986).

Scale formation is also affected by system requirements and equipment. As shown in Figure 8, the rate of scaling increases with temperature and usage; this is because calcium carbonate and other scaling compounds lose solubility at higher temperatures. In water tube-type equipment, scaling problems can be offset by increasing the water velocity over the heat transfer surfaces, which reduces the tube surface temperature. Also, the turbulence of the flow, if high enough, works to keep any scale that does precipitate off the surface. When water hardness is over 140 mg/L, water softening or other water treatment is often recommended.

Corrosion problems increase with temperature because corrosive oxygen and carbon dioxide gases are released from the water. Electrical conductivity also increases with temperature, enhancing electrochemical reactions such as rusting (Toaborek et al. 1972). A deposit of scale provides some protection from corrosion; however, this deposit also reduces the heat transfer rate, and it is not under the control of the system designer (Talbert et al. 1986).

Steel vessels can be protected to varying degrees by galvanizing them or by lining them with copper, glass, cement, electroless nickel-phosphorus, or other corrosion-resistant material. Glass-lined vessels are almost always supplied with electrochemical protection. Typically, one or more anode rods of magnesium, aluminum, or zinc alloy are installed in the vessel by the manufacturer. This electrochemically active material sacrifices itself to reduce or prevent corrosion of the tank (the cathode). A higher temperature, softened water, and high water use may lead to rapid anode consumption. Manufacturers recommend periodic replacement of the anode rod(s) to prolong the life of the vessel. Some waters have very little electrochemical activity. In this instance, a standard anode shows little or no activity, and the vessel is not adequately protected. If this condition is suspected, the equipment manufacturer should be consulted on the possible need for a high potential anode, or the use of vessels made of nonferrous material should be considered.

Water heaters and hot water storage tanks constructed of stainless steel, copper, or other nonferrous alloys are protected against oxygen corrosion. However, care must still be taken, as some...
stainless steel may be adversely affected by chlorides, and copper may be attacked by ammonia or carbon dioxide.

**SAFETY DEVICES FOR HOT WATER SUPPLIES**

Regulatory agencies differ as to the selection of protective devices and methods of installation. It is therefore essential to check and comply with the manufacturer’s instructions and the applicable local codes. In the absence of such instructions and codes, the following recommendations may be used as a guide:

- Water expands when it is heated. Although the water heating system is initially under service pressure, the pressure will rise rapidly if backflow is prevented by devices such as a check valve, pressure-reducing valve, or backflow preventer in the cold water line or by temporarily shutting off the cold water. When backflow is prevented, the pressure rise during heating may cause the safety relief valve to weep to relieve the pressure. However, if the safety relief valve is inadequate, inoperative, or missing, the pressure rise may rupture the tank or cause other damage. Systems having this potential problem must be protected by a properly sized expansion tank located on the cold water line downstream of and as close as practical to the device preventing back flow.

- Temperature limiting devices (energy cutoff/high limit) prevent water temperatures from exceeding 99°C by stopping the flow of fuel or energy. These devices should be listed and labeled by a recognized certifying agency.

- Safety relief valves open when the pressure exceeds the valve setting. These valves are typically applied to hot water heating and hot water supply boilers. The set pressure should not exceed the maximum allowable working pressure of the boiler. The heat input pressure steam rating (in kW) should equal or exceed the maximum output rating for the boiler. The valves should comply with current applicable standards or the ASME Boiler and Pressure Vessel Code.

- Temperature and pressure safety relief valves also open if the water temperature reaches 99°C. These valves are typically applied to water heaters and hot water storage tanks. The heat input temperature/steam rating (in kW) should equal or exceed the heat input rating of the water heater. Combination temperature and pressure relief valves should be installed with the temperature-sensitive element located in the top 150 mm of the tank, i.e., where the water is hottest.

- To reduce scald hazards, discharge temperature at fixtures accessible to the occupant should not exceed 50°C. Thermostatically controlled mixing valves can be used to blend hot and cold water in order to maintain safe service hot water temperatures.

- A relief valve should be installed in any part of the system containing a heat input device that can be isolated by valves. The heat input device may be solar water heating panels, desuperheater water heaters, heat recovery devices, or similar equipment.

**SPECIAL CONCERNS**

**Legionella pneumophila (Legionnaires’ Disease)**

Legionnaires’ disease (a form of severe pneumonia) is caused by inhaling the bacteria *Legionella pneumophila*. It has been discovered in the service water systems of various buildings throughout the world. Infection has often been traced to *Legionella pneumophila* colonies in shower heads. Ciesielki et al. (1984) determined that *Legionella pneumophila* can colonize in hot water maintained at 46°C or lower. Segments of service water systems in which the water stagnates (e.g., shower heads, faucet aerators, and certain sections of storage-type water heaters) provide ideal breeding locations.

Service water temperature in the 60°C range is recommended to limit the potential for *Legionella pneumophila* growth. This high temperature increases the potential for scalding, so care must be taken such as installing an anti scald or mixing valve. Supervised periodic flushing of fixture heads with 77°C water is recommended in hospitals and health care facilities because the already weakened patients are generally more susceptible to infection.

**Temperature Requirement**

Typical temperature requirements for some services are shown in Table 3. A 60°C water temperature minimizes flue gas condensation in the equipment.

**Hot Water from Tanks and Storage Systems**

With storage systems, 60 to 80% of the hot water in a tank is assumed to be usable before dilution by cold water lowers the temperature below an acceptable level. However, better designs can exceed 90%. Thus, the hot water available from a self-contained storage heater is usually considered to be

\[
V_t = Rd + MS_t
\]

where

- \(V_t\) = available hot water, L
- \(R\) = recovery rate at the required temperature, L/s
- \(d\) = duration of peak hot water demand, s
- \(M\) = ratio of usable water to storage tank capacity
- \(S_t\) = storage capacity of the heater tank, L

Usable hot water from an unfired tank is

\[
V_u = MS_u
\]

where

- \(V_u\) = usable water available from an unfired tank, L
- \(S_u\) = capacity of unfired tank, L

*Note:* Assumes tank water at required temperature.
Service Water Heating

Hot water obtained from a water heater using a storage heater with an auxiliary storage tank is

\[ V_c = V_i + V_a = Rd + M(S_r + S_a) \]  

(5)

where \( V_c \) = total hot water available during one peak in litres.

Placement of Water Heaters

Many types of water heaters may be expected to leak at the end of their useful life. They should be placed where such leakage will not cause damage. Alternatively, suitable drain pans piped to drains must be provided.

Water heaters not requiring combustion air may generally be placed in any suitable location, as long as relief valve discharge pipes open to a safe location.

Water heaters requiring ambient combustion air must be located in areas with air openings large enough to admit the required combustion/dilution air (see NFPA Standard 54/ANSI Z223.1).

For water heaters located in areas where flammable vapors are likely to be present, precautions should be taken to eliminate the probable ignition of flammable vapors. For water heaters installed in residential garages, additional precautions should be taken. Consult local codes for additional requirements or see sections 5.1.9 through 5.1.12 of NFPA Standard 54/ANSI Z223.1.

Outdoor models with a weather-proofed jacket and that are to be installed outdoors are available. Direct-vent gas and oil-fired models are also available. They are to be installed indoors, but are not vented via a conventional chimney or gas vent. They use ambient air for combustion. They must be installed with the means for venting (typically horizontal) and the means for supplying air for combustion from outside the building that is supplied or specified by the equipment manufacturer.

HOT WATER REQUIREMENTS AND STORAGE EQUIPMENT SIZING

Methods for sizing storage water heaters vary. Those using recovery versus storage curves are based on extensive research. All methods provide adequate hot water if the designer allows for unusual conditions.

RESIDENTIAL

Table 4 shows typical hot water usage in a residence. In its Minimum Property Standards for One- and Two-Family Living Units, No. 4900.1-1982, HUD-FHA established minimum permissible water heater sizes [Table 5]. Storage water heaters may vary from the sizes shown in the table if combinations of recovery and storage are used that produce the required 1-h draw.

The first hour rating (FHR) is the amount of hot water that the water heater can supply in one hour of operation under specific test conditions (DOE 1993). The FHR is under review regarding its use for system sizing. The linear regression lines shown in Figure 9 represent the FHR for 1556 electric heaters and 2901 gas heaters (GAMA 1997, Hiller 1998). Regression lines are not included for

 cAlso for 1 to 1.5 baths and 4 bedrooms for indirect water heaters.
oil-fired and heat-pump water heaters because of limited data. The FHR represents water heater performance characteristics that are similar to those represented by the one-hour draw values listed in Table 5.

Another factor to consider when sizing water heaters is the set point temperature. At lower storage tank water temperatures, the tank volume and/or energy input rate may need to be increased to meet a given hot water demand. Currently, manufacturers are shipping residential water heaters with a recommendation that the initial set point be approximately 49°C to minimize the potential for scalding. Reduced set points generally lower standby losses and increase the water heater’s efficiency and recovery capacity.

Over the last decade, the structure and life-style of a typical family has altered the household’s hot water consumption. Due to variations in family size, age of family members, presence and age of children, hot water use volume and temperature, and other factors, demand patterns fluctuate widely in both magnitude and time distribution.

Perlman and Mills (1985) developed the overall and peak average hot water use volumes shown in Table 6. Average hourly patterns and 95% confidence level profiles are illustrated in Figures 10 and 11. Samples of results from the analysis of similarities in hot water use are given in Figures 12 and 13.

COMMERCIAL AND INSTITUTIONAL

Most commercial and institutional establishments use hot or warm water. The specific requirements vary in total volume, flow rate, duration of peak load period, and temperature. Water heaters and systems should be selected based on these requirements.

This section covers sizing recommendations for central storage water heating systems. Hot water usage data and sizing curves for dormitories, motels, nursing homes, office buildings, food service establishments, apartments, and schools are based on EEI-sponsored research (Werden and Spielvogel 1969). Caution must be taken in applying these data to small buildings. Also, within any given category there may be significant variation. For example, the motel category encompasses standard, luxury, resort, and convention motels.

When additional hot water requirements exist, a designer should increase the recovery and/or storage capacity accordingly.
For example, if there is food service in an office building, the recovery and storage capacities required for each additional hot water use should be added when sizing a single central water heating system.

Peak hourly and daily demands for various categories of commercial and institutional buildings are shown in Table 7. These demands for central storage hot water represent the maximum flows metered in this 129-building study, excluding extremely high and very infrequent peaks. Table 7 also shows average hot water consumption figures for these buildings. Averages for schools and food service establishments are based on actual days of operation, while all others are based on total days. These averages can be used to estimate monthly consumption of hot water.

Research conducted for ASHRAE (Becker et al. 1991, Thrasher and DeWerth 1994) and others (Goldner 1993, 1994a,b) included a compilation and review of service hot water use information in commercial and multifamily structures along with new monitoring data. Some of this work found consumption comparable to those shown in Table 7, however, many of the studies showed higher consumption.

*a* Interpolate for intermediate values.

*b* Per day of operation.
recommendations are for establishments serving food at tables, counters, booths, and parked cars. Establishments that use disposable service exclusively are not covered in Table 7.

Dish washing, as metered in these tests, is based on the normal practice of dish washing after meals, not on indiscriminate or continuous use of machines irrespective of the flow of soiled dishes. The recommendations include hot water supplied to dishwasher booster heaters.

**Apartments**

Hot water requirements for both garden-type and high-rise apartments are for one- and two-bath apartments, showers, lavatories, kitchen sinks, dishwashers, clothes washers, and general cleaning purposes. Clothes washers can be either in individual apartments or centrally located. These data apply to central water heating systems only.

**Elementary Schools**

Hot water requirements are for lavatories, cafeteria and kitchen use, and general cleaning purposes. When showers are used, their additional hot water requirements should be added. The recommendations include hot water for dishwashers but not for extended school operation such as evening classes.

**High Schools**

Senior high schools, grades 9 or 10 through 12, require hot water for showers, lavatories, dishwashers, kitchens, and general cleaning. Junior high schools having no showers follow the recommendations for elementary schools.

Requirements for high schools are based on daytime use. Recommendations do not take into account hot water usage for additional activities such as night school. In such cases, the maximum hourly demand remains the same, but the maximum daily and the average daily usage increases, usually by the number of additional students using showers and, to a lesser extent, eating and washing facilities.

**Additional Data**

**Fast Food Restaurants.** Hot water is used for food preparation, cleanup, and rest rooms. Dish washing is usually not a significant load. In most facilities, peak usage occurs during the cleanup period, typically soon after opening and immediately prior to closing. Hot water consumption varies significantly among individual facilities. Fast food restaurants typically consume 1000 to 2000 L per day (EPRI 1994).

**Supermarkets.** The trend in supermarket design is to incorporate food preparation and food service functions, substantially increasing the usage of hot water. Peak usage is usually associated with cleanup periods, often at night, with a total consumption of 1100 to 3800 L per day (EPRI 1994).

**Apartments.** Table 8 differs from Table 3 in that it represents low-medium-high (LMH) guidelines rather than specific singular values. The values presented in Table 8 are based on monitored domestic hot water consumption found in the studies by Becker et al. (1991), Thrasher and DeWerth (1994), Goldner (1993, 1994a,b), and Goldner and Price (1996).

**1999 ASHRAE Applications Handbook (SI)**

“Med” is the overall average. “Low” is the lowest peak value. Such values are generally associated with apartment buildings having such occupant demographics as (1) all occupants working, (2) seniors, (3) couples with children, (4) middle income, or (5) higher population density. “High” is the maximum recurring value. These values are generally associated with (1) high percentage of children, (2) low income, (3) public assistance, or (4) no occupants working.

In applying these guidelines, the designer should note that a building may outlast its current use. This may be a reason to increase the design capacity for domestic hot water or allow for future enhancement of the service hot water system. Building management practices, such as the explicit prohibition (in the lease) of apartment clothes washers or the existence of bath/kitchen hook-ups, should be factored into the design process. A diversity factor that lowers the probability of coincident consumption should also be used in larger buildings.

**Examples**

In the following examples, results are often rounded to the accuracy appropriate for the assumptions made.

**Example 1.** Determine the required water heater size for a 300-student women’s dormitory for the following criteria:

- a. Storage with minimum recovery rate.
- b. Storage with recovery rate of 2.6 mL/s per student.
- c. With the additional requirement for a cafeteria to serve a maximum of 300 meals per hour for minimum recovery rate, combined with item a; and for a recovery rate of 1.9 mL/s per maximum meals per hour, combined with item b.

**Solution:**

- a. The minimum recovery rate from Figure 15 for women’s dormitories is 1.1 mL/s per student or 330 mL/s total. At this rate, storage required is 45 L per student or 13.5 m³ total. On a 70% net usable basis, the necessary tank size is 13.5/0.7 = 19.3 m³.

**Figures 14 through 21** show the relationships between recovery and storage capacity for the various building categories. Any combination of storage and recovery rates that falls on the proper curve will satisfy the building requirements. Using the minimum recovery rate and the maximum storage capacity on the curves yields the smallest hot water capacity capable of satisfying the building requirement. The higher the recovery rate, the greater the 24-h heating capacity and the smaller the storage capacity required.

These curves can be used to select recovery and storage requirements to accommodate water heaters that have fixed storage or recovery rates. Where hot water demands are not coincident with peak electric, steam, or gas demands, greater heater inputs can be selected if they do not create additional energy system demands, and the corresponding storage tank size can be selected from the curves.

Ratings of gas-fired water heating equipment are based on sea level operation and apply for operation at elevations up to 600 m. For operation at elevations above 600 m and in the absence of specific recommendations from the local authority, equipment ratings should be reduced at the rate of 4% for each 300 m above sea level.

Reciprocity rates in Figures 14 through 21 represent the actual hot water required without considering system heat losses. Heat losses from storage tanks and recirculating hot water piping should be calculated and added to the recovery rates shown. Storage tanks and hot water piping must be insulated.

The storage capacities shown are net usable requirements. Assuming that 60 to 80% of the hot water in a storage tank is usable, the actual storage tank size should be increased by 25 to 66% to compensate for unusable hot water.
Fig. 18  Food Service

Fig. 19  Apartments

Fig. 20  Elementary Schools

Fig. 21  High Schools
**Example 3. Service Water Heating**

- The same curve shows 20 L storage per student at 2.6 mL/s recovery, or 300 × 19 = 5700 L storage with recovery of 300 × 2.6 = 780 m/L. The tank size will be 5700/0.7 = 8140 L.
- The requirements for a cafeteria can be determined from Figure 15 and added to those for the dormitory. For the case of minimum recovery rate, the cafeteria (Type A) requires 300 × 0.47 = 140 mL/s recovery rate and 300 × 26.5/0.7 = 11.4 m³ of additional storage. The entire building then requires 330 + 140 = 470 mL/s recovery and 19.3 + 11.4 = 30.7 m³ of storage.

With 1.0 mL/s recovery at the maximum hourly meal output, the recovery required is 300 mL/s, with 300 × 7.5/0.7 = 3260 mL/s of additional storage. Combining this with item b, the entire building requires 780 + 300 = 1080 mL/s recovery and 8140 + 3260 = 11400 L = 11.4 m³ of storage.

**Note:** Recovery capacities shown are for heating water only. Additional capacity must be added to offset the system heat losses.

**Solution:**

- **a.** With minimum recovery rate, the cafeteria (Type A) requires 300 mL/s per student from Figure 22 for high schools, 320 mL/s recovery is required. The storage required is 11.5 L per student, or 2000 × 11.5 = 23 m³. If 70% of the hot water is usable, the tank size is 23/0.7 = 32.9 m³.
- **b.** The net storage capacity will be 0.7 × 15 = 10.5 m³, or 5.25 L per student. From the curve, a recovery capacity of 0.41 mL/s per student or 2000 × 0.41 = 820 mL/s is required.
- **c.** From Table 7, monthly hot water consumption is 2000 students × 1.868 L per student per day × 22 days = 299 m³.

**Note:** Recovery capacities shown are for heating water only. Additional capacity must be added to offset the system heat loss.

**Example 4. Determine the water heater size and monthly hot water consumption for a 2000-student high school.**

- **a.** Storage with minimum recovery rate.
- **b.** Storage with 15 m³ maximum storage capacity.
- **c.** Monthly hot water consumption.

**Solution:**

- **a.** With the minimum recovery rate of 0.16 mL/s per student (from Figure 22), the probable maximum demand, multiply the total quantity for the fixtures by the demand factor in line 19. The heater or coil should have a water heating capacity equal to this probable maximum demand. The storage tank should have a capacity equal to the probable maximum demand multiplied by the storage capacity factor in line 20.

**Example 5. Determine heater and storage tank size for an apartment building from a number of fixtures.**

**Solution:**

- 60 lavatories = 7.6 = 46 L/h
- 30 bathtubs = 76 = 2280 L/h
- 30 showers = 114 = 3420 L/h
- 60 kitchen sinks = 38 = 2280 L/h
- 15 laundry tubs = 76 = 1140 L/h

Possible maximum demand = 9576 L/h

Probable maximum demand = 9576 × 0.30 = 2870 L/h

Heater or coil capacity = 2870/3600 = 0.80 L/s

Storage tank capacity = 2870 × 1.25 = 3590 L/s

\^a Dishwasher requirements should be taken from this table or from manufacturers’ data for the model to be used, if this is known.
\^b Ratio of storage tank capacity to probable maximum demand/h. Storage capacity may be reduced where an unlimited supply of steam is available from a central steam system or large boiler plant.

Food Service

In a restaurant, bacteria are usually killed by rinsing the washed dishes with 82 to 90°C water for several seconds. In addition, an ample supply of general-purpose hot water, usually 60 to 65°C, is required for the wash cycle of dishwashers. Although a water temperature of 60°C is reasonable for dish washing in private dwellings, in public places, the NSF or local health departments require 82 to 90°C water in the rinsing cycle. However, the NSF allows a lower temperature when certain types of machines and chemicals are used. The two-temperature hot water requirements of food service establishments present special problems. The lower temperature water is distributed for general use, but the 82°C water should be confined to the equipment requiring it and should be obtained by boosting the temperature. It would be dangerous to distribute 82°C water for general use. NSF Standard 26 covers the design of dishwashers and water heaters used by restaurants. The American Gas Association (Dunn et al. 1959) has published a recommended procedure for sizing water heaters for restaurants that consists of determining the following:

1. Types and sizes of dishwashers used (manufacturers’ data should be consulted to determine the initial fill requirements of the wash tanks)
2. Required quantity of general-purpose hot water
3. Duration of peak hot water demand period
4. Inlet water temperature
5. Type and capacity of existing water heating system
6. Type of water heating system desired

After the quantity of hot water withdrawn from the storage tank each hour has been taken into account, the following equation may be used to size the required heater(s). The general-purpose and 82 to 90°C water requirements are determined from Tables 10 and 11.

\[ q_i = \frac{Q_h \cdot c_p \cdot \rho \cdot \Delta t}{\eta} \]  

where

- \( q_i \) = heater input, W
- \( Q_h \) = flow rate, mL/s
- \( c_p \) = specific heat of water = 4.18 kJ/(kg·K)
- \( \rho \) = density of water = 1.0 kg/L
- \( \Delta t \) = temperature rise, K
- \( \eta \) = heater efficiency

To determine the quantity of usable hot water from storage, the duration of consecutive peak demand must be estimated. This peak usually coincides with the dishwashing period during and after the main meal and may last from 1 to 4 h. Any hour in which the dishwasher is used at 70% or more of capacity should be considered a peak hour. If the peak demand lasts for 4 h or more, the value of a storage tank is reduced, unless especially large tanks are used. Some storage capacity is desirable to meet momentary high draws.

NSF Standard 5 recommendations for hot water rinse demand are based on 100% operating capacity of the machines, as are the data provided in Table 10. NSF Standard 5 states that 70% of operating rinse capacity is all that is normally attained, except for rackless-type conveyor machines.

Examples 6, 7, and 8 demonstrate the use of Equation (6) in conjunction with Tables 10 and 11.
Solution: The required quantities of general purpose (60°C) and rinse (82°C) water for the equipment, from Tables 10 and 11 and given values, are shown in the following tabulation:

The total consumption of 60°C water is 395 mL/s. The total consumption of 82°C water is 516 mL/s. Based on the requirements taken from Table 11, or approximately 360 mL/s (0.70 × 516 = 361 mL/s). For an instantaneous heater without internal storage capacity, the total quantity of 82°C water consumed must be based on the flow demand. From Table 11, the quantity required for the dishwasher is 290 mL/s; for the makeup, 146 mL/s; and for the utensil washer, 500 mL/s. The total consumption of 82°C water is 290 + 146 + 500 + 936 mL/s, or approximately 940 mL/s.

Example 7. Determine fuel input requirements (assume 75% heater efficiency) for heating water in the cafeteria kitchen described in Example 6, by the following systems, which are among many possible solutions:

a. Separate, self-contained, storage-type heaters.

b. Single instantaneous-type heater having no internal storage, to supply both 82°C and 60°C water through a mixing valve.

c. Separate instantaneous-type heaters having no internal storage.

Solution:

a. The temperature rise for 60°C water is 60 − 15 = 45 K. From Equation (6), the fuel input required to produce 395 mL/s of 60°C water with a 45 K temperature rise at 75% efficiency is about 100 kW. One or more heaters may be selected to meet this total requirement.

From Equation (6), the fuel input required to produce 516 mL/s of 82°C water with a temperature rise of 82 − 15 = 67 K at 75% efficiency is 193 kW. One or more heaters with this total requirement may be selected from manufacturers’ catalogs.

b. The correct sizing of instantaneous-type heaters depends on the flow rate of the 82°C rinse water. From Example 6, the consumption of 82°C water based on the flow rate is 940 mL/s; consumption of 60°C water is 395 mL/s.

Fuel input required to produce 940 mL/s (290 + 146 + 500) of 82°C water with a 67 K temperature rise is 350 kW. Fuel input to produce 395 mL/s of 60°C water with a temperature rise of 45 K is 100 kW. Total heater requirement is 350 + 100 = 450 kW. One or more heaters meeting this total input requirement can be selected from manufacturers’ catalogs.

c. Fuel input required to produce 60°C water is the same as for Solution b, 100 kW. One or more heaters meeting this total requirement can be selected.

Fuel input required to produce 82°C water is also the same as in Solution b, 350 kW. One or more heaters meeting this total requirement can be selected.

Example 8. A luncheonette has purchased a door-type dishwasher that will handle 410 × 410-mm racks. The existing hot water system is capable of supplying the necessary 60°C water to meet all requirements for general-purpose use and for the booster heater that is to be installed. Determine the size of the following booster heaters operating at 75% thermal efficiency required to heat 60°C water to provide sufficient 82°C rinse water for the dishwasher:

a. Booster heater with no storage capacity.

b. Booster heater with enough storage capacity to meet flow demand.

Solution:

a. Because the heater is the instantaneous type, it must be sized to meet the 82°C water demand at a rated flow. From Table 10, this rated flow is 440 mL/s. From Equation (6), the required fuel input with a 22 K temperature rise is 54 kW. A heater meeting this input requirement can be selected from manufacturers’ catalogs.

b. In designing a system with a booster heater having storage capacity, the dishwasher’s hourly flow demand can be used instead of the flow demand used in Solution a. The flow demand from Table 11 is 73 mL/s when the dishwasher is operating at 100% mechanical capacity. From Equation (6) with a 22 K temperature rise, the fuel input required is 6300 W. A booster heater with this input can be selected from manufacturers’ catalogs.

Estimating Procedure. Hot water requirements for kitchens are sometimes estimated on the basis of the number of meals served (assuming eight dishes per meal). Demand for 82°C water for a dishwasher is

\[ D_1 = C_1 N / \theta \]  

(7)

where

\[ D_1 = \text{water for dishwasher, mL/s} \]
\[ N = \text{number of meals served} \]
\[ \theta = \text{hours of service} \]
\[ C_1 = 0.84 \text{ for single-tank dishwasher} \]
\[ = 0.53 \text{ for two-tank dishwasher} \]

Demand for water for a sink with gas burners is

\[ D_2 = C_2 V \]  

(8)
Demand for general-purpose hot water at 60°C is

\[ D_3 = \frac{C_3N}{(\theta + 2)} \]  

(9)

Total demand is

\[ D = D_1 + D_2 + D_3 \]

For soda fountains and luncheonettes, use 75% of the total demand. For hotel meals or other elaborate meals, use 125%.

### Schools

Service water heating in schools is needed for janitorial work, laboratories, cafeterias, shower rooms, and sometimes swimming pools.

Hot water used in cafeterias is about 70% of that usually required in a commercial restaurant serving adults and can be estimated by the method used for restaurants. Where NSF sizing is required, follow *Standard S*.

Shower and food service loads are not ordinarily concurrent. Each should be determined separately, and the larger load should determine the size of the water heater(s) and the tank. Provision must be made to supply 82°C sanitizing rinse. The booster must be sized according to the temperature of the supply water. If feasible, the same water can be used for both needs. If the distance between the two points of need is great, a separate water should be used.

A separate heater system for swimming pools can be sized as outlined in the section on Swimming Pools/Health Clubs.

### Domestic Coin-Operated Laundries

Small domestic machines in coin laundries or apartment house laundry rooms have a wide range of draw rates and cycle times. Domestic machines provide a wash water temperature (normal) as low as 50°C. Some manufacturers recommend a temperature of 70°C; however, the average appears to be 60°C. Hot water sizing calculations must assure a supply to both the instantaneous draw requirements of a number of machines filling at one time and the average hourly requirements.

The number of machines that will be drawing at any one time varies widely; the percentage is usually higher in smaller installations. One or two customers starting several machines at about the same time has a much sharper effect in a laundry with 15 or 20 machines than in one with 40 machines. Simultaneous draw may be estimated as follows:

- 1 to 11 machines: 100% of possible draw
- 12 to 24 machines: 80% of possible draw
- 25 to 35 machines: 60% of possible draw
- 36 to 45 machines: 50% of possible draw

Possible peak draw can be calculated from

\[ F = 1000NV_f/T \]  

(10)

where

- \( F \) = peak draw, mL/s
- \( N \) = number of washers installed
- \( P \) = number of washers drawing hot water divided by \( N \)
- \( V_f \) = quantity of hot water supplied to machine during hot wash fill, L
- \( T \) = wash fill period, s

Recovery rate can be calculated from

\[ R = \left(1000NV_f/[60(\theta + 10)]\right) = 16.7NV_f/(\theta + 10) \]

(11)

where

- \( R \) = total hot water (machines adjusted to hottest water setting), mL/s
- \( \theta \) = actual machine cycle time,

**Note:** \( (\theta + 10) \) is the cycle time plus 10 min for loading and unloading.

### Commercial Laundries

Commercial laundries generally use a storage water heater. The water may be softened to reduce soap use and improve quality. The trend is toward installation of high-capacity washer-extractor wash wheels, resulting in high peak demand.

#### Sizing Data

Laundries can normally be divided into five categories. The required hot water is determined by the mass of the material processed. Average hot water requirements at 82°C are:

- Institutional: 4.6 mL/(kg·s)
- Commercial: 4.6 mL/(kg·s)
- Linen supply: 5.8 mL/(kg·s)
- Industrial: 5.8 mL/(kg·s)
- Diaper: 5.8 mL/(kg·s)

Total mass of the material times these values give the average hourly hot water requirements. The designer must consider peak requirements; for example, a 270-kg machine may have a 1.25 L/s average requirement, but the peak requirement could be 22 L/s.

In a multiple-machine operation, it is not reasonable to fill all machines at the momentary peak rate. Diversity factors can be estimated by using 1.0 of the largest machine plus the following balance:

<table>
<thead>
<tr>
<th>Total number of machines</th>
<th>2</th>
<th>3 to 5</th>
<th>6 to 8</th>
<th>9 to 11</th>
<th>12 and over</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.0 +</td>
<td>0.6</td>
<td>0.45</td>
<td>0.4</td>
<td>0.35</td>
<td>0.3</td>
</tr>
</tbody>
</table>

For example, four machines would have a diversity factor of 1.0 + 0.45 = 1.45.

#### Types of Systems

Service water heating systems for laundries are pressurized or vented. The pressurized system uses city water pressure, and the full peak flow rates are received by the softeners, reclaimers, condensate cooler, water heater, and lines to the wash wheels. The flow surges and stops at each operation in the cycle. A pressurized system depends on an adequate water service.

The vented system uses pumps from a vented (open) hot water heater or tank to supply hot water. The tank's water level fluctuates from about 150 mm above the heating element to a point 300 mm from the top of the tank; this fluctuation defines the working volume. The level drops for each machine fill, while makeup water runs continuously at the average flow rate under water service pressure during the complete washing cycle. The tank is sized to have full working volume at the beginning of each cycle. Lines and softeners may be sized for the average flow rate from the water service to the tank, not the peak machine fill rate as with a closed, pressurized system.

The waste heat exchangers have a continuous flow across the heating surface at a low flow rate, with continuous heat reclamation from the wastewater and flash steam. Automatic flow-regulating valves on the inlet water manifold control this low flow rate. Rapid fill of machines increases production; i.e., more batches can be processed.

#### Heat Recovery

Commercial laundries are ideally suited for heat recovery because 58°C wastewater is discharged to the sewer. Fresh water can be conservatively preheated to within 8 K of the wastewater temperature for the next operation in the wash cycle. Regions with an annual average temperature of 13°C can increase to 50°C the initial temperature of fresh water going into the hot water heater. For each litre or kilogram per hour of water preheated 37 K (13 to 50°C), heat reclamation and associated energy savings is 155 kW.
Swimming Pools/Health Clubs

Flash steam from a condensate receiving tank is often wasted to the atmosphere. The heat in this flash steam can be reclaimed with a suitable heat exchanger. Makeup water to the heater can be preheated 5 to 10 K above the existing makeup temperature with the flash steam.

Swimming Pools/Health Clubs

The desirable temperature for swimming pools is 27°C. Most manufacturers of water heaters and boilers offer specialized models for pool heating; these include a pool temperature controller and a water bypass to prevent condensation. The water heating system is usually installed prior to the return of treated water to the pool. A circulation rate to generate a change of water every 8 h for residential pools and 6 h for commercial pools is acceptable. An indirect heater, in which piping is embedded in the walls or floor of the pool, has the advantage of reduced corrosion, scaling, and condensation because pool water does not flow through the pipes. The disadvantage of this type of system is the high initial installation cost.

The installation should have a pool temperature control and a water pressure or flow safety switch. The temperature control should be installed at the inlet to the heater, while the pressure or flow switch can be installed at either the inlet or outlet, depending on the manufacturer’s instructions. It affords protection against inadequate water flow.

Sizing should be based on four considerations:

1. Conduction through the pool walls
2. Convection from the pool surface
3. Radiation from the pool surface
4. Evaporation from the pool surface

Except in aboveground pools and in rare cases where cold groundwater flows past the pool walls, conduction losses are small and can be ignored. Because convection losses depend on temperature differentials and wind speed, these losses can be greatly reduced by the installation of windbreaks such as hedges, solid fences, or buildings.

Radiation losses occur when the pool surface is subjected to temperature differentials; these frequently occur at night, when the sky temperature may be as much as 45 K below ambient air temperature. This usually occurs on clear, cool nights. During the daytime, however, an unshaded pool will receive a large amount of radiant energy, often as much as 30 kW. These losses and gains may offset each other. An easy method of controlling nighttime radiation losses is to use a floating pool cover; this also substantially reduces evaporative losses.

Evaporative losses constitute the greatest heat loss from the pool—50 to 60% in most cases. If it is possible to cut evaporative losses drastically, the heating requirement of the pool may be cut by as much as 50%. The floating pool cover can accomplish this reduction.

A pool heater with an input great enough to provide a heat-up time of 24 h would be the ideal solution. However, it may not be the most economical system for pools that are in continuous use during an extended swimming season. In this instance, a less expensive unit providing an extended heat-up period of as much as 48 h can be used. Pool water may be heated by several methods. Fuel-fired water heaters and boilers, electric boilers, tankless electric circulation water heaters, air-source heat pumps, and solar heaters have all been used successfully. Air-source heat pumps and solar heating systems would probably be used to extend a swimming season rather than to allow intermittent use with rapid pickup.

The following equations provide some assistance in determining the area and volume of pools:

Elliptical

Area = 3.14 \(AB\)

\(A = \) short radius
\(B = \) long radius

Volume = Area \times Average Depth

Kidney Shape

Area = 0.45 \(L(A+B)\) (approximately)

\(L = \) length
\(A = \) width at one end
\(B = \) width at other end

Volume = Area \times Average Depth

Oval (for circular, set \(L = 0\))

Area = 3.14 \(R^2 + LW\)

\(L = \) length of straight sides
\(W = \) width or 2\(R\)
\(R = \) radius of ends

Volume = Area \times Average Depth

Rectangular

Area = LW

\(L = \) length
\(W = \) width

Volume = Area \times Average Depth

The following is an effective method for heating outdoor pools. Additional equations can be found in Chapter 4.

1. Obtain pool water capacity, in gallons, from the above.
2. Determine the desired heat pickup time in hours.
3. Determine the desired pool temperature—if not known, use 27°C.
4. Determine the average temperature of the coldest month of use.

The required heater output \(q_t\) can now be determined by the following equations:

\[ q_t = \rho c_p V(t_f - t_i) / \theta \] \hspace{1cm} (12)

where

\(q_t = \) pool heat-up rate, kW
\(\rho = 998 \) kg/m³
\(c_p = \) specific heat of water = 4.18 kJ/(kg·K)
\(V = \) pool volume, m³
\(t_f = \) desired temperature (usually 27°C)
\(t_i = \) initial temperature of pool, °C
\(\theta = \) pool heat-up time, h

\[ q_2 = UA(t_f - t_a) \] \hspace{1cm} (13)

where

\(q_2 = \) heat loss from pool surface, kW
\(U = \) surface heat transfer coefficient = 0.060 kW/(m²·K)
\(A = \) pool surface area, m²
\(t_f = \) pool temperature, °C
\(t_a = \) ambient temperature, °C

\[ q_t = q_1 + q_2 \] \hspace{1cm} (14)

Notes: These heat loss equations assume a wind velocity of 5 to 8 km/h. For pools sheltered by nearby fences, dense shrubbery, or buildings, an average wind velocity of less than 5.6 km/h can be assumed. In this case, use 75% of the values calculated by Equation (13) for a velocity of 8 km/h, multiply by 1.25; for 16 km/h, multiply by 2.0.

Because Equation (13) applies to the coldest monthly temperatures, the calculated results may not be economical. Therefore, a value of one-half the surface loss plus the heat-up value yields a more viable heater output figure. The heater input then equals the output divided by the efficiency of the fuel source.
Whirlpools and Spas

Hot water requirements for whirlpool baths and spas depend on temperature, fill rate, and total volume. Water may be stored separately at the desired temperature or, more commonly, regulated at the point of entry by blending. If rapid filling is desired, provide storage at least equal to the volume needed; fill rate can then be varied at will. An alternative is to establish a maximum fill rate and provide an instantaneous water heater that will handle the flow.

Industrial Plants

Hot water (potable) is used in industrial plants for cafeterias, showers, lavatories, gravity sprinkler tanks, and industrial processes. Employee cleanup load is usually heaviest and not concurrent with other uses. The other loads should be checked before sizing, however, to be certain that this is true.

The employee cleanup load consists of one or more of the following: (1) wash troughs or standard lavatories, (2) multiple wash sinks, and (3) showers. Hot water requirements for employees using standard wash fixtures can be estimated at 3.8 L of hot water for each clerical and light-industrial employee per work shift and 7.6 L for each heavy-industrial worker.

For sizing purposes, the number of workers using multiple wash fountains is disregarded. Hot water demand is based on full flow for the entire cleanup period. This usage over a 10-min period is indicated in Table 12. The shower load depends on the flow rate of the shower heads and their length of use. Table 12 may be used to estimate flow based on a 15-min period.

Shower heads and their length of use. Table 12 may be used to estimate flow based on a 15-min period.

Part of the heat may be obtained by heating the aggregate bin by circulating hot water through pipe coils in the walls or sides of the bin. If the aggregate is warmed in this manner, the temperature of the mixing water may be lower, and the aggregate will flow easily from the bins. When aggregate is not heated, it often freezes into chunks, which must be thawed before they will pass through the dump gates. If hot water is used for thawing, too much water accumulates in the aggregate, and control of the final product may vary beyond allowable limits. Therefore, jets of steam supplied by a small boiler and directed on the large chunks are often used for thawing.

SIZING INSTANTANEOUS AND SEMI-INSTANTANEOUS WATER HEATERS

The methods for sizing storage water heating equipment should not be used for instantaneous and semi-instantaneous heaters. The following is based on the Hunter method for sizing hot and cold water piping, with diversity factors applied for hot water and various building types.

The heater can then be selected for the total demand and the total temperature rise required. For critical applications such as hospitals, multiple heaters with 100% standby are recommended. Consider multiple heaters for buildings in which continuity of service is important. The minimum recommended size for semi-instantaneous

### Table 13 Water Heater Sizing for Ready-Mix Concrete Plant

<table>

</tr>
<tr>
<td>8.4</td>
<td>2430</td>
<td>10</td>
</tr>
</tbody>
</table>

*This table assumes that there is 10-min loading time for each truck. Thus, for a 50-min interval between trucks, it is assumed that 1 truck/h is served. For 0 min between trucks, it is assumed that one truck loads immediately after the truck ahead has pulled away. Thus, 6 trucks/h are served.

READY-MIX CONCRETE

In cold weather, ready-mix concrete plants need hot water to mix the concrete so that it will not be ruined by freezing before it sets. Operators prefer to keep the mix at about 21°C by adding hot water to the cold aggregate. Usually, water at about 65°C is considered proper for cold weather. If the water temperature is too high, some of the concrete will flash set.

Generally, 150 L of hot water per cubic metre of concrete mix is used for sizing. To obtain the total hot water load, this number is multiplied by the number of trucks loaded each hour and the capacity of the trucks. The hot water is dumped into the mix as quickly as possible at each loading, so ample hot water storage or large heat exchangers must be used. Table 13 shows a method of sizing water heaters for concrete plants.

*Based on 43°C wash water and 5°C cold water at average flow rates.

Based on 40°C shower water and 5°C cold water.

![Fig. 22 Modified Hunter Curve for Calculating Hot Water Flow Rate](Image)
heaters is 0.65 L/s, except for restaurants, in which it is 0.95 L/s. When the flow for a system is not easily determined, the heater may be sized for the full flow of the piping system. Heaters with low flows must be sized carefully, and care should be taken in the estimation of diversity factors. Unusual hot water requirements should be analyzed to determine whether additional capacity is required. One example is a dormitory in a military school, where all showers and lavatories are used simultaneously when students return from a drill. In this case, the heater and piping should be sized for the full flow of the system.

While the fixture count method bases heater size of the diversified system on hot water flow, hot water piping should be sized for the full flow to the fixtures. Recirculating hot water systems are adaptable to instantaneous heaters. When recirculating systems are installed, the heater capacity should be checked and increased if necessary to offset heat losses of the recirculating system.

To make preliminary estimates of hot water demand when the fixture count is not known, use Table 14 with Figure 22 or Figure 23. The result will usually be higher than the demand determined from the actual fixture count. Actual heater size should be determined from Table 1. Hot water consumption over time can be assumed the same as that in the section on Hot Water Requirements and Storage Equipment Sizing.

Example 9. A 600-student elementary school has the following fixture count: 60 public lavatories, 6 service sinks, 4 kitchen sinks, 6 showers, and 1 dishwasher at 0.54 L/s. Determine the hot water flow rate for sizing a semi-instantaneous heater based on the following:

a. Estimating the number of fixture units.
b. Actual fixture count.

Solution:

a. Use Table 14 to find the estimated fixture count: 600 students \( \times 0.3 \) fixture units per student = 180 fixture units. As showers are not included, Table 1 shows 1.5 fixture units per shower \( \times 6 \) showers = 9 additional fixture units. The basic flow is determined from curve D of Figure 23, which shows that the total flow for 189 fixture units is 1.4 L/s.

b. To size the unit based on actual fixture count and Table 1, the calculation is as follows:

<table>
<thead>
<tr>
<th>Fixture Type</th>
<th>Units per...</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Public lavatories</td>
<td>1.0</td>
<td>60 FU</td>
</tr>
<tr>
<td>Service sinks</td>
<td>2.5</td>
<td>15 FU</td>
</tr>
<tr>
<td>Kitchen sinks</td>
<td>0.75</td>
<td>3 FU</td>
</tr>
<tr>
<td>Showers</td>
<td>1.5</td>
<td>9 FU</td>
</tr>
<tr>
<td><strong>Subtotal</strong></td>
<td></td>
<td><strong>87 FU</strong></td>
</tr>
</tbody>
</table>

At 87 fixture units, curve D of Figure 23 shows 1.0 L/s, to which must be added the dishwasher requirement of 0.54 L/s. Thus, the total flow is 1.54 L/s.

Comparing the flow based on actual fixture count to that obtained from the preliminary estimate shows the preliminary estimate to be slightly lower in this case. It is possible that the preliminary estimate could have been as much as twice the final fixture count. To prevent such oversizing of equipment, use the actual fixture count method to select the unit.

**SIZING REFRIGERANT-BASED WATER HEATERS**

Refrigerant-based water heaters such as heat pump water heaters and refrigeration heat reclaim systems cannot be sized like conventional systems to meet peak loads. The seasonal and instantaneous efficiency and output of these systems vary greatly with operating conditions. Computer software that performs detailed performance simulations taking these factors into account should be used for sizing and analysis. The capacities of these systems and any related supplemental water heating equipment should be selected to achieve a high average daily run time and the lowest combination of operating and equipment cost. For heat pump water heaters, the adequacy of the heat source and the potential effect of the cooling output must be addressed.

**BOILERS FOR INDIRECT WATER HEATING**

When service water is heated indirectly by a space heating boiler, Figure 24 may be used to determine the additional boiler capacity required to meet the recovery demands of the domestic water heating load. Indirect heaters include immersion coils in boilers as well as heat exchangers with space heating media. Because the boiler capacity must meet not only the water supply requirement but also the space heating loads, Figure 24 indicates the reduction of additional heat supply for water heating if the ratio of water heating load to space heating load is low. This reduction is possible because

1. Maximum space heating requirements do not occur at the time of day when the maximum peak hot water demands occur.
2. Space heating requirements are based on the lowest outdoor design temperature, which may occur for only a few days of the total heating season.
3. An additional heat supply or boiler capacity to compensate for pickup and radiation losses is usual. The pickup load cannot occur at the same time as the peak hot water demand because the building must be brought to a comfortable temperature before the occupants will be using hot water.

The factor obtained from Figure 24 multiplied by the peak water heating load to obtain the additional boiler output capacity required.

For reduced standby losses in summer and improved efficiency in winter, step-fired modular boilers may be used. Units not in operation cool down and reduce or eliminate jacket losses. The heated boiler water should not pass through an idle boiler. Figure 25 shows a typical modular boiler combination space and water heating arrangement.
Typical Control Sequence

1. Any control zone or indirectly fired water heater thermostat starts its circulating pump and supplies power to boiler No. 1 control circuit.
2. If T1 is not satisfied, burner is turned on, boiler cycles as long as any circulating pump is on.
3. If after 5 min TA is not satisfied, V1 opens and boiler No. 2 comes on line.
4. If after 5 min TB is not satisfied, V2 opens and boiler No. 3 comes on line.
5. If TC is satisfied and two boilers or fewer are firing for a minimum of 10 min, V2 closes.
6. If TB is satisfied and only one boiler is firing for a minimum of 10 min, V1 closes.
7. If all circulating pumps are off, boiler No. 1 shuts down.

The ASHRAE/IES Standard 90 series discusses combination service water heating/space heating boilers and establishes restrictions on their use. The ASHRAE/IES Standard 100 section on Service Water Heating also has information on this subject.

CHAPTER 49

SNOW MELTING

Heating Requirement (Hydronic and Electric) ......................................................... 49.1
Pavement Design (Hydronic and Electric) ................................................................. 49.9
Control (Hydronic and Electric) ............................................................................. 49.9
Hydronic System Design ....................................................................................... 49.10
Electric System Design ....................................................................................... 49.12

The practicality of melting snow by supplying heat to the snow-covered surface has been demonstrated in a large number of installations, including sidewalks, roads, ramps, and runways. Melting eliminates the need for snow removal, provides greater safety for pedestrians and vehicles, and reduces the labor of slush removal.

This chapter covers three types of snow-melting systems:
1. Hot fluid circulated in embedded pipes (hydronic)
2. Embedded electric heater cables or wire (electric)
3. Overhead high-intensity infrared radiant heating (infrared)

Components of the system design include (1) heating requirement, (2) pavement design, (3) control, and (4) hydronic or electric system design.

HEATING REQUIREMENT

(HYDRONIC AND ELECTRIC)

The heat required for snow melting depends on five atmospheric factors: (1) rate of snowfall, (2) air dry-bulb temperature, (3) humidity, (4) wind speed, and (5) apparent sky temperature. The dimensions of the snow-melting slab affect the heat and mass transfer rates at the surface. Other factors such as back and edge heat losses must be considered in the complete design.

The processes that establish the heating requirement at the snow-melting surface can be described by inspecting the terms in the following equation, which is the steady-state energy balance for the required total heat flux (power per unit surface area) \( q_o \) at the upper surface of a snow-melting slab during snowfall. The general discussion of the heat balance will be followed by a detailed description of how each of the terms is evaluated.

\[
q_o = q_s + q_m + A_r (q_h + q_e)
\]

where
- \( q_o \) = total required heat flux, W/m²
- \( q_s \) = sensible heat flux, W/m²
- \( A_r \) = snow-free area ratio, dimensionless
- \( q_m \) = latent heat flux, W/m²
- \( q_h \) = convective and radiative heat flux from snow-free surface, W/m²
- \( q_e \) = heat flux needed for evaporation, W/m²

Heat Balance

Sensible and Latent Heat Requirements. The sensible heat flux \( q_s \) is the heat flux required to raise the temperature of the snow falling on the slab to the melting temperature plus, after the snow has been melted, to raise the temperature of the liquid to the assigned temperature \( t_f \) of the liquid film. The snow is assumed to fall at atmospheric temperature \( t_a \). The latent heat flux \( q_m \) is the heat flux required to melt the snow. Under steady-state conditions, both \( q_s \) and \( q_m \) are directly proportional to the snowfall rate \( s \).

Free Area Ratio. The heating loads due to sensible and latent (melting) heat flux are imposed on the entire slab during snowfall. On the other hand, the rates of heat and mass transfer from the surface depend on whether there is a snow layer on the surface of the slab. Any snow accumulation on the slab acts to partially insulate the surface from heat losses and evaporation. The insulating effect of partial snow cover can be large. Because snow may cover a portion of the slab area, it is convenient to think of the insulating effect in terms of an effective or equivalent snow-covered area \( A_e \), which is perfectly insulated and from which no evaporation occurs. The balance is then considered to be the equivalent snow-free area \( A_r \).

This area is assumed to be completely covered with a thin liquid film; therefore, both heat and mass transfer occur at the maximum rates for the existing environmental conditions. It is convenient to define a dimensionless snow-free area ratio \( A_r \):

\[
A_r = \frac{A_f}{A_{fr}}
\]

where
- \( A_f \) = equivalent snow-free area, m²
- \( A_{fr} \) = equivalent snow-covered area, m²
- \( A_t = A_f + A_{fr} \) = total area, m²

Therefore,

\[
0 \leq A_r \leq 1
\]

For \( A_r = 1 \), the system must melt snow rapidly enough that no accumulation occurs. For \( A_r = 0 \), the surface must be covered with snow of sufficient thickness to prevent heat and evaporation losses. Practical snow-melting systems operate somewhere between these limits. Earlier studies indicate that sufficient snow-melting system design information is obtained by considering three values of the free area ratio: 0, 0.5, and 1.0 (Chapman 1952).

Heat Losses due to Surface Convection, Radiation, and Evaporation. Using the concept of the snow-free area ratio, the appropriate heat and mass transfer relations can then be written for the snow-free portion of the slab. These appear as the third term on the right-hand side of Equation (1). On the snow-free surface, maintained at film temperature \( t_f \), there is heat transfer to the surroundings and evaporation from the liquid film. The heat flux \( q_h \) includes the convective losses to the ambient air at temperature \( t_a \) and radiative losses to the surroundings, which are at a mean radiant temperature \( T_{MR} \). The convection heat transfer coefficient is a function of the wind speed and a characteristic dimension of the snow-melting surface. This heat transfer coefficient is also a function of the thermodynamic properties of the air, which vary slightly over the temperature range for various snowfall events. The mean radiant temperature depends on air temperature, relative humidity, cloudiness, cloud height, and whether precipitation is falling.

The heat flux \( q_e \) needed for the evaporation is equal to the evaporation rate multiplied by the heat of vaporization. The evaporation rate is driven by the difference in vapor pressure between the wet
surface of the snow-melting slab and the ambient air. The mass transfer coefficient is a function of the wind speed, a characteristic dimension of the slab, and the thermodynamic properties of the ambient air.

**Heat Flux Equations**

**Sensible Heat Flux.** The sensible heat flux $q_s$ is given by the following equation. The snow is assumed to fall at temperature $T_a$. 

$$q_s = \rho_{water} s [c_{p, ice}(t_s - t_a) + c_{p, water}(t_f - t_a)]/c_1$$  

(3)

where

- $c_{p, ice}$ = specific heat of ice, J/(kg·K)
- $c_{p, water}$ = specific heat of water, J/(kg·K)
- $s$ = snowfall rate, mm of liquid water equivalent per hour
- $t_s$ = ambient temperature, °C
- $t_f$ = liquid film temperature, °C
- $t_a$ = melting temperature, °C
- $\rho_{water}$ = density of water, kg/m$^3$
- $c_1 = 1000$ mm/m$\times 3600$ s/h = $3.6 \times 10^6$

The density of water, specific heat of ice, and specific heat of water are approximately constant over the temperature range of interest and are evaluated at 0°C. The ambient temperature and snowfall rate are available from the weather data. The liquid film temperature is usually taken as 0.56°C.

**Melting Heat Flux.** The heat flux $q_m$ required to melt the snow is given by the following equation:

$$q_m = \rho_{water} s h_{fg}/c_1$$  

(4)

where $h_{fg}$ = heat of fusion of snow, J/kg.

**Convective and Radiative Heat Flux from a Snow-Free Surface.** The corresponding heat flux $q_h$ is given by the following equation:

$$q_h = h_c (t_f - t_a) + \sigma \epsilon_s (T_f^4 - T_{MR}^4)$$  

(5)

where

- $h_c$ = convection heat transfer coefficient for turbulent flow, W/(m$^2$·K)
- $T_f$ = liquid film temperature, K
- $T_{MR}$ = mean radiant temperature of surroundings, K
- $\sigma$ = Stefan-Boltzmann constant = $5.670 \times 10^{-8}$ W/(m$^2$·K$^4$)
- $\epsilon_s$ = emittance of surface

The convection heat transfer coefficient over the slab is given by the following equation (Incropera and DeWitt 1996):

$$h_c = 0.037 \left( \frac{k_{air}}{L} \right) \text{Re}_L^{0.8} Pr^{1/3}$$  

(6)

where

- $k_{air}$ = thermal conductivity of air at $t_a$, W/(m·K)
- $L$ = characteristic length of slab measured in the direction of the wind, m
- $Pr$ = Prandtl number of the air, taken as $Pr = 0.7$
- $\text{Re}_L$ = Reynolds number based on characteristic length $L$

and

$$\text{Re}_L = \frac{VL}{\nu_{air}} c_2$$  

(7)

where

- $V$ = design wind speed, km/h
- $\nu_{air}$ = kinematic viscosity of air, m$^2$/s
- $c_2 = 1000 m/km \times 1 h/3600 s = 0.278$

From Equations (6) and (7), it can be seen that the turbulent convective heat transfer coefficient is a function of $L^{-0.2}$. Because of this relationship, shorter snow-melting slabs have higher convective heat transfer coefficients than longer snow-melting slabs. For design, the shortest dimension should be used (e.g., for a long narrow driveway of sidewalk, use the shorter width). A snow-melting slab length $L = 6.1$ m is used in the heat transfer calculations which resulted in Tables 1, 2, and 3.

The mean radiant temperature $T_{MR}$, which appears in Equation (5), is the equivalent blackbody temperature of the surroundings of the snow-melting slab. Under snowfall conditions, the entire surroundings are approximately at the ambient air temperature (i.e., $T_{MR} = T_a$). When there is no snow precipitation (e.g., during idling and after snowfall operations for $A_r < 1$), the mean radiant temperature is approximated by the following equation:

$$T_{MR} = \left[ F_{sc} T_{cloud}^4 + T_{sky clear}^4 (1 - F_{sc}) \right]^{1/4}$$  

(8)

where

- $F_{sc}$ = fraction of the radiation exchange that takes place between the slab and clouds
- $T_{cloud}$ = temperature of clouds, K
- $T_{sky clear}$ = temperature of clear sky, K

The equivalent blackbody temperature of a clear sky is primarily a function of the ambient air temperature and the water content of the atmosphere. An approximation for the clear sky temperature is given by the following equation, which is a curve fit of data in Ramseym et al. (1982).

$$T_{sky clear} = T_a - (1.1058 \times 10^3 - 7.562 T_a$$  

$$+ 1.333 \times 10^{-3} T_a^2 - 31.292 \phi + 14.58 \phi^2)$$  

(9)

where

- $T_a$ = ambient temperature, K
- $\phi$ = relative humidity of the air at the elevation for which typical weather measurements are made, decimal

The cloud-covered portion of the sky is assumed to be at $T_{cloud}$. The height of the clouds may be assumed to be 3000 m. The temperature of the clouds at 3000 m is calculated by subtracting the product of the average lapse rate (rate of decrease of atmospheric temperature with height), and the altitude from the atmospheric temperature $T_a$. The average lapse rate, determined from the tables of U.S. Standard Atmospheres (1962), is 6.4 K per 1000 m of elevation (Ramsey et al. 1982). Therefore, for clouds at 3000 m,

$$T_{cloud} = T_a - 19.2$$  

(10)

Under most conditions, this method of approximating the temperature of the clouds provides an acceptable estimate. However, when the atmosphere contains a very high water content, the temperature calculated for a clear sky using Equation (9) may be warmer than the temperature estimated for the clouds using Equation (10). When that condition exists, the temperature $T_{cloud}$ of the clouds is set equal to the calculated clear sky temperature $T_{sky clear}$.

**Evaporation Heat Flux.** The heat flux $q_e$ required to evaporate water from a wet surface is given by the following equation.

$$q_e = \rho_{dry air} h_m (W_f - W_a) h_{fg}$$  

(11)

where

- $h_m$ = mass transfer coefficient, m/s
- $W_f$ = humidity ratio of ambient air, kg$\text{water}/\text{kg} \text{air}$
- $W_a$ = humidity ratio of saturated air at the film surface temperature, kg$\text{water}/\text{kg} \text{air}$

1999 ASHRAE Applications Handbook (SI)
Snow Melting

\( h_{fv} \) = heat of vaporization (enthalpy difference between saturated water vapor and saturated liquid water), J/kg

\( \rho_{dry \, air} \) = density of dry air, kg/m³

The determination of the mass transfer coefficient is based on the analogy between heat transfer and mass transfer. A detailed discussion of the analogy is given in Chapter 3 of the 1997 ASHRAE Handbook—Fundamentals. For external flow where mass transfer occurs at the convective surface and the water vapor component is dilute, the following equation relates the mass transfer coefficient \( h_m \) to the heat transfer coefficient \( h \). (Equation (6))

\[
 h_m = \frac{(Pr \, Sc)^{2/3}}{Pr \, \rho_{dry \, air} \, p \, \epsilon_{p,a}} \quad (12)
\]

where \( Sc = \) Schmidt number. In applying Equation (11), the values \( Pr = 0.7 \) and \( Sc = 0.6 \) are used to generate the values in Tables 1 through 4.

The humidity ratios both in the atmosphere and at the surface of the water film are calculated using the standard psychrometric relation given in the following equation (from Chapter 6 of the 1997 ASHRAE Handbook—Fundamentals).

\[
 W = 0.622 \left( \frac{p_v}{p - p_v} \right) \quad (13)
\]

where

\( p = \) atmospheric pressure

\( p_v = \) partial pressure of water vapor

The atmospheric pressure in Equation (13) is corrected for altitude using the following equation (Kuehn et al. 1998):

\[
 p = p_{std} \left(1 - \frac{z}{T_o} \right)^{-5.265} \quad (14)
\]

where

\( p_{std} = \) standard atmospheric pressure

\( A = 0.0065 \) K/m

\( z = \) altitude of the location above sea level, m

\( T_o = 288.2 \) K

The vapor pressure \( p_v \) for the calculation of \( W \) is equal to the saturation vapor pressure \( p_v \) at the dew-point temperature of the air. Saturated conditions exist at the water film surface. Therefore, the vapor pressure used in calculating \( W \) is the saturation pressure at the film temperature \( T_f \). The saturation partial pressures of water vapor for temperatures above and below freezing can be found in tables of the thermodynamic properties of water at saturation or can be calculated using appropriate equations. Both are presented in Chapter 6 of the 1997 ASHRAE Handbook—Fundamentals.

Heat Load Calculations. Equations (13) through (14) can be used to determine the required heat loads of a snow-melting system. However, calculations must be made for coincident values of the climatic factors, snowfall rate, wind speed, ambient temperature, and dew-point temperature (or another measure of humidity). By computing the load for each snowfall hour over a period of several years, a frequency distribution of hourly loads can be developed. Annual averages or maximums for climatic factors should never be used in sizing a system because they are unlikely to occur simultaneously. Finally, it is critical for the designer to note that the above analysis only describes what is happening at the upper surface of the snow-melting surface. Edge losses and back losses have not been taken into account.

Example 1. During the snowfall that occurred during the 8 P.M. hour on December 26, 1985, in the Detroit metropolitan area, the following simultaneous conditions existed: air dry-bulb temperature = –8.3°C, dew-point temperature = –10°C, wind speed = 31.7 km/h, and snowfall rate = 2.5 mm of liquid water equivalent per hour. Assuming \( L = 6.1 \) m, \( Pr = 0.7 \), and \( Sc = 0.6 \), calculate the heat flux (load) \( q_o \) for a snow-free area ratio of \( A_f = 1.0 \). The thermodynamic and transport properties used in the calculation are taken from Chapters 6 and 36 of the 1997 ASHRAE Handbook—Fundamentals.

Solution:
By Equation (3):

\[
 q_s = 1000 \times \frac{0.00254}{3600} \left((1.2100(0.83) + 15.0629(0.56 - 0.0))\right) = 1.40 \text{ W/m}^2
\]

By Equation (4):

\[
 q_m = 1000 \times \frac{0.00254}{3600} \times 334000 = 235.6 \text{ W/m}^2
\]

By Equation (7):

\[
 Re_L = \frac{31.7 \times 6.1 \times 0.278}{1.3 \times 10^{-5}} = 4.13 \times 10^6
\]

By Equation (6):

\[
 h_v = 0.037 \left(\frac{0.0235}{6.1}\right) \left(4.13 \times 10^6\right)^{0.8} (0.7)^{1/3} = 24.8 \text{ W/(m}^2 \cdot \text{K})
\]

By Equation (5):

\[
 q_s = 24.8(0.56 + 0.83) + (5.76 \times 10^{-9})(1.0)(273.7^4 - 264.9^4)
\]

\[
 = 258.7 \text{ W/m}^2
\]

By Equation (12):

\[
 h_m = \left[\frac{0.7}{0.6}\right]^{2/3} \frac{24.8}{1.33 \times 1005^7} = 0.0206 \text{ m/s}
\]

Obtain the values of the saturation vapor pressures at the dew-point temperature –10°C and the film temperature 0.56°C from Table 3 in Chapter 6 of the 1997 ASHRAE Handbook—Fundamentals. Then, use Equation (13) to obtain \( W = 0.00160 \) kg_vap/kg_air and \( W_f = 0.00393 \) kg_vap/kg_air. By Equation (11),

\[
 q_o = 1.33 \times 0.0206/(0.00393 - 0.00160) \times 2499 \times 10^3 = 159.5 \text{ W/m}^2
\]

By Equation (11),

\[
 q_o = 14.0 + 235.6 + 1.0(258.7 + 159.5) = 668 \text{ W/m}^2
\]

It should be emphasized that this is the heat flux needed at the snow-melting surface of the slab. Back and edge losses must be added as discussed in the section on Back and Edge Heat Losses.

Weather Data and Load Calculation Results

Table 1 shows frequencies of snow-melting loads for 46 cities in the United States (Ramsey et al. 1999). For the calculations, the temperature of the surface of the snow-melting slab was taken to be 0.56°C. Any time the ambient temperature was below 0°C and it was not snowing, it was assumed that the system was idling (i.e., that heat was supplied to the slab so that melting would start immediately when snow began to fall).

Weather data were taken for the years 1982 through 1993. These years were selected because of their completeness of data. The weather data included hourly values of the precipitation amount in equivalent depth of liquid water, precipitation type, ambient dry-bulb and dew-point temperatures, wind speed, and sky cover. All weather elements for the years 1982 to 1990 were obtained from the Solar and Meteorological Surface Observation Network 1961 to 1990 (SAMSON), Version 1.0 (NCDC 1993). For the years 1991 to 1993, all weather elements except precipitation were taken from DAI/S2 data obtained from the National Climatic Data Center as described in Colliver et al. (1998). The precipitation data for these years were taken from NCDC’s Hourly Cooperative Dataset (NCDC 1990).

*a Loads are losses from top surface only. See text for calculation of back and edge losses.*
All wind speeds used in the calculations were taken directly from the weather data. Wind speed is usually measured at an elevation of approximately 10 m and will be referred to as $V_{\text{met}}$. As indicated in the section on Heat Balance, the heat and mass transfer coefficients are functions of a characteristic dimension of the snow-melting slab. The dimension used in generating the values of Table 1 was 6.1 m. Sensitivity of the load to both the wind speed and the characteristic dimension is included in Table 2. During snowfall conditions, the sky temperature was taken as equal to the ambient temperature.

The first data column in Table 1 presents the average number of snowfall hours per year for each location. All loads were computed for snow-free area ratios of 1, 0.5, and 0, and the frequency of the snow-melting loads are presented. This frequency indicates the percentage of time that the required snow-melting load does not exceed the value in the table for the particular area ratio. Figures 1 and 3 are maps showing the distribution of snow-melting loads for snow-free area ratios of 1.0 and 0.5, respectively. The values presented are those needed to satisfy the loads 99% of the time (as listed in the 99% column of Table 1). These maps show how the loads vary throughout the United States. If local data are unavailable, values can be approximated by interpolating between values given on the figure. However, care must be taken because special local climatological conditions exist for some areas (e.g., lake effect snows).

Example for Heat Load Calculation Using Table 1

Example 2. Consider the design of a system for Albany, New York, which has an installed heat flux capacity at the top surface of approximately 471 W/m². Based on the data in Table 1, this system will keep the surface completely free of snow 95% of the time. Because there are 156 snowfall hours in an average year, this design would have some accumulation of snow during approximately 8 h per year (the remaining 5% of the 156 h). This design will also meet the load for more than 98% of the time (i.e., more than 153 of the 156 snowfall hours) at an area ratio of 0.5 and more than 99% of the time for an area ratio of 0. $A_r = 0.5$ means that there is a thin layer of snow over all or part of the slab such that it acts as though half the slab is insulated by a snow layer; $A_r = 0$ means that a snow layer exists which is sufficient to insulate the surface from heat and evaporation losses, but that snow is melting at the base of this layer at the same rate that it is falling on the top of the layer.

Therefore, for this system we can interpret the mean values shown in Table 1 for the area ratio of 0.5 to mean that the designer is warranted in assuming the snow load to be 0.5 of the actual snow load, or in other words, the snow load is 50% less than the actual snow load. To check the design, we can take the 0.5 sensitivity value, and then multiply it by the actual snow load to determine the heat load.

Sensitivity of Design Load to Wind Speed and Surface Size

Some snow-melting systems are in sheltered areas, while others may exist in locations where surroundings create a wind tunnel effect. Similarly, systems vary in size from the baseline characteristic length of 6.1 m. For example, sidewalks exposed to a cross-wind may have a characteristic length on the order of 1.5 m. In such cases, the wind speed will be either less than or greater than the meteorological value $V_{\text{met}}$ used in establishing Table 1. To establish the sensitivity of the load to wind speed and characteristic length, calculations were performed at combinations of wind speeds $0.5V_{\text{met}}$, $V_{\text{met}}$, $2V_{\text{met}}$, and $L$-values of 1.5 m and 6.1 m for area ratios $A_r$ of 1.0 and 0.5. Wind speed and system size do not affect the load values for $A_r = 0$ because the calculations assume that no heat or mass transfer from the surface occurs at this condition. Table 2 presents a set of mean values of multipliers that can be applied to the loads presented in Table 1; these multipliers were established by looking at the effect on the 99% nonexceedance values. The designer is cautioned that these are to be used only as guidelines on the impact of wind speed and size variations.

Back and Edge Heat Losses

The heat loads presented in Table 1 do not account for heat losses from the back and edges of the slab. Adlam (1950) demonstrated that these back and edge losses may vary from 4 to 50%, depending on factors such as pavement construction, operating temperature, ground temperature, and back and edge insulation and exposure. With the construction shown in Figure 3 or Figure 4 and ground temperature of 4.5°C at a depth of 600 mm, back losses are on the order of 20%. Higher losses would be expected with (1) colder ground, (2) more cover over the pipe or cable, or (3) exposed back, such as on bridges or parking decks.

Annual Operating Data

Annual operating data for the cities included in Table 1 are presented in Table 3. The number of melting and idling hours are summarized in this table along with the energy per unit area needed to operate the system during an average year based on calculations performed for the years 1982 to 1993. Back and edge losses are not included in the energy values in Table 3. Data are presented for snow-free area ratios of 1.0, 0.5, and 0. The melting loads are based on systems designed to satisfy the loads 99% of the time (i.e., at the levels indicated in the 99% column in Table 1) for each of the three area ratios. The energy use for each melting hour is taken as either (1) the actual output required to maintain the surface at 0.56°C or (2) the design output, whichever is less. The design output differs, of course, depending on whether the designer is using $A_r = 1.0$, 0.5, or 0; therefore, the annual melting energy differs as well.

The idling hours include all non-snowfall hours when the ambient temperature is below 0°C. The surface is dry; therefore, Equation (5) approximates the surface heat loss. The mean radiant temperature that appears in Equation (5) is evaluated using Equations (8), (9), and (10). The fraction $F_{\text{red}}$ of radiation between the surface and the clouds is equal to the cloud cover fraction in the meteorological data. The energy consumption for each idling hour is taken as either (1) the actual output required to maintain the surface at 0°C or (2) the design output, whichever is less.

\[ O = \frac{A_r \cdot F}{1 - (B/100)} \tag{15} \]

Where:
- $O$ = operating cost, $/yr$
- $A_r = $area, m$^2$
- $q_a = $annual output, J/m$^2$ per year or kWh/m$^2$ per year
- $F = $fuel cost, $/J$ or $$/kWh$
- $B = $back loss, %

Operating cost for fossil fuel is

\[ O = \left(200 \times 965.5 \times 9 \times 10^{-3}\right)/\left[1 - (30/100)\right] \]

\[ = 248/\text{yr} \]

\(a\) Does not include back and edge heat losses

Table 3 also includes a column labeled “2% Min. Snow Temp.” This is the temperature below which only 2% of the snowfall hours occur.

Operating Cost Example

Example 3. A snow-melting system of 200 m$^2$ is to be installed in Chicago. The application is considered critical enough that the system is designed to remain snow-free 99% of the time. For this application, Table 3 shows that the annual heat requirement to melt the snow is 26.8 kWh/m$^2$. Assuming a fossil fuel cost of $9 per GJ, an electric cost of $0.07 per kWh, and back loss at 30%, find the annual cost to melt the snow.

Solution: Operating cost $O$ may be expressed as follows:
Snow Melting

Operating cost for electric heat is

\[ O = \frac{[200(26.8)(0.07)]}{[1 – (30/100)]} = $536/\text{yr} \]

**PAVEMENT DESIGN (HYDRONIC AND ELECTRIC)**

Either concrete or asphalt pavement may be used for snow-melting systems. The thermal conductivity of asphalt is less than that of concrete; pipe or cable spacing and required fluid temperatures are thus different. Hot asphalt may damage plastic or electric snow-melting systems unless adequate precautions are taken. For specific recommendations, refer to the sections on **Hydronic System Design** and **Electric System Design**.

Concrete slabs containing hydronic or electric snow-melting apparatus must be designed and constructed with a subbase, expansion-contraction joints, reinforcement, and drainage to prevent slab cracking; otherwise, crack-induced shearing or tensile forces would break the pipe or cable. The pipe or cable must not run through expansion-contraction joints, keyed construction joints, or control joints (dummy grooves); however, the pipe or cable may be run under 3 mm score marks (block and other patterns). Control joints must be placed wherever the slab changes size or incline. The maximum distance between control joints for ground-supported slabs must be less than 4.6 m, and the length should be no greater than twice the width, except for ribbon driveways or sidewalks. In ground-supported slabs, most cracking occurs during the early cure. Depending on the amount of water used in the concrete mix, shrinkage during cure may be up to 60 mm per 100 m. If the slab is more than 4.6 m long, the concrete does not have sufficient strength to overcome friction between it and the ground while shrinking during the cure period.

If the slabs are poured in two separate layers, the top layer, which contains the snow-melting apparatus, usually does not contribute toward total slab strength; therefore, the lower layer must be designed to provide the total strength.

The concrete mix of the top layer should give maximum weatherability. The compressive strength should be 28 to 34 MPa; recommended slump is 75 mm maximum, 50 mm minimum. Aggregate size and air content should be as follows:

<table>
<thead>
<tr>
<th>Maximum Size Crushed Rock</th>
<th>Air Content, %</th>
</tr>
</thead>
<tbody>
<tr>
<td>Aggregate, mm</td>
<td></td>
</tr>
<tr>
<td>64</td>
<td>5 ± 1</td>
</tr>
<tr>
<td>25</td>
<td>6 ± 1</td>
</tr>
<tr>
<td>13</td>
<td>7.5 ± 1</td>
</tr>
</tbody>
</table>

Note: Do not use river gravel or slag.

The pipe or cable may be placed in contact with an existing sound pavement (either concrete or asphalt) and then covered as described in the sections on **Hydronic System Design** and **Electric System Design**. If there are signs of cracking or heaving, the pavement should be replaced. Pipe or cable should not be placed over existing expansion-contraction, control, or construction joints. The finest grade of asphalt is best for the top course; stone diameter should not exceed 10 mm.

A moisture barrier should be placed between any insulation and the fill. The joints in the barrier should be sealed and the fill made smooth enough to eliminate holes or gaps for moisture transfer. Also, the edges of the barrier should be flashed to the surface of the pavement to seal the ends.

Snow-melting systems should have good surface drainage. When the ambient air temperature is 0°C or below, runoff from melting snow freezes immediately on leaving the heated area. Any water that is able to get under the pavement also freezes when the system is deenergized, causing extreme frost heaving. Runoff should be piped away in drains that are heated or below the frost line.

The area to be protected by the snow-melting system must first be measured and planned. For total snow removal, hydronic or electric heat must cover the entire area. In larger installations, it may be desirable to melt snow and ice from only the most frequently used areas, such as walkways and wheel tracks for trucks and autos. Planning for separate circuits should be considered so that areas within the system can be heated individually, as required.

Where snow-melting apparatus must be run around obstacles (e.g., a storm sewer grate), the pipe or cable spacing should be uniformly reduced. Because some drifting will occur adjacent to walls or vertical surfaces, extra heating capacity should be provided in these areas, if possible also in the vertical surface. Drainage flowing through the area expected to be drifted tends to wash away some snow.

**CONTROL (HYDRONIC AND ELECTRIC)**

Snow-melting systems can be controlled either manually or automatically.

**Manual Control**

Manual operation is strictly by on-off control; an operator must activate and deactivate the system when snow falls. If the system is not turned off after snowfall, operating cost increases.

**Automatic Control**

If the snow-melting system is not turned on until snow starts falling, it may not melt snow effectively for several hours, giving additional snowfall a chance to accumulate and increasing the time needed to melt the area. Automatic controls provide satisfactory operation because they turn on the system when light snow starts, allowing adequate warm-up before heavy snowfall develops. Automatic turn-off reduces operating costs.

**Snow Detectors.** Snow detectors monitor precipitation and temperature. They allow operation only when snow is present and may incorporate a delay-off timer. Snow detectors located in the heated area activate the snow-melting system when precipitation (snow) occurs at a temperature below the preset pavement temperature (usually 4°C). Another type of snow detector is mounted above ground, adjacent to the heated area, without cutting into the existing system; however, it does not detect tracked or drifting snow. Both types of sensors should be located so that they are not affected by overhangs, trees, blown snow, or other local conditions.

**Pavement Temperature Sensor.** To limit energy waste during normal and light snow conditions, it is common to include a remote temperature sensor installed midway between two pipes or cables in the pavement; the set point is adjusted between 5 and 15°C. Thus, during mild weather snow conditions, the system is automatically modulated or cycled on and off to keep the pavement temperature at the sensor set point.

**Outdoor Thermostat.** The control system may include an outdoor thermostat that turns the system off when the outdoor ambient temperature rises above 2 to 5°C as automatic protection against accidental operation in summer or mild weather.

**Control Selection**

For optimum operating convenience and minimum operating cost, all of the aforementioned controls should be incorporated in the snow-melting system.

**Operating Cost**

To evaluate operating cost during idling or melting, use the annual output data from Table 3. Idling and melting data are based on pavement surface temperature control at 0°C during idling,
which requires a pavement temperature sensor. Without a pavement temperature sensor, operating costs will be substantially higher.

**HYDRONIC SYSTEM DESIGN**

Hydronic system design includes selection of the following components: (1) heat transfer fluid, (2) piping, (3) fluid heater, (4) pump(s) to circulate the fluid, and (5) controls. With concrete pavement, thermal stress is also a design consideration.

**Heat Transfer Fluid**

A variety of fluids, including brine, oils, and glycol-water, is suitable for transferring the heat from the fluid heater to the pavement. Freeze protection is essential because most systems will not be operated continuously in subfreezing weather. Without freeze protection, power loss or pump failure could cause freeze damage to the piping and pavement.

**Brine** is the least costly heat transfer fluid, but it has a lower specific heat than glycol. The use of brine may be discouraged because of the cost of heating equipment that can resist its corrosive potential.

Although **heat transfer oils** are not corrosive, they are more expensive than and have a lower specific heat and higher viscosity than brine or glycol. Petroleum distillates used as fluids in snow-melting systems are classified as nonflammable but have fire points between 150 and 180°C. When oils are used as heat transfer fluids, any oil dripping from the seals on the pump should be collected. It is good practice to place a barrier between the oil lines and the boiler so that a flashback from the boiler cannot ignite a possible oil leak. Other nonflammable fluids, such as those used in some transformers, can be used as antifreeze.

**Glycols** (ethylene and propylene) are used the most often in snow-melting systems because of their moderate cost, high specific heat, and low viscosity; ease of corrosion control is another advantage. Automotive glycols containing silicates are not recommended because they can cause fouling, pump seal wear, fluid gelation, and reduced heat transfer. The piping should be designed for periodic addition of inhibitor. Glycols should be tested annually to determine any change in reserve alkalinity and freeze protection. Only inhibitors obtained from the manufacturer of the glycol should be added. Heat exchanger surfaces should be kept below 140°C, which corresponds to about 280 kPa (gage) steam. Temperatures above 150°C accelerate the deterioration of the inhibitors.

Because ethylene glycol and petroleum distillates are toxic, no permanent connection should be installed between the snow-melting system and the drinking water supply. Gordon (1950) discusses precautions concerning internal corrosion, flammability, toxicity, cleaning, joints, and hook-up that should be taken during the installation of hydronic piping. The properties of brine and glycol are discussed in Chapter 20 of the 1997 *ASHRAE Handbook—Fundamentals*. The effect of glycol on system performance is detailed in Chapter 12 of the 2000 *ASHRAE Handbook—Systems and Equipment*.

**Piping**

Piping may be metal, plastic, or ethylene-propylene terpolymer (EPDM). Steel, iron, and copper pipes have long been used. Steel and iron may corrode rapidly if the pipe is not shielded by a coating and/or cathodic protection. Both the use of salts for deicing and the elevated temperature accelerate corrosion of metallic components. NACE (1978) states that the corrosion rate roughly doubles for each 10 K rise in temperature.

Chapman (1952) derived the equation for the fluid temperature required to provide an output \( q_o \). For construction similar to that shown in Figure 3, the equation is

\[
\begin{align*}
{ t_m } &= 0.089 { q_o } + { t_f } \quad (16)
\end{align*}
\]

where \( t_m \) = mean fluid (antifreeze solution) temperature, °C. Equation (16) applies to 25 mm as well as 20 mm IPS pipe [Figure 3].

For specific conditions or for cities other than those given in Table 1, Equations (1) and (16) are used. Table 2 gives solutions to these equations at a relative humidity of 80%.

It is satisfactory to use 20 mm pipe or tube on 300 mm centers as a standard coil. If pumping loads require reduced friction, the pipe size can be increased to 25 mm, but the pavement depth must be increased accordingly. The piping should be supported by a minimum of 50 mm of concrete above and below. This requires 130 mm pavement for 20 mm pipe and 140 mm pavement for 25 mm pipe.

**Plastic Pipe.** Plastic pipe (polyethylene (PE), polybutylene (PB), cross-linked polyethylene (PEX)) is popular due to its lower material cost, lower installation cost, and corrosion resistance. Considerations when using plastic pipe include stress crack resistance, temperature limitations, and thermal conductivity. Heat transfer oils should not be used with plastic pipe. Plastic pipe is furnished in coils. The smaller sized pipe can be bent to form a variety of heating panel designs without elbows or joints. Mechanical compression connections can be used to connect the heating panel pipe to the larger supply and return piping leading to the pump and fluid heater. PE and PB plastic pipe may be fused using the appropriate fittings and fusion equipment. Fusion joining eliminates metallic components and thus the possibility of corrosion in the piping; however, it requires considerable installation training.

When plastic pipe is used, the system must be designed so that the fluid temperature required will not damage the pipe. If a design requires a temperature above the tolerance of plastic pipe, the heat output will never meet design requirements. A logical solution is to decrease the pipe spacing. Adlam (1950) addresses the parameter of pipe size and the effect of pipe spacing on heat output. A typical solution is summarized in Table 5, which shows a way of designing pipe spacing according to heating requirements. This table also shows adjustments for the effect of more than 50 mm of concrete or paver over the pipe.

**Pipe Installation.** It is good design practice to avoid passing any embedded piping through a concrete expansion joint; otherwise, the pipe may be stressed and possibly ruptured. Figure 4 shows a method of protecting piping that must pass through a concrete expansion joint from stress under normal conditions.

Note: Table based on a characteristic pavement length of 6.1 m, standard atmospheric pressure, a water film temperature of 0.56°C, and relative humidity of 80%.

$A_s =$ free area ratio
$q_o =$ slab heating load, W/m²
$t_u =$ atmospheric dry-bulb temperature, °C
$tm =$ mean fluid temperature based on construction shown in Figure 3.
After pipe installation, but before pavement installation, all piping should be air-tested to about 700 kPa (gage). This pressure should be maintained until all welds and connections have been checked for leaks. Testing should not be done with water for the following reasons: (1) small leaks may not be observed during pavement installation; (2) water leaks may damage the concrete during installation; (3) the system may freeze before antifreeze is added; and (4) it is difficult to add antifreeze when the system is filled with water.

Air Control. Because introduction of air causes deterioration of the antifreeze, the piping should not be vented to the atmosphere. It should be divided into smaller zones to facilitate filling and allow isolation when service is necessary.

Air can be eliminated from the piping during the initial filling by pumping the antifreeze from an open container into isolated zones of the piping. A properly sized pump and piping system that maintains an adequate fluid velocity, together with an air separator and expansion tank, will keep air from entering the system during operation.

A strainer, sediment trap, or other means for cleaning the piping system may be provided. It should be placed in the return line ahead of the isolation tank, will keep air from entering the system during operation. Testing should not be done with water for the following reasons: (1) small leaks may not be observed during pavement installation; (2) water leaks may damage the concrete during installation; (3) the system may freeze before antifreeze is added; and (4) it is difficult to add antifreeze when the system is filled with water.

An ASME safety relief valve of adequate capacity should be installed on a closed system.

Fluid Heater

The heat transfer fluid can be heated using any of a variety of energy sources, depending on availability at the location of the snow-melting system. A fluid heater can use steam, hot water, gas, oil, or electricity. In some applications, heat may be available from secondary sources, such as engine generators, condensate, and other waste heat sources.

The design capacity of the fluid heater can be established by evaluating the data in the section on Heating Requirement (Hydronic and Electric). It is usually 630 to 950 W/m², which includes back and edge losses.

Design of the fluid heater should follow standard practice, with adjustments for the film coefficient. Consideration should be given to flue gas condensation and thermal shock in boilers due to low fluid temperatures. Bypass flow controls may be necessary to maintain recommended boiler temperatures. Boilers should be derated for high-altitude applications.

Pump Selection

The proper pump is selected based on (1) the fluid flow rate; (2) the energy requirements of the piping system; (3) the specific heat of the fluid; and (4) the viscosity of the fluid, particularly during a cold start-up.

### Pump Selection Example

Example 3. An area of 1000 m² is to be designed with a snow-melting system. Using the criteria of Equation (1) a heating requirement (including back and edge losses) of 790 W/m² is selected. Thus the total fluid heater output must be 790 kW. Size the heater for fuel efficiency and heat transfer fluid used.

For a fluid with a specific heat of 3.5 kJ/(kg·K), the flow or temperature drop must be adjusted by 15%. From Equation (16) in Chapter 12 of the 2000 ASHRAE Handbook—Systems and Equipment, a 13 K temperature drop, flow would be 17.4 L/s. If glycol were used at 55°C, the effect on pipe pressure loss and pump performance would be negligible. If the system pressure were determined to be 120 kPa and pump efficiency 60%, pump power would be 3.5 kW. Centrifugal pump design criteria may be found in Chapter 18 of the 2000 ASHRAE Handbook—Systems and Equipment.

**Controls**

The controls discussed in the section on Control (Hydronic and Electric) provide convenience and operating economy but are not required for operation. Hydronic systems require fluid temperature control for safety and for component longevity. Pavement stress and the temperature limits of the heat transfer fluid, pipe components, and fluid heater need to be considered. Certain nonmetallic pipe materials should not be subjected to temperatures above 60°C. If the primary control fails, a secondary fluid temperature sensor should deactivate the snow-melting system and possibly activate an alarm.

**Thermal Stress**

Chapman (1955) discusses the problems of thermal stress in concrete pavement. In general, thermal stress will cause no problems if the following installation and operation rules are observed:

1. Minimize the temperature difference between the fluid and the slab surface by maintaining (a) close pipe spacing (see Figure 3), (b) a low temperature differential in the fluid (less than 11 K), and (c) continuous operation (if economically feasible).

2. Install pipe with a gap of at least 50 mm of the surface.

3. Use reinforcing steel designed for thermal stress if high structural loads are expected (such as on highways).

Thermal shock to the pavement may occur if heated fluid is introduced from a large source of residual heat such as a storage tank, a large piping system, or another snow-melting area. The pavement should be brought up to temperature by maintaining the fluid temperature differential at less than 11 K.

### ELECTRIC SYSTEM DESIGN

Snow-melting systems using electricity as an energy source have heating elements in the form of (1) mineral insulated (MI) cable, (2) self-regulating cable, (3) constant wattage cable, or (4) high-intensity infrared heaters.

**Heat Flux**

The basic load calculations for electric systems are the same as presented in the section on Heating Requirement (Hydronic and Electric). However, because electric system output is determined by the resistance installed and the voltage impressed, it cannot be altered by fluid flow rates or temperatures. Consequently, neither safety factors nor marginal capacity systems are deemed considerations.

Heat flux within a slab can be varied by altering the cable spacing to compensate for anticipated drift areas or other high heat loss areas. Power density should not exceed 1300 W/m² (NFPA Standard 70).

### Snow Melting

#### Electrical Equipment

The installation and design of electric snow-melting systems is governed by Article 426 of the National Electrical Code (NFPA Standard 70). The NEC requires that each electric snow-melting circuit be provided with a ground fault protection device. An equipment protection device (EPD) with a trip level of 30 mA should be used to reduce the likelihood of nuisance tripping.

Double-pole, single-throw switches or tandem circuit breakers should be used to open both sides of the line. The switchgear may be in any protected, convenient location. It is also advisable to include a pilot lamp on the load side of each switch so that there is a visual indication when the system is energized.

Junction boxes located at grade level are susceptible to water ingress. Weatherproof junction boxes installed above grade should be used for terminations.

The power supply conduit is run underground, outside the slab, or in a prepared base. With concrete pavement, this conduit should be installed before the reinforcing mesh.

#### Mineral Insulated Cable

Mineral insulated (MI) heating cable is a magnesium oxide (MgO)-filled, die-drawn cable with one or two copper or copper alloy conductors and a seamless copper or stainless steel alloy sheath. The metal outer sheath is protected from salts and other chemicals by a high-density PE jacket that is important whenever MI cable is embedded in a medium. Although it is heavy-duty cable, MI cable is practical in any snow-melting installation.

**Cable Layout.** To determine the characteristics of the MI heating cable needed for a specific area, the following must be known:

- Heated area size
- Power density required
- Voltage(s) available
- Approximate cable length needed

To find the approximate MI cable length, estimate 6 linear metres of cable per square metre of concrete. This corresponds to 150 mm on-center spacing. Actual cable spacing will vary between 75 and 230 mm to provide the proper power density.

Cable spacing is dictated primarily by the heat-conducting ability of the material in which the cable is embedded. Concrete has a higher heat transmission coefficient than asphalt, permitting wider cable spacing. The following is a procedure to select the proper MI heating cable:

1. Determine total power required for each heated slab.
   \[ W = A w \]  

2. Determine total resistance.
   \[ R = E^2 / W \]  

3. Calculate cable resistance per foot.
   \[ r_1 = R / L_1 \]  

   where:
   - \( W \) = total power needed, W
   - \( A \) = heated area of each heated slab, m²
   - \( w \) = required power density input, W/m²
   - \( R \) = total resistance of cable, Ω
   - \( E \) = voltage available, V
   - \( r_1 \) = calculated cable resistance, Ω per metre of cable
   - \( L_1 \) = estimated cable length, m
   - \( L \) = actual cable length needed, m
   - \( r \) = actual cable resistance, Ω/m

   4. Determine actual cable length needed to give the wattage desired.
   \[ L = R / r \]  

5. Determine cable spacing within the heated area.
   \[ S = 1000 A / L \]  

6. Determine cable spacing within the heated area.

7. Determine the current required for the cable.
   \[ I = E / R, \text{ or } I = W / E \]  

8. Choose cold lead cable as dictated by typical design guidelines and local electrical codes (see Table 6).

**Cold Lead Cable.** Every MI heating cable is factory-fabricated with a non-heat-generating cold lead cable attached. The cold lead cable must be long enough to reach a dry location for termination and of sufficient wire gage to comply with local and NEC standards. The NEC requires a minimum cold lead length of 180 mm in

**Table 6 Mineral Insulated Cold Lead Cables**

(Maximum Voltage—600 V)

Source: National Electrical Code (NFPA Standard 70).
the junction box. Mineral insulated cable junction boxes must be located such that the box remains dry and at least 0.9 m of cold lead cable is available at the end for any future service [Figure 5]. Preferred junction box locations are indoors; on the side of a building, utility pole, or wall; or inside a manhole on the wall. Boxes should have a hole in the bottom to drain condensation. Outdoor boxes should be completely watertight except for the condensation drain hole. Where junction boxes are mounted below grade, the cable end seals must be coated with an epoxy to prevent moisture entry. Cable end seals should extend into the junction box far enough to allow the end seal to be removed if necessary.

Although MgO, the insulation in MI cable, is hygroscopic, the only vulnerable part of the cable is the end seal. However, should moisture penetrate the seal, it can easily be detected with a megohmmeter and driven out by applying a torch 0.6 to 0.9 m from the end and working the flame toward the end.

**Installation.** When mineral insulated electric heating cable is installed in a concrete slab, the slab may be poured in one or two layers. In single-pour application, the cable is hooked on top of the reinforcing mesh before the pour is started. In two-layer application, the cable is laid on top of the bottom structural slab and embedded in the finish layer. For a proper bond between the layers, the finish slab should be poured within 24 h of the bottom slab, and a bonding grout should be applied. The finish slab should be at least 50 mm thick. Cable should not run through expansion, control, or dummy joints (score or groove). If the cable must cross such a joint, the cable should exit the bottom of the slab at least 100 mm from one side of the joint and reenter the slab through the bottom at least 100 mm from the joint on the opposite side.

**Fig. 5** Typical Mineral Insulated Heating Cable Installation in Concrete Slab

The cable is uncoiled from reels and laid as described in the section on Cable Layout. Prepunched copper or stainless steel spacing strips are often nailed to the lower slab for uniform spacing.

A polyvinyl chloride (PVC) jacket is extruded over the cable to protect the cold lead from chemical damage and to protect the cable from physical damage without adding excessive thermal insulation.

Calcium chloride or other chloride additives should not be added to a concrete mix in winter because chlorides are destructive to copper. Cinder or slag fill under snow-melting panels should also be avoided. Where the cold lead cable exits the slab, it should be

**Fig. 6** Typical Section, Mineral Insulated Heating Cable in Asphalt
(Potter 1967)
Snow Melting

wrapped with PVC or PE tape to protect it from fertilizer corrosion and other ground attack. Within 0.6 m of the heating section, only PE should be used because heat may break down PVC. Underground, the leads should be installed in suitable conduits to protect them from physical damage.

In asphalt slabs, the MI cable is fixed in place on top of the base pour with prepunched stainless steel strips or 150 mm by 150 mm wire mesh. A coat of bituminous binder is applied over the base and the cable to prevent them from floating when the top layer is applied. The layer of asphalt over the cable should be 40 mm to 75 mm thick (Figure 6).

Testing. Mineral insulated heating cables should be thoroughly tested before, during, and after installation to ensure they have not been damaged either in transit or during installation.

Because of the hygroscopic nature of the MgO insulation, damage to the cable sheath is easily detectable with a 500 V field megohmmeter. Cable insulation resistance should be measured on arrival of the cable. Cable with insulation resistance of less than 20 MΩ should not be used. Cable that shows a marked loss of insulation resistance after installation should be investigated for damage. Cable should also be checked for electrical continuity.

Self-Regulating Cable

Self-regulating heating cables consist of two parallel conductors embedded in a heating core made of conductive polymer. These cables automatically adjust their power output to compensate for local temperature changes. Heat is generated as electric current passes through the core between the conductors. As the slab temperature drops, the number of electrical paths increases, and more heat is produced. Conversely, as the slab temperature rises, the core has fewer electrical paths, and less heat is produced.

Power output of self-regulating cables may be specified as watts per unit length at a particular temperature or in terms of snow-melting performance at a given cable spacing. In typical slab-on-grade applications, adequate performance may be achieved with cables spaced up to 300 mm apart. Narrower cable spacings may be required to achieve the desired snow-melting performance. The parallel construction of the self-regulating cable allows it to be cut to length in the field without affecting the rated power output.

Layout. For uniform heating, the heating cable should be arranged in a serpentine pattern that covers the area with 300 mm on-center spacing (or alternate spacing determined for the design). The heating cable should not be routed closer than 100 mm to the edge of the pavement, drains, anchors, or other material in the concrete.

Crossing expansion, control, or other pavement joints should be avoided. Self-regulating heating cables may be crossed or overlapped as necessary. Because the cables limit power output locally, they will not burn out.

Both ends of the cable should terminate in an above-ground weatherproof junction box. Junction boxes installed at grade level

Fig. 7 Typical Self-Regulating Cable Installation
are susceptible to water ingress. An allowance of heating cable should be provided at each end for termination. The maximum circuit length published by the manufacturer for the cable type should be respected to prevent tripping of circuit breakers. Use ground fault circuit protection as required by national and local electrical codes.

**Installation.** Figure 7 shows a typical self-regulating cable installation. The procedure for installing a self-regulating system is as follows:

1. Hold a project coordination meeting to discuss the role of each trade and contractor. Good coordination helps ensure a successful installation.
2. Attach the heating cable to the concrete reinforcing steel or wire mesh using plastic cable ties at approximately 300 mm intervals. Reinforcing steel or wire mesh is necessary to ensure that the pavement is structurally sound and that the heating cable is installed at the design depth.
3. Test the insulation resistance of the heating cable using a 2500 V dc megohmmeter connected between the braid and the two bus wires. Readings of less than 20 MΩ indicate cable jacket damage. Replace or repair damaged cable sections before the slab is poured.
4. Pour the concrete, typically in one layer. Take precautions to protect the cable during the pour. Do not strike the heating cable with sharp tools or walk on it during the pour.
5. Terminate one end of the heating cable to the power wires, and seal the other end using connection components provided by the manufacturer.

**Constant Wattage Systems**

In a constant wattage system, the resistance elements may consist of a length of copper wire or alloy with a given amount of resistance. When energized, these elements produce the required amount of heat. Witsken (1965) describes this system in further detail.

Elements are either solid-strand conductors or conductors wrapped in a spiral around a nonconducting fibrous material. Both types are covered with a layer of insulation such as PVC or silicone rubber.

The heat-generating portion of an element is the conductive core. The resistance is specified in ohms per linear metre of core. Alternately, a manufacturer may specify the wire in terms of watts per metre of core, where the power is a function of the resistance of the core, the applied voltage, and the total length of core. As with MI cable, the power output of constant wattage cable does not change with temperature.

Considerations in the selection of insulating materials for heating elements include power density, chemical inertness, application, and end use. Polyvinyl chloride is the least expensive insulation and is widely used because it is inert to oils, hydrocarbons, and alkalies. An outer covering of nylon is often added to increase its physical strength and to protect it from abrasion. The heat output of embedded PVC is limited to 16 W per linear metre. Silicone rubber is not inert to oils or hydrocarbons. It requires an additional covering—metal braid, conduit, or fiberglass braid—for protection. This material can dissipate up to 30 W/m.

Lead can be used to encase resistance elements insulated with glass fiber. The lead sheath is then covered with a vinyl material. Output is limited to approximately 30 W/m by the PVC jacket.

Teflon has good physical and electrical properties and can be used at temperatures up to 260°C.

Low watt density (less than 30 W/m) resistance wires may be attached to plastic or fiber mesh to form a mat unit. Prefabricated factory-assembled mats are available in a variety of watt densities for embedding in specified paving materials to match desired snow-melting capacities. Mats of lengths up to 18 m are available for installation in asphalt sidewalks and driveways.

Preassembled mats of appropriate widths are also available for stair steps. Mats are seldom made larger than 5.6 m², since larger ones are more difficult to install, both mechanically and electrically. With a series of cuts, mats can be tailored to follow contours of curves and fit around objects, as shown in Figure 8. Extreme care should be exercised to prevent damage to the heater wire (or lead) insulation during this operation.

The mats should be installed 40 to 75 mm below the finished surface of asphalt or concrete. Installing the mats deeper decreases the snow-melting efficiency. Only mats that can withstand hot asphalt compaction should be used for asphalt paving.

**Layout.** Heating wires should be long enough to fit between the concrete slab dummy groove control or construction joints. Because concrete forms may be inaccurate, 50 to 100 mm of clearance should be allowed between the edge of the concrete and the heating wire. Approximately 100 mm should be allowed between adjacent heating wires at the control or construction joints.

For asphalt, the longest wire or largest heating mat that can be used on straight runs should be selected. The mats must be placed at least 300 mm in from the pavement edge. Adjacent mats must not overlap. Junction boxes should be located so that each accommodates the maximum number of mats. Wiring must conform to requirements of the NEC (NFPA Standard 70). It is best to position junction boxes adjacent to or above the slab.

**Installation**

**General**

1. Check the wire or mats with an ohmmeter before, during, and after installation.
2. Temporarily lay the mats in position and install conduit feeders and junction boxes. Leave enough slack in the lead wires to permit temporary removal of the mats during the first pour. Carefully ground all leads using the grounding braids provided.
3. Secure all splices with approved crimped connectors or set screw clamps. Tape all of the power splices with plastic tape to make them waterproof. All junction boxes, fittings, and snug bushings.
must be approved for this class of application. The entire installation must be completely waterproof to ensure trouble-free operation.

In Concrete
1. Pour and finish each slab area between the expansion joints individually. Pour the base slab and rough level to within 40 to 50 mm of the desired finish level. Place the mats in position and check for damage.
2. Pour the top slab over the mats while the rough slab is still wet, and cover the mats to a depth of at least 40 mm, but not more than 50 mm.
3. Do not walk on the mats or strike them with shovels or other tools.
4. Except for brief testing, do not energize the mats until the concrete is completely cured.

In Asphalt
1. Pour and level the base course. If units are to be installed on an existing asphalt surface, clean it thoroughly.
2. Apply a bituminous binder course to the lower base, install the mats, and apply a second binder coating over the mats. The finish topping over the mats should be applied in a continuous pour to a depth of 30 to 40 mm. Note: Do not dump a large mass of hot asphalt on the mats because the heat could damage the insulation.
3. Check all circuits with an ohmmeter to be sure that no damage occurred during the installation.
4. Do not energize the system until the asphalt has completely hardened.

Infrared Snow-Melting Systems

While overhead infrared systems can be designed specifically for snow-melting and pavement drying, they are usually installed for the additional features they offer. Infrared systems provide comfort heating, which can be particularly useful at the entrances of plants, office buildings, and hospitals or on loading docks. Infrared lamps can improve the security, safety, and appearance of a facility. These additional benefits may justify the somewhat higher cost of infrared systems.

Infrared fixtures can be installed under entrance canopies, along building facades, and on freestanding poles. Approved equipment is available for recess, surface, and pendant mounting.

Infrared Fixture Layout. The same infrared fixtures used for comfort heating installations (as described in Chapter 15 of the 2000 ASHRAE Handbook—Systems and Equipment) can be used for snow-melting systems. The major differences in fixture selection result from the difference in the orientation of the target area. Whereas in comfort applications the vertical surfaces of the human body constitute the target of irradiation, in snow-melting applications it is a horizontal surface that is targeted. When snow melting is the primary design concern, fixtures with narrow beam patterns confine the radiant energy within the target area for more efficient operation. Asymmetric reflector fixtures, which aim the thermal radiation primarily to one side of the fixture centerline, are often used near the periphery of the target area.

Infrared fixtures usually have a longer energy pattern parallel to the long dimension of the fixture than at right angles to it (Frier 1965). Therefore, fixtures should be mounted in a row parallel to the longest dimension of the area. If the target area is 2.4 m or more in width, it is best to locate the fixtures in two or more parallel rows. This arrangement also provides better comfort heating because radiation is directed across the target area from both sides at a more favorable incident angle.

Radiation Spill. In theory, the most desirable energy distribution would be uniform throughout the snow-melting target area at a density equal to the design requirement. The design of heating fixture reflectors determines the percentage of the total fixture output scattered outside the target area design pattern.

Even the best controlled beam fixtures do not produce a completely sharp cutoff at the beam edges. Therefore, if uniform distribution is maintained for the full width of the area, a considerable amount of radiant energy falls outside the target area. For this reason, infrared snow-melting systems are designed so that the intensity on the pavement begins to decrease near the edge of the area (Frier 1964). This design procedure minimizes stray radiant energy losses.

Figure 9 shows the power density values obtained in a sample snow-melting problem (Frier 1965). The sample design average is 480 W/m². It is apparent that the incident power density is above the design average value at the center of the target area and below average at the periphery. Figure 9 shows how the power density and distribution in the snow-melting area depend on the number, wattage, beam pattern, and mounting height of the heaters, and on their position relative to the pavement (Frier 1964).

With distributions similar to the one in Figure 9, snow begins to collect at the edges of the area as the energy requirements for snow melting approach or exceed system capacity. As the snowfall lessens, the snow at the edges of the area and possibly beyond is then melted if the system continues to operate.

Target Area Power Density. Theoretical target area power densities for snow melting with infrared systems are the same as those for commercial applications of constant wattage systems; however, it should be emphasized that theoretical density values are for radiation incident on the pavement surface, not that emitted from the lamps. Merely multiplying the recommended snow-melting power density by the pavement area to obtain the total power input for the system does not result in good performance. Experience has shown that multiplying this product by a correction factor of 1.6 gives a more realistic figure for the total required power input. The resulting wattage compensates not only for the radiant inefficiency involved, but also for the radiation falling outside the target area. For small areas, or when the fixture mounting height exceeds 5 m, the multiplier can be as large as 2.0; large areas with sides of approximately equal length can have a multiplier of about 1.4.

The point-by-point method is the best way to calculate the fixture requirements for an installation. This method involves dividing the target area into 1 m squares and adding the radiant energy from each infrared fixture incident on each square (Figure 9). The radiant energy distribution of a given infrared fixture can be obtained from the equipment manufacturer and should be followed for that fixture size and placement.

Fig. 9 Typical Power Density Distribution for Infrared Snow-Melting System
(Potter 1967)
System Operation. With infrared energy, the target area can be preheated to snow-melting temperatures in 20 to 30 min, unless the air temperature is well below −7°C or wind velocity is high (Frier 1965). This short warm-up time makes it unnecessary to turn on the system before snow begins to fall. The equipment can be turned on either manually or with a snow detector. A timer is sometimes used to turn the system off 4 to 6 h after snow stops falling, allowing time for the pavement to dry completely.

If the snow is allowed to accumulate before the infrared system is turned on, there will be a delay in clearing the pavement, as is the case with embedded hydronic or electric systems. Because the infrared energy is absorbed in the top layer of snow rather than by the pavement surface, the length of time needed depends on the snow depth and on atmospheric conditions. Generally, a system that maintains a clear pavement by melting 25 mm of snow per hour as it falls requires 1 h to clear 25 mm of accumulated snow under the same conditions.

To ensure maximum efficiency, fixtures should be cleaned at least once a year, preferably at the beginning of the winter season. Other maintenance requirements are minimal.

Snow Melting in Gutters and Downspouts

Electrical heating cables are used to prevent heavy snow and ice accumulation on roof overhangs and to prevent ice dams from forming in gutters and downspouts (Lawrie 1966). Figure 10 shows a typical cable layout for protecting a roof edge and downspout. Cable for this purpose is generally rated at approximately 20 to 50 W/m, and about 2.5 m of wire is installed per linear metre of roof edge. One metre of heated wire per linear metre of gutter or downspout is usually adequate.

If the roof edge or gutters (or both) are heated, downspouts that carry away melted snow and ice must also be heated. A heated length of cable (weighted, if necessary) is dropped inside the downspout to the bottom, even if it is underground.

Lead wires should be spliced or plugged into the main power line in a waterproof junction box, and a ground wire should be installed from the downspout or gutter. Ground fault circuit protection is required per the NEC (NFPA Standard 70).

Manual switch control is generally used, although a protective thermostat that senses outdoor temperature should be used to prevent system operation at ambient temperatures above 5°C.

Evaporative cooling is energy-efficient, environmentally benign, and cost-effective in many applications. Applications range from comfort cooling in residential, agricultural, commercial and institutional buildings, to industrial applications for spot cooling in mills, foundries, power plants, and other hot environments. Several types of apparatus cool by evaporating water directly in the airstream, including (1) direct evaporative coolers, (2) spray-filled and wetted surface air washers, (3) sprayed coil units, and (4) humidifiers. Indirect evaporative cooling equipment combine the evaporative cooling effect in a secondary air stream with a heat exchanger to produce cooling without adding moisture to the primary airstream.

Direct evaporative cooling reduces the dry bulb temperature and increases the relative humidity of the air. It is most commonly applied to dry climates or to applications requiring high air exchange rates. Innovative schemes combining evaporative cooling with other equipment have resulted in energy efficient designs.

When temperature and/or humidity must be controlled within narrow limits, heat and mechanical refrigeration can be combined with evaporative cooling in stages. Evaporative cooling equipment, including unitary equipment and air washers, is covered in Chapter 50 of the 2000 ASHRAE Handbook—Systems and Equipment.

**GENERAL APPLICATIONS**

Cooling

Evaporative cooling is used in almost all climates. The wet-bulb temperature of the entering airstream limits direct evaporative cooling. The wet bulb temperature of the secondary airstream limits indirect evaporative cooling.

Design wet-bulb temperatures are rarely higher than 25°C, in which case direct evaporative cooling is economical for spot cooling, kitchens, laundries, agricultural, and industrial applications. At lower wet-bulb temperatures, evaporative cooling can be effectively used for comfort cooling, although some climates may require mechanical refrigeration for part of the year.

Indirect applications lower the air wet-bulb temperature and can produce leaving dry-bulb temperatures that approach the wet-bulb temperature of the secondary airstream. Using room exhaust as secondary air or incorporating precooled air in the secondary airstream lowers the wet-bulb temperature of the secondary air and further enhances the cooling capability of the indirect evaporative cooler.

The direct evaporative cooling process is an adiabatic exchange of heat. Heat must be added to evaporate water. The air into which water is evaporated supplies the heat. The dry-bulb temperature is lowered and sensible cooling results. The amount of heat removed from the air equals the amount of heat absorbed by the water evaporated as heat of vaporization. If water is recirculated in the direct evaporative cooling apparatus, the water temperature in the reservoir approaches the wet-bulb temperature of the air entering the process. By definition, no heat is added to, or extracted from, an adiabatic process. The initial and final conditions of an adiabatic process fall on a line of constant total heat (enthalpy), which nearly coincides with a line of constant wet-bulb temperatures.

The maximum reduction in dry-bulb temperature is the difference between the entering air dry- and wet-bulb temperatures. If the air is cooled to the wet-bulb temperature, it becomes saturated and the process would be 100% effective. Effectiveness is the depression of the dry-bulb temperature of the air leaving the apparatus divided by the difference between the dry- and wet-bulb temperatures of the entering air. Theoretically, adiabatic direct evaporative cooling is less than 100% effective, although evaporative coolers are 85 to 95% or even more effective.

When a direct evaporative cooling unit alone cannot provide the desired conditions, several alternatives can satisfy application requirements and still be energy effective and economical to operate. The recirculating water supplying the direct evaporative cooling unit can be increased in volume and chilled by mechanical refrigeration to provide lower leaving wet-and dry-bulb temperatures and lower humidity. Compared to the cost of using mechanical refrigeration only, this arrangement reduces operating costs by as much as 25 to 40%. Indirect evaporative cooling applied as a first stage, upstream from a second, direct evaporative stage, reduces both the entering dry- and wet-bulb temperatures before the air enters the direct evaporative cooler. Indirect evaporative cooling may save as much as 60 to 75% of the total cost of operating mechanical refrigeration to produce the same cooling effect. Systems may combine indirect evaporative cooling, direct evaporative cooling, heaters, and mechanical refrigeration, or any combination of these processes.

The psychrometric chart in Figure 1 illustrates what happens when air is passed through a direct evaporative cooler. In the example shown, assume an entering condition of 35°C db and 24°C wb. The initial difference is 35 − 24 = 11 K. If the effectiveness is 80%, the depression is 0.80 × 11 = 8.8 K. The dry-bulb temperature leaving the direct evaporative cooler is 35 − 8.8 = 26.2°C. In the adiabatic evaporative cooler, only a portion of the water recirculated is assumed to evaporate and the water supply is recirculated. The recirculated water will reach an equilibrium temperature that is approximately the same as the wet bulb temperature of the entering air.

The performance of an indirect evaporative cooler can also be shown on a psychrometric chart [Figure 1]. Many manufacturers of indirect evaporative cooling equipment use a similar definition of effectiveness as is used for a direct evaporative cooler. In indirect evaporative cooling, the cooling process in the primary airstream follows a line of constant moisture content (constant dew point). Indirect evaporative cooling effectiveness is the dry-bulb depression in the primary airstream divided by the difference between the entering dry-bulb temperature of the primary airstream and the entering wet-bulb temperature of the secondary air. Depending on the heat exchanger design and relative air quantities of primary and secondary air, effectiveness ratings may be as high as 85%.

Assuming an effectiveness of 60%, and assuming both primary air and secondary air enter the apparatus at the outdoor condition of 35°C db and 24°C wb, the dry-bulb depression is 0.60 × (35 − 24) = 6.6 K. The dry-bulb temperature leaving the indirect evaporative
Saturation depends on the extent of the contact between air and washer spray arrangements is between 50 and 98%. The degree of typical saturation or humidifying effectiveness of various air approaches the thermodynamic wet-bulb temperature of the entering air. Evaporation occurs from the recirculated liquid its temperature exceed the final required dew-point temperature, with 0.5 to 1 K below dew-point being common. The dust removal efficiency of direct evaporative coolers depends largely on the size, density, wettability, and solubility of the dust particles. Larger, more wettable particles are the easiest to remove. Separation is largely a result of the impingement of particles on the wetted surface of the eliminator plates or on the surface of the media. Because the force of impact increases with the size of the solid, the impact (together with the adhesive quality of the wetted surface) determines the cooler's usefulness as a dust remover. The standard low-pressure spray is relatively ineffective in removing smoke, because the small particles (less than 1 µm) do not impinge with sufficient impact to pierce the water.

The airstream can not be brought to complete saturation, but its state point changes adiabatically along a line of constant enthalpy. As evaporation occurs from the recirculated liquid its temperature approaches the thermodynamic wet-bulb temperature of the entering air.

The airstream can not be brought to complete saturation, but its state point changes adiabatically along a line of constant enthalpy. As evaporation occurs from the recirculated liquid its temperature approaches the thermodynamic wet-bulb temperature of the entering air.

Fig. 1 Psychrometrics of Evaporative Cooling

cooling process is 35 – 6.6 = 28.4°C. Because the process cools without adding moisture, the wet-bulb temperature is also reduced. Plotting on the psychrometric chart shows that the final wet-bulb temperature is 22.1°C. Because both the wet- and the dry-bulb temperatures in the indirect evaporative cooling process are reduced, indirect evaporative cooling can be used as a substitute for a portion of the refrigeration load in many applications.

Humidification

Air can be humidified with a direct evaporative cooler by three methods: (1) Using recirculated water without prior treatment of the air, (2) preheating the air and treating it with recirculated water, or (3) heating recirculated water. The air leaving an evaporative cooler that is being used as either a humidifier or a dehumidifier will be substantially saturated when in operation. Usually, the spread between leaving dry- and wet-bulb temperatures is less than 1 K. The temperature difference between leaving air and leaving water depends on the difference between entering dry- and wet-bulb temperatures and on certain physical features, such as the length and height of a spray chamber, the cross-sectional area and depth of the media being used, quantity and velocity of air, quantity of water, and the spray pattern. In any direct evaporative humidifier installation, the air should not enter with a dry-bulb temperature of less than 4°C; otherwise, the water may freeze.

Recirculated Water. Except for the small amount of energy added by shaft work from the recirculating pump and the small amount of heat leakage into the apparatus through the unit enclosure, the evaporative humidification process is strictly adiabatic. As evaporation occurs from the recirculated liquid its temperature approaches the thermodynamic wet-bulb temperature of the entering air.

The airstream can not be brought to complete saturation, but its state point changes adiabatically along a line of constant enthalpy. Typical saturation or humidifying effectiveness of various air washer spray arrangements is between 50 and 98%. The degree of saturation depends on the extent of the contact between air and water. Other conditions being equal, a low-velocity airflow is conducive to higher humidifying effectiveness.

Preheated Air. Preheating the air increases both the dry- and wet-bulb temperatures and lowers the relative humidity; it does not, however, alter the humidity ratio (i.e., the mass ratio of water vapor to dry air) or the dew-point temperature of the air. At a higher wet-bulb temperature, but with the same humidity ratio, more water can be absorbed per unit mass of dry air in passing through the direct evaporative humidifier. The analysis of the process that occurs in the direct evaporative humidifier is the same as that for recirculated water. The desired conditions are achieved by heating the desired wet-bulb temperature and evaporatively cooling at constant wet-bulb temperature to the desired dry-bulb temperature and relative humidity. Relative humidity of the leaving air may be controlled by (1) bypassing air around the direct evaporative humidifier or (2) reducing the number of operating spray nozzles or the area of media wetted.

Heated Recirculated Water. Heating of humidifier water increases the effectiveness of a direct evaporative humidifier. When heat is added to the recirculated water, the mixing in the direct evaporative humidifier may still be modeled as an adiabatic process. The state point of the mixture should move toward the specific enthalpy of the heated water. By elevating the water temperature, the air temperature (both dry and wet-bulb) may be raised above the dry-bulb temperature of the entering air. The relative humidity of the leaving air may be controlled by methods similar to those used with preheated air.

Dehumidification and Cooling

Direct evaporative coolers may also be used to cool and dehumidify air. If the entering water temperature is cooled below the entering wet-bulb temperature, both the dry- and wet-bulb temperatures of the leaving air are lowered. Dehumidification results if the leaving water temperature is maintained below the entering air dew point. Moreover, the final water temperature is determined by the sensible and latent heat absorbed from the air and the amount of water circulated. However, the final water temperature cannot exceed the final required dew-point temperature, with 0.5 to 1 K below dew-point being common.

The air leaving a direct evaporative cooler that is being used as a dehumidifier is substantially saturated. Usually, the spread between dry- and wet-bulb temperatures is less than 0.5 K. The temperature difference between leaving air and leaving water depends on the difference between entering dry- and wet-bulb temperatures and on certain design features, such as the cross-sectional area and depth of the media or spray chamber, quantity and velocity of air, quantity of water, and the water distribution.

Air Cleaning

Direct evaporative coolers of all types perform some air cleaning. Rigid media direct evaporative coolers are effective at removing particulate down to about 1 µm in size. Air washers are effective down to about 10 µm. The dust removal efficiency of direct evaporative coolers depends largely on the size, density, wettability, and solubility of the dust particles. Larger, more wettable particles are the easiest to remove. Separation is largely a result of the impingement of particles on the wetted surface of the eliminator plates or on the surface of the media. Because the force of impact increases with the size of the solid, the impact (together with the adhesive quality of the wetted surface) determines the cooler’s usefulness as a dust remover. The standard low-pressure spray is relatively ineffective in removing most atmospheric dusts. Direct evaporative coolers are of little use in removing soot particles because their greasy surface will not adhere to the wet plates or media. Direct evaporative coolers are also ineffective in removing smoke, because the small particles (less than 1 µm) do not impinge with sufficient impact to pierce the water.
Outdoor Air Systems

Control of Gaseous Contaminants. When used in a makeup air system comprised of a mixture of outside air and recirculated air, direct evaporative coolers function as scrubbers and reduce some of the gaseous contaminants found in the atmosphere. These contaminants may concentrate in the recirculating water, so some water needs to be bled off. For more information regarding the control of gaseous contaminants, see Chapter 44.

INDIRECT EVAPORATIVE COOLING

Outdoor Air Systems

Because indirect evaporative cooling does not increase the absolute humidity in the primary airstream, it is well suited for precooling the air entering a refrigerated coil. This precooling reduces the sensible load on the refrigerated coil and compressor. As a result, the size of refrigeration equipment may be reduced, which reduces energy use and operating cost. By contrast, direct evaporative cooling equipment, when used with a refrigerated coil, exchanges latent heat for sensible heat, increasing the latent load on the coil in proportion to the sensible cooling achieved. The enthalpy of the air entering the coil is not changed. The power input per kilowatt of cooling effect is substantially lower with indirect evaporative cooling than with conventional refrigerated equipment.

Peterson and Runn (1991) observed in a study in Dallas that (1) the seasonal energy efficiency ratio (SEER) of an indirect evaporative cooler can be 70% higher than that of a conventional air conditioner and (2) nearly 12% of the air-conditioning capacity can be displaced by the indirect evaporative cooler. However, the additional static pressure created by the indirect equipment increases the motor power of the primary air fan and must be considered, even when continuous cooling is not required. The additional static pressure loss may be as low as 50 Pa, which increases the supply fan power very little. Also, the equipment may require additional energy for water pumping and for moving secondary air across the evaporative surfaces.

The cooling configuration is shown in Figure 2. The primary air side of the indirect unit is positioned at the intake to the refrigerated cooling coil. The secondary air to the unit can come from outdoor ambient air or from room exhaust air. Exhaust air from the space may have a lower wet-bulb temperature than outdoor ambient, depending on climate, time of year, and space latent load. Latent cooling may be possible in the primary airstream using room exhaust air as secondary air. This may occur if the dew-point temperature of the primary air is above the exhaust (secondary air) wet-bulb temperature. As mixture temperature increases, or as secondary air wet-bulb decreases, the precooling contribution becomes more significant.

In variable-air-volume (VAV) systems, a decrease in supply air volume (during periods of reduced load) results in lower air velocity through the indirect evaporative cooler; this increases equipment effectiveness. Lower static pressure loss reduces the energy consumed by the supply fan motor.

Indirect Evaporative Cooling With Heat Recovery

In indirect evaporative cooling, outside supply air passes through an air-to-air heat exchanger and is cooled by evaporatively cooled air exhausted from the building or application. The two air streams never mix or come into contact, so no moisture is added to the supply air stream. Cooling the building’s exhaust air results in a larger overall temperature difference across the heat exchanger and a greater cooling of the supply air. Indirect evaporative cooling requires only fan and water pumping power, so the coefficient of performance tends to be high. The principle of indirect evaporative cooling is effective in most air-conditioned buildings, because the evaporative cooling process is applied to the exhaust air rather than the outside air.

Indirect evaporative cooling has been applied in a number of heat recovery applications (Mathur 1993a). For example, plate heat exchangers (Scofield and DesChamps 1984, Wu and Yellot 1987), heat pipe exchangers (Mathur 1991, 1998; Scofield 1986), rotary regenerative heat exchangers (Woolridge et al. 1976), and two phase thermosiphon loop heat exchangers (Mathur 1992, 1990). The principle of indirect evaporative cooling has also been applied to residential air conditioning where the outside condensing unit is evaporatively cooled to enhance performance (Mathur 1997; Mathur and Goswami 1995, Mathur et al. 1993b). Indirect evaporative cooling with heat recovery is covered in detail in Chapter 44.

Fig. 2 Indirect Evaporative Cooling Configuration

mixed air is more than a few degrees above the wet-bulb temperature of the secondary airstream, indirect evaporative cooling of the mixed air-stream may reduce the amount of refrigerated cooling required. The cooling contribution depends on the differential between the mixed air dry-bulb temperature and secondary air wet-bulb temperature. As mixture temperature increases, or as secondary air wet-bulb decreases, the precooling contribution becomes more significant.

In variable-air-volume (VAV) systems, a decrease in supply air volume (during periods of reduced load) results in lower air velocity through the indirect evaporative cooler; this increases equipment effectiveness. Lower static pressure loss reduces the energy consumed by the supply fan motor.

Indirect Evaporative Cooling With Heat Recovery

In indirect evaporative cooling, outside supply air passes through an air-to-air heat exchanger and is cooled by evaporatively cooled air exhausted from the building or application. The two air streams never mix or come into contact, so no moisture is added to the supply air stream. Cooling the building’s exhaust air results in a larger overall temperature difference across the heat exchanger and a greater cooling of the supply air. Indirect evaporative cooling requires only fan and water pumping power, so the coefficient of performance tends to be high. The principle of indirect evaporative cooling is effective in most air-conditioned buildings, because the evaporative cooling process is applied to the exhaust air rather than the outside air.

Indirect evaporative cooling has been applied in a number of heat recovery applications (Mathur 1993a). For example, plate heat exchangers (Scofield and DesChamps 1984, Wu and Yellot 1987), heat pipe exchangers (Mathur 1991, 1998; Scofield 1986), rotary regenerative heat exchangers (Woolridge et al. 1976), and two phase thermosiphon loop heat exchangers (Mathur 1992, 1990). The principle of indirect evaporative cooling has also been applied to residential air conditioning where the outside condensing unit is evaporatively cooled to enhance performance (Mathur 1997; Mathur and Goswami 1995, Mathur et al. 1993b). Indirect evaporative cooling with heat recovery is covered in detail in Chapter 44.

BOOSTER REFRIGERATION

Staged evaporative coolers can totally cool office buildings, schools, gymnasiums, sports facilities, department stores, restaurants, factory space, and other buildings. These coolers can control

Fig. 3. Indirect/Direct Two-Stage System Performance

In dry climates, evaporative cooling is effective, with lower air velocities than those required in humid climates. Packaged direct evaporative coolers are used for residential and commercial applications. Cooler capacity may be determined from standard heat gain calculations (see Chapters 27 and 28 of the 1997 ASHRAE Handbook—Fundamentals).

Detailed calculation of heat load, however, is usually not economically justified. Instead, one of several estimates give satisfactory results. In one method, the difference between dry-bulb design temperature and coincident wet-bulb temperature multiplied by 10 is equal to the number of seconds needed for each air change. This or any other arbitrary method for equating cooling capacity with airflow depends on a direct evaporative cooler effectiveness of 70 to 80%. Obviously, the method must be modified for unusual conditions such as large unshaded glass areas, uninsulated roof exposure, or high internal heat gain. Also, such empirical methods make no attempt to predict air temperature at specific points; they merely establish an air quantity for use in sizing equipment.

Example 1. An indirect evaporative cooler is to be installed in a 15 by 24.4 m one-story office building with a 3 m ceiling and a flat roof. The following heat gains are to be used in the design:

Find the required airflow, the temperature and humidity ratio of the air leaving the cooler (entering the office), and the temperature and humidity ratio of the air leaving the office.

Solution: A temperature rise of 5°C in the cooling air is assumed. The dry-bulb temperature of the air leaving the indirect evaporative cooler is found from the following equation:

\[
\frac{q_s}{\rho c_p(t_i - t_f)} = \rho c_p(t_i - t_f) = 8.0 \text{ m}^3/\text{s}
\]

where:

- \( Q_{ua} \) = required airflow, m³/s
- \( q_s \) = instantaneous sensible heat load, kW
- \( t_i \) = indoor air dry-bulb temperature, °C
- \( t_f \) = room supply air dry-bulb temperature, °C
- \( \rho c_p \) = density times specific heat of air = 1.2 kJ/(m³·K)

This air volume represents a 137 s [15 × 24.4 × 38.0] air change for a building of this size. The indirect evaporative air cooler is assumed to have a saturation effectiveness of 80%. This is the ratio of the reduction of the dry-bulb temperature to the wet-bulb depression of the entering air. The dry-bulb temperature of the air leaving the indirect evaporative cooler is found from the following equation:
Evaporative Cooling Applications

\[ t_2 = t_1 - \frac{q_e}{100} (t_1 - t') = 35 - \frac{80}{100} (35 - 18.3) = 21.6^\circ \text{C} \]  \hspace{1cm} (2)

where:
- \( t_2 \) = dry-bulb temperature of leaving air, °C
- \( t_1 \) = dry-bulb temperature of entering air, °C
- \( q_e \) = humidifying or saturating effectiveness, %
- \( t' \) = thermodynamic wet-bulb temperature of entering air, °C

From the psychrometric chart, the humidity ratio \( W_e \) of the cooler discharge air is 11.85 g/kg dry air. The humidity ratio \( W_i \) of the air leaving the space being cooled is found from the following equation:

\[ W_3 = Q_{ra} + W_2 \]  \hspace{1cm} (3)

\[ W_3 = \frac{6.2}{3.010 \times 8.0} + 11.85 = 12.11 \text{ g/kg (dry air)} \]

where \( q_e \) = latent heat load in kW.

The remaining values of wet-bulb temperature and relative humidity for the problem may be found from the psychrometric chart. Figure 4 illustrates the various relationships of outdoor air, supply air to the space, and discharge air.

The wet-bulb depression (WBD) method to estimate airflow gives the following result:

\[ \text{WBD} \times 10 = (35 - 18.3) \times 10 = 167 \text{ s per air change} \]

\[ Q_{ra} = \frac{\text{volume}}{\text{air change rate}} = \frac{15 \times 24.4 \times 3}{167} = 6.6 \text{ m}^3/\text{s} \]

While not exactly alike, these two air volume calculations are close enough to select cooler equipment of the same size.

![Psychrometric Diagram for Example 1](image)

**EXHAUST REQUIRED**

If air is not exhausted freely, the increased static pressure will reduce airflow through the evaporative cooler. This result is a marked increase in the moisture and the heat absorbed per unit mass of air leaving the evaporative cooler. This reduced airflow also reduces the air velocity in the room. The combination of these effects reduces the comfort level. Properly designed systems should have a maximum air velocity of 2.5 m/s through the exhaust. If the exhaust area is not sufficient, a powered exhaust should be used. The amount of power depends on the total airflow and the amount of free or gravity exhaust. Some applications require that the powered exhaust capacity equal the cooler output.

**TWO-STAGE COOLING**

Two-stage coolers for commercial applications can extend the range of atmospheric conditions under which comfort requirements can be met, as well as reduce the energy cost. (For the same design conditions, two-stage cooling provides lower cool air temperatures, which reduces the required airflow.)

**INDUSTRIAL APPLICATIONS**

In factories with large internal heat loads, it is difficult to simply ventilate and approach outdoor conditions during the summer without using extremely large quantities of outdoor air. Both direct and indirect evaporative cooling may be used to reduce heat stress with less outdoor air. Evaporative cooling normally results in lower effective temperatures than ventilation alone, regardless of the ambient relative humidity.

**Effective Temperature.** Comfort cooling in air-conditioned spaces is usually based on providing space temperature and relative humidity conditions designed to provide human comfort without a draft. The effective temperature relates the cooling effects of air motion and air relative humidity to the effect of air-conditioned (refrigerated) air. Figure 5 shows an effective temperature chart for air velocities ranging from 0.1 to 3.5 m/s. Although the maximum velocity shown on the chart is 3.5 m/s, workers exposed to high heat-producing operations may request air movement up to 20 m/s to offset the radiant heat effect of the equipment. Because the normal working range of the chart is approximately midway between the vertical dry- and wet-bulb scales, changes in either dry-bulb or wet-bulb temperatures have similar impacts on worker comfort. A reduction in either one will decrease the effective temperature by about one-half of the reduction. Lines ED and CD on the chart graphically illustrate this.

A condition of 35°C dry bulb and 24°C wet bulb was chosen as the original state, because this condition is usually considered the summer design criteria in most areas. Reducing the temperature 8 K by evaporating water adiabatically provides an effective temperature reduction of 3 K for air moving at 0.1 m/s and a reduction of 5 K for air moving at 3.5 m/s—an improvement of 2 K.

The reduction in dry-bulb temperature through water evaporation increases the effectiveness of the cooling power of moving air in this example by 137%. On Line ED, the effective temperature varies from 28.5°C at 0.1 m/s to 26.5°C at 3.5 m/s with unconditioned air, whereas Line CD indicates an effective temperature of 25.5°C at 0.1 m/s and 21.5°C at 3.5 m/s with air cooled by a simple direct evaporative process. In the unconditioned case, increasing the air velocity from 0.1 to 3.5 m/s resulted in only a 2 K decrease in effective temperature. This contrasts with a 4 K decrease in effective temperature for the same range of air movement when the dry-bulb temperature was lowered by water evaporation. This demonstrates that direct evaporative cooling can provide a more comfortable environment regardless of geographical location.

Two methods are demonstrated to illustrate the environmental improvement that may be achieved with evaporative coolers. In one
method, shown in [Figure 6], temperature is plotted against time of day to illustrate effective temperature depression over time. Curve A shows ambient maximum dry-bulb temperature recordings. Curve B shows the corresponding wet-bulb temperatures. Curve C depicts the effective temperature when unconditioned air is moved over a person at 1.5 m/s. Curve D illustrates air conditioned in an 80% effective direct evaporative cooler before being projected over the person at 1.5 m/s. Curve E shows the additional decrease in effective temperature with air velocities of 3.5 m/s. While a maximum suggested effective temperature of 27°C is briefly exceeded with unconditioned air at 1.5 m/s (Curve C), both the differential and the total hours are substantially reduced from still air conditions. Curves D and E illustrate that, in spite of the high wet-bulb temperatures, the in-plant environment can be continuously maintained below the suggested upper limit of 27°C effective temperature. This demonstration assumes that the combination of air velocity, duct length, and insulation between the evaporative cooler and the duct outlet is such that there is little heat transfer between air in the ducts and warmer air under the roof.

[Figure 7] illustrates another method of demonstrating the effect of using direct evaporative coolers by plotting effective comfort zones using ambient wet- and dry-bulb temperatures on an ASHRAE Psychrometric Chart (Crow 1972). The dashed lines show the improvement to expect when using an 80% effective direct evaporative cooler.

**Area Cooling**

Both direct and indirect evaporative cooling may be used for area or spot cooling of industrial buildings. Both can be controlled either
automatically or manually. In addition, evaporative coolers can supply tempered air during fall, winter, and spring. Gravity or power ventilators exhaust the air. Area cooling works well in buildings where personnel move about and workers are not subjected to concentrated, radiant heat sources. Area cooling may be used in either high- or low-bay industrial buildings, but may provide significant advantages in high-bay construction where cooling loads associated with roofs, lighting, and heat from equipment may be effectively eliminated by taking advantage of stratification. When cooling an area, the ductwork should be designed to distribute air to the lower 3 m of the space to ensure that air is supplied to the workers.

Cooling requirements change from day to day and season to season, so, if discharge grilles are used, they should be adjustable to prevent drafts. The horizontal blades of an adjustable grille can be adjusted so that the air is discharged above the workers’ heads rather than directly on them. In some cases, the air volume can be adjusted, either at each outlet or the entire system, in which case, the exhaust volume may need to be varied accordingly.

**Spot Cooling**

Spot cooling yields more efficient use of the equipment when personnel work in one spot. The cool air is brought to the spot at levels below 3 m, and may even be delivered from floor outlets. Selection of the duct height may depend on the location of other equipment in the area. For best results, air velocity should be kept low. Controls may be automatic or manual, with the fan often operating throughout the year. Workers are especially appreciative of spot cooling in hot environments, such as in chemical plants and die casting shops, and near glass-forming machines, billet furnaces, and pig and ingot casting.

When spot cooling a worker, the air volume depends on the throw of the air jet, the activity of the worker, and the amount of heat that must be overcome. Air volumes can vary from 90 to 2400 L/s per worker, with target velocities ranging between 1 to 20 m/s. The outlets should be between 1.2 to 3 m from the workstations to avoid entrainment of warm air and to effectively blanket workers with cooler air. Provisions should be made for workers to control the direction of air discharge, because air motion that is appropriate for hot weather may be too great for cool weather or even cool mornings. Volume controls may be required to prevent overcooling of the building and to minimize excessive grille blade adjustment.

Spot cooling is useful in rooms with elevated temperatures, regardless of climatic or geographical location. When the dry-bulb temperature of the air is below skin temperature, convection rather than evaporation cools workers. An 27°C airstream feels so good that its relative humidity is inconsequential.

**Cooling Large Motors**

Electrical generators and motors are generally rated for a maximum ambient temperature of 40°C. When this temperature is exceeded, excessive temperatures develop in the electrical windings unless the load on the motor or generator is reduced. By providing evaporatively cooled air to the windings, this equipment may be safely operated without reducing the load. Likewise, transformer capacity can be increased using evaporative cooling.

The heat emitted by high-capacity electrical equipment may also be sufficient to raise the ambient condition to an uncomfortable level. With mill drive motors, an additional problem is often encountered with the commutator. If the air used to ventilate the motor is dry, the temperature rise through the motor results in a still lower relative humidity. At a lower relative humidity, the brush film can be destroyed, with unusual brush and commutator wear as well as the occurrence of dusting.

As a rule, a motor having a temperature rise of 14 K requires approximately 60 L/s of ventilating air per kilowatt hour of loss. If the inlet air to the motor is 35°C, the air leaving the motor would be 49°C. This average motor temperature rise of over 42°C is 2 K higher than it should be for the normal 40°C ambient. The same quantity of 35°C inlet air, having a 24°C wet-bulb can be cooled
with a direct evaporative cooler having a 97% saturation effectiveness. The resulting 31°C average motor temperature would eliminate the need for special high-temperature insulation and improve the ability of the motor to absorb temporary overloads. By comparison, an air quantity of 90 L/s would be required if supplied by a cooler with 80% saturation effectiveness. Figure 8 shows three basic arrangements for motor cooling.

The air from the evaporative cooler may be directed on the motor windings or into the room. Doing so requires an increased air volume to compensate for the building heat load. Operation of a direct evaporative cooler should be keyed to the motor operation to ensure that (1) saturated or nearly saturated air is never introduced into a motor until it has had time to warm up, and (2) if more than one motor is served by a single system, air circulation through idle motors should be prevented.

**Cooling Gas Turbine Engines and Generators**

Combustion turbines used for electric power production are normally rated at 15°C. Their performance is greatly influenced by the compressor inlet air temperature because temperature affects air density and therefore mass flow. As the ambient temperature increases, the demand on electric utilities also increases. At the same time, the capacity of the combustion turbine decreases. Recovery of capacity due to inlet air cooling is approximately 0.2%/K (cooling). Direct and indirect evaporative cooling is beneficial to gas turbine performance in almost all climates because when the air is the hottest, it generally has the lowest relative humidity. Expected increases in output using direct evaporative cooling ranges from 5.8% in Albany, New York, to 14% in Yuma, Arizona. In addition to increasing gas turbine output, direct evaporative cooling also improves heat rate and reduces NOx emissions.

For an installation of this type, the following precautions must be taken: (1) mist eliminators must be provided to stop the entrainment of free moisture droplets, (2) coolers must be turned off at a temperature below 7°C to prevent icing, and (3) water quality must be monitored closely (Stewart 1999).

**Process Cooling**

In the manufacture of textiles and tobacco and in processes such as spray coating, accurate relative humidity control is required, which can be provided by direct evaporative coolers. For example, textile manufacturing requires relatively high humidity and the machinery load is heavy; so a split system is customarily used whereby free moisture is introduced directly into the room. The air handled is reduced to approximately 60% of that normally required by an all-outdoor air, direct evaporative cooler.

**Cooling Laundries**

Laundries have one of the most severe environments in which direct evaporative air cooling is applied because heat is produced not only by the processing equipment, but by steam and water vapor as well. A properly-designed direct evaporative cooler reduces the temperature in a laundry 3 to 6 K below the outdoor temperature. With only fan ventilation, laundries usually exceed the outdoor temperature by at least 5 K. Air distribution should be designed for a maximum throw of not more than 9 m. A minimum circulated velocity of 0.5 to 1 m/s should prevail in the occupied space. Ducts can be located to discharge the air directly onto workers in the exceptionally hot areas, such as the pressing and ironing departments. For these outlets, there should be some means of manual control to direct the air where it is desired, with at least 250 to 500 L/s at a target velocity of 3 to 4.5 m/s for each workstation.

**Cooling Wood and Paper Products Facilities**

Wood processing plants and paper mills are good applications for evaporative cooling because of the high temperatures and gasses associated with wood processing equipment. Attention should be paid to keeping wood dust out of the sumps of evaporative coolers that use sumps for recirculation. Wood dust contains microorganisms and worm larvae that will grow in sumps.

Because of the types of gasses and particulates present in most paper plants, water-cooled systems are preferred over air-cooled systems. The most prevalent contaminant is wood dust. Chlorine gas, caustic soda, sulfur, hydrogen sulfide, and other compounds are also serious problems, because they accelerate the corrosion of steel and yellow metals. With more efficient air scrubbing, ambient air quality in and about paper mills has become less corrosive, which has allowed the use of equipment with well-analyzed and properly applied coatings on coils and housings. Phosphor-free brazed coil joints should be used in areas where sulfur compounds are present.

Heat is readily available from the processing operations and should be used whenever possible. Most plants have quality hot water and steam, which can be readily geared to unit heater, central station, or reheat use. Newer plant air-conditioning methods, including evaporative cooling, that use energy conservation techniques (such as temperature stratification) lend themselves to this type of large structure. Chapter 23 has further information on air-conditioning of paper facilities.

**OTHER APPLICATIONS**

**Cooling Power Generation Facilities**

An appropriate air cooling system can be selected once the preliminary heating and cooling loads are determined and the criteria are established for temperature, humidity, pressure, and airflow control. The same considerations for selection apply to power generation facilities and industrial facilities.

**Cooling Mines**

Chapter 24 describes various evaporative cooling methods developed for cooling mines.

**Cooling Animals**

The design criteria for farm animal environments and the need for cooling animal shelters are discussed in Chapter 21. Direct evaporative cooling is ideally suited to farm animal shelters because 100% outside air is used. The fresh air removes odors and reduces the harmful effects of ammonia fumes. At night and in the spring and fall, direct evaporative cooling can also be used for ventilation.

The equipment should be sized to change the air in the shelter in 1 to 2 min, assuming the ceiling height does not exceed 3 m. This flow rate will usually keep the shelter at 27°C or lower. In addition, conditions can be improved with portable or packaged spot coolers.

For poultry housing most applications require an air change every 0.75 to 1.5 min., with the majority at 1 min. Placement of the fans at the ends or the center of the house, with the direct evaporative cooler located at the opposite end, creates a tunnel ventilation system with an air velocity of 1.5 to 2.5 m/s. The fans are generally selected for a total pressure drop of 30 Pa, which means that the direct evaporative cooling media cannot have a pressure drop in excess of 20 Pa. Thus, to guard against an inadequate volume of air being pulled through the poultry house, the designer must carefully size media being selected.

Using direct evaporative cooling for poultry broiler houses decreases bird mortality, improves feed conversion ratio, and increases the growth rate. Poultry breeder houses are evaporatively cooled to improve egg production and fertility during warm weather. Evaporative cooling of egg layers improves feed conversion, shell quality, and egg size. When the ambient outside temperature exceeds 38°C, evaporative cooling is often the only way to keep a flock alive. Direct evaporative cooling is also used to cool swine farrowing and gestation houses to improve production.
Evaporative Cooling Applications

Produce Storage Cooling

Potatoes. Direct evaporative cooling for bulk potato storage should pass air directly through the pile. The ventilation and cooling system should provide 10 to 15 m³/s per kilogram of potatoes. Average potato density is 720 kg/m³ in the pile. Pile depth range from 3.5 to 6 m deep, which creates a static pressure of 40 to 60 Pa. Ventilation consists of fresh air inlets, return air openings, exhaust air openings, main air ducts, and lateral ducts with holes or slots to distribute air uniformly through the pile. Distribution ducts should be placed no further apart than 80% of the potato pile depth, and should extend to within 450 mm of the walls of the storage. Ducts, the direct evaporative cooling media, and any refrigeration coils cause a static pressure ranging from 120 to 250 Pa. Typically the static pressure ranges from 200 to 300 Pa depending on the equipment. The velocity through each of the openings in the ventilation/cooling system should be as listed in Table 1.

Direct evaporative cooling media should be 90 to 95% effective depending on the climate. In arid regions, 95% effective media is recommended. In the more humid climates, such as in the midwestern and eastern United States, 90% effective media is commonly used. The velocity through the media should be 2.5 to 2.8 m/s to assure high pad efficiency with low static pressure penalty.

Apples. Direct evaporative cooling for apple storage without refrigeration should distribute cool air to all parts of the storage. The evaporative cooler may be floor-mounted or located near the ceiling in a fan room. Air should be discharged horizontally at ceiling level. Because the prevailing wet-bulb temperature limits the degree of cooling, a cooler with the maximum reasonable size should be installed to reduce the storage temperature rapidly and as close to the desired temperature as possible. Generally, a cooler designed to exchange air every 3 min (20 air changes per hour) is the largest that can be installed. This capacity provides a complete air change every 1 to 1.5 min (40 to 60 air changes per hour) when the storage is loaded.

For further information on apple storage, see Chapter 21 of the 1998 ASHRAE Handbook—Refrigeration.

Citrus. The chief purpose of evaporative cooling as it is applied to fruits and vegetables is to provide an effective, yet inexpensive, means of improving storage. However, it also serves a special function in the case of oranges, grapefruit, and lemons. Although mature and ready for harvest, citrus fruits are often still green. Color change (degreening) is achieved through a sweating process in rooms equipped with direct evaporative cooling. Air with a high relative humidity and a moderate temperature is circulated continuously during the operation. Ethylene gas, the concentration depending on the variety and intensity of green pigment in the rind, allowing the yellow or orange color to become evident. During the degreening operation, a temperature of 21°C and a relative humidity of 88 to 90% are maintained in the sweat room. (In the Gulf States, 28 to 30°C with 90 to 92% rh is used.) The evaporative cooler is designed to deliver 1.9 L/s per field box of fruit (0.11 L/s per kilogram).

Direct and indirect evaporative cooling is also used as a supplement to refrigeration in the storage of citrus fruit. Citrus storage requires refrigeration in the summer, but the required conditions can often be obtained using evaporative cooling during the fall, winter, and spring when the outdoor wet-bulb temperature is low. For further information, see Chapter 22 of the 1998 ASHRAE Handbook—Refrigeration.

Cooling Greenhouses

Proper regulation of greenhouse temperatures during the summer is essential for developing high-quality crops. The principal load on a greenhouse is solar radiation, which at sea level at about noon in the temperate zone is approximately 630 W/m². Smoke, dust, or heavy clouds reduce the radiation load. Table 2 gives solar radiation loads for representative cities in the United States. Note that the values cited are average solar heat gains, not peak loads. Temporary rises in temperature inside a greenhouse can be tolerated; an occasional rise above design conditions is not likely to cause damage.

Not all the solar radiation that reaches the inside of the greenhouse becomes a cooling load. About 2% of the total solar radiation is used in photosynthesis. Transpiration of moisture varies from crop to crop, but typically uses about 48% of the solar radiation. This leaves 50% to be removed by the cooler. Example 2 shows a method for calculating the size of a greenhouse evaporative cooling system.

Example 2. A direct evaporative cooler is to be installed in a 15 m by 30 m greenhouse. Design conditions are assumed to be 34°C db and 23°C wb, and the average solar radiation is 435 W/m². An indoor temperature of 32°C db must not be exceeded at design conditions.

Solution: The direct evaporative air cooler is assumed to have a saturation effectiveness of 80%. Equation (2) may be used to determine the dry-bulb temperature of the air leaving the direct evaporative cooler:

$$t_2 = \frac{34 - 80}{100} (34 - 23) = 25.2°C$$

The following equation may be used to calculate the airflow rate that must be supplied by the direct evaporative cooler:

$$Q_{ca} = \frac{0.5A}{\rho c_p (t_1 - t_2)}$$

where

- $A = $ greenhouse floor area, m²
- $t_1 = $ total incident solar radiation, W/m² of receiving surface
- $\rho c_p = $ density times specific heat = 1150 J/(m³ K) at design conditions

For this problem

$$Q_{ca} = \frac{0.5 \times 15 \times 30 \times 435}{1150(32 - 25.2)} = 12.5 m³/s$$

Horizontal illumination from the direct rays of a noonday summer sun with a clear sky can be as much as 100 klx; under clear glass, this is approximately 90 klx. Crops such as chrysanthemums and carnations grow best in full sun, but many foliage plants, such as gloxinias and orchids, do not need more than 16 to 22 klx. Solar radiation is nearly proportional to light intensity. Thus, the greater the amount of shade, the smaller the cooling capacity required. A value of 1 klx is approximately equivalent to 9 W/m². Although atmospheric conditions, such as clouds and haze, affect the relationship, this is a safe conversion factor. This relationship should be used instead of the information given in Table 2 where illumination can be determined by design or by measurement.

Direct evaporative cooling for greenhouses may be under either positive or negative pressure. Regardless of the type of system used, the length of air travel should not exceed 50 m. The rise in temperature of the cool air limits the throw to this value. Air movement must be kept low due to possible mechanical damage to the plants,

</table>

But it should generally not be less than 0.5 m/s in areas occupied by workers.

**ECONOMIC FACTORS**

Design of direct and indirect evaporative cooling systems and sizing of equipment is based on the load requirements of the application and on the local dry- and wet-bulb design conditions, which may be found in Chapter 2 of the 1997 ASHRAE Handbook—Fundamentals. Total energy use for a specific application during a set period may be forecasted by using annual weather data. Dry-bulb and mean coincident wet-bulb temperatures, with the hours of occurrence, can be summarized and used in a modified bin procedure. The calculations must reflect the hours of use, conditions of load, and occupancy. Because of annual variations in dry and wet-bulb temperatures, and the affect of increasing cooling capacity with decreasing wet-bulb temperatures, bin calculations using mean coincident wet-bulb temperatures generally produce conservative results. When comparing the various cooling systems, the cost analysis should include the annual energy reduction at the applicable electrical rate, plus the anticipated energy cost escalation over the expected life.

Many areas have time-of-day electrical metering as an incentive to use energy during off-peak hours when rates are lowest. Reducing air-conditioning kilowatt demand is especially important in areas with ratcheted demand rates (Scotfield and DesChamps, 1980). Thermal storage using ice banks or chilled water storage may be used as part of a multistage evaporative-refrigerated cooler to combine the energy-saving advantages of evaporative cooling and off-peak savings of thermal storage (Eskra 1980).

**Direct Evaporation Energy Saving**

Direct evaporative cooling may be used in all climates to save cooling and humidification energy. In humid climates, the benefits of direct evaporation are realized during periods when outside air is warm and dry, but cooling savings are unlikely to be realized during peak design conditions. In more arid areas, direct evaporative cooling may partially, or fully, offset mechanical cooling at peak load conditions. Humidification energy savings may be realized during the heating season when outside air is used to provide cooling and humidification. If properly controlled, direct evaporative cooling can use waste heat otherwise rejected from buildings when outside air is used for cooling.

**Indirect Evaporation Energy Saving**

Indirect evaporative cooling may be used in all climates to save cooling and, in some applications, heating energy. In humid climates, indirect evaporative cooling may be used throughout the cooling cycle to precool outside air. Indirect evaporative cooling can be used to extend the range of 100% outside air ventilation to both higher and lower temperatures, and it can be used to increase the percentage of outdoor air a system can support at any given temperature through heat recovery. In high-humidity areas, indirect evaporative cooling may be used (1) to partially offset mechanical cooling requirements at peak load conditions and (2) to provide better control over low-load humidity conditions by permitting the use of smaller refrigeration equipment to provide ventilation over a wider range of outside air conditions. The cost of heating may be reduced when operating below temperatures when minimum outside air quantities exceed the rates of ventilation required for free cooling by using heat recovered from building exhausts.

**Water Cost for Evaporative Cooling**

Typically, tap water is used for evaporative cooling to avoid excessive scaling and associated problems with poor water quality. In designing evaporative coolers, the cost of water treatment is included in the overall project cost. However, water cost is typically ignored for evaporative coolers because it is usually an insignificant part of the operational cost. Depending on the ambient dry-bulb temperature and wet-bulb depression for a specific location, the cost of water could become a significant part of the operational cost (Mathur 1997, 1998).

**PSYCHROMETRICS**

Figure 9 projects space conditions in each city at 25.5°C dry-bulb for these second-stage supply temperatures based on a 95% room sensible heat factor, i.e., room sensible heat/total heat. With the exception of Wichita, Los Angeles, and Seattle, room cond-
An ideal condition for maximum use with minimum energy consumption of a two- and three-stage indirect/direct system is a room sensible heat factor of 90% and higher, a supply air temperature of 16°C, and a dry-bulb room design temperature of 25.5°C. In many cases, third-stage refrigeration is required to ensure satisfactory dry-bulb temperature and relative humidity. Example 3 shows a method for determining the refrigeration capacity for three-stage cooling.

Example 3. Assume the following:
1. Supply air quantity = 11.3 m³/s; supply air temperature = 16°C
2. Design condition = 37°C db and 20°C wb
3. Effectiveness of indirect unit = 60%;
4. Effectiveness of direct unit = 90%

Using Equation (2) indirect unit performance is
\[ 37 - 0.60(37 - 20) = 26.8°C \text{ leaving dry-bulb (16.6°C wb)} \]

Using Equation (2) direct unit performance is
\[ 26.8 - 0.90(26.8 - 16.6) = 17.6°C \text{ db supply air temperature} \]

Calculate booster refrigeration capacity to drop the supply air temperature from 17.6°C to the required 16°C.

If the refrigerating coil is located ahead of the direct unit, the refrigeration capacity is:
\[ \text{kW cooling} = \frac{(h_1 - h_2) \text{ (supply air, L/s)}}{\text{specific volume dry air at leaving air condition}} \]

With numeric values of enthalpies \(h_1\) and \(h_2\) (in kJ/kg) and the specific volume of air (in m³/kg dry air) taken from ASHRAE Psychrometric Chart No. 1, the cooling load is calculated as follows:
\[ (46.5 - 42.8)11.3/0.860 = 48.6 \text{ kW} \]

The load for a coil located in the leaving air of the direct unit is
\[ (46.6 - 42.9)11.3/0.838 = 49.9 \text{ kW} \]

Depending on the location of the booster coil, the above calculations can be used to determine third-stage refrigeration capacity and to select a cooling coil.

Using this example, refrigeration sizing can be compared to conventional refrigeration without staged evaporative cooling. Assuming mixed air conditions to the coil of 27°C db and 19.1°C wb, and the same 16°C db supply air as shown in Figure 11 the refrigerated capacity is
\[ (54.1 - 42.9)11.3/0.833 = 152 \text{ kW} \]

This represents an increase of 103 kW. The staged evaporative effect reduces the required refrigeration by 68%.

**ENTERING AIR CONSIDERATIONS**

The effectiveness of direct and indirect evaporative cooling depends on the condition of the entering air. Where outdoor air is used in a direct evaporative cooler, the design is affected by the prevailing outdoor dry- and wet-bulb temperatures as well as by the application. Where conditioned exhaust air is used as the secondary air for indirect evaporative cooling, the design is less affected by local weather conditions, which makes evaporative cooling viable in hot and humid environments.

For example, in arid areas like Reno, Nevada, a simple, direct evaporative cooler with as effectiveness of 80% provides a leaving air temperature of 19.8°C when dry-bulb and wet-bulb temperatures of the entering air are 35 and 16°C, respectively. In the same location, the addition of an indirect evaporative precooling stage, with an effectiveness of 80%, produces a leaving air condition of 12°C.

In a geographic location such as Atlanta, Georgia, with design temperatures of 34 and 23.5°C, the same direct evaporative cooler could supply only 25.6°C. This could be reduced to 22.1°C by the addition of an indirect evaporative precooling stage that is 80% effective (Supple 1982). If exhaust air from the building served is provided at a stable 24°C dry-bulb and 17°C wet-bulb, an indirect evaporative precooler could deliver air at 20.5°C, substantially...
reducing outside air cooling loads. Under these conditions, indirect evaporative precoolers can provide limited dehumidification capabilities.

Long-term benefits to owners of direct evaporative cooling systems include a 20 to 40% reduction of utility costs compared to mechanical refrigeration (Watt 1988). When used to provide humidity control, the reduction in cooling and humidification energy use ranges from 35 to 90% (Lentz 1991). While direct evaporative cooling does not reduce peak cooling loads in other than arid areas, direct evaporative cooling can reduce both total cooling energy and humidification energy requirements in a wide range of environments, including environments that are considered hot and humid.

Indirect evaporative cooling lowers the temperature (both dry and wet-bulb) of the air entering a direct evaporative cooling stage and, consequently, lowers the supply air temperature. When used with mechanical cooling on 100% outside air systems, where the secondary air is taken from the conditioned space, the precooling effect may reduce peak cooling loads between 50 and 70%. Total cooling requirements may be reduced between 40 and 85% annually depending on location, system configuration, and load characteristics. Indirect evaporative coolers may also function as heat recovery systems, which expands the range of conditions over which the process is used. Indirect evaporative cooling, when used with building exhaust air, is especially effective in hot and humid climates.

CHAPTER 51

FIRE AND SMOKE MANAGEMENT

In building fires, smoke often flows to locations remote from the fire, threatening life and damaging property. Stairwells and elevators frequently fill with smoke, thereby blocking or inhibiting evacuation. Smoke causes the most deaths in fires. Smoke is defined as the airborne solid and liquid particulates and gases produced when a material undergoes pyrolysis or combustion, together with the air that is entrained or otherwise mixed into the mass.

The idea of using pressurization to prevent smoke infiltration of stairwells began to attract attention in the late 1960s. This concept was followed by the idea of the pressure sandwich (i.e., venting or exhausting the fire floor and pressurizing the surrounding floors). Frequently, a building’s ventilation system is used for this purpose. Smoke control systems use fans to pressurize appropriate areas to limit smoke movement in fire situations. Smoke management systems include pressurization and all other methods that can be used singly or in combination to modify smoke movement.

The objective of fire safety is to provide some degree of protection for a building’s occupants, the building and the property inside it, and neighboring buildings. Various forms of analysis have been used to help quantify protection. Specific life safety objectives differ with occupancy; for example, nursing home requirements are different from those for office buildings.

Two basic approaches to fire protection are (1) to prevent fire ignition and (2) to manage fire impact. Figure 1 shows a decision tree for fire protection. The building occupants and managers have the primary role in preventing fire ignition. The building design team may incorporate features into the building to assist the occupants and managers in this effort. Because it is impossible to prevent fire ignition completely, managing fire impact has become significant in fire protection design. Examples of fire impact management include compartmentation, suppression, control of construction materials, exit systems, and smoke management. The Fire Protection Handbook (NFPA 1997a) and Smoke Movement and Control in High-Rise Buildings (Tamura 1994) contain detailed fire safety information.

Historically, fire safety professionals have considered the HVAC system a potentially dangerous penetration of natural building membranes (walls, floors, and so forth) that can readily transport smoke and fire. For this reason, the HVAC has traditionally been shut down when fire is discovered. Although shutting down

---

The preparation of this chapter is assigned to TC 5.6, Control of Fire and Smoke.
by the testing laboratories. Each classification is proprietary, and each applies to use with a specific set of conditions, so numerous types are usually required on any given project.

The construction manager and general contractor, not the architects and engineers, make work assignments. Sometimes they assign fire stopping to the discipline making the penetration; other times, they assign it to a specialty fire stopping subcontractor. The Construction Specifications Institute (CSI) assigns fire stopping specifications to Division 7. Such placement accomplishes three goals:

- It encourages continuity of fire stopping products on the project by consolidating their requirements (e.g., TPFS, expansion joint fire stopping, floor-to-wall joint fire stopping, etc.).
- It maintains flexibility of work assignments for the general contractor and the construction manager.
- It encourages prebid discussions between the contractor and subcontractors regarding appropriate work assignments.

**SMOKE MOVEMENT**

A smoke control system must be designed so that it is not overpowered by the driving forces that cause smoke movement, which include stack effect, buoyancy, expansion, wind, and the HVAC system. During a fire, smoke is generally moved by a combination of these forces.

**Stack Effect**

When it is cold outside, air tends to move upward within building shafts (e.g., stairwells, elevator shafts, dumbwaiter shafts, mechanical shafts, or mail chutes). This normal stack effect occurs because the air in the building is warmer and less dense than the outside air. Normal stack effect is large when outside temperatures are low, especially in tall buildings. However, normal stack effect can exist even in a one-story building.

When the outside air is warmer than the building air, there is a natural tendency for downward airflow, or reverse stack effect, in shafts. At standard atmospheric pressure, the pressure difference due to either normal or reverse stack effect is expressed as

$$\Delta p = 3460 \left( \frac{1}{T_o} - \frac{1}{T_i} \right) h $$

(1)

where

- $\Delta p$ = pressure difference, Pa
- $T_o$ = absolute temperature of outside air, K
- $T_i$ = absolute temperature of air inside shaft, K
- $h$ = distance above neutral plane, m

For a building 60 m tall with a neutral plane at midheight, an outside temperature of $-18^\circ$C (255 K), and an inside temperature of $21^\circ$C (294 K), the maximum pressure difference due to stack effect would be 54 Pa. This means that at the top of the building, a shaft would have a pressure 54 Pa greater than the outside pressure. At the base of the building, the shaft would have a pressure 54 Pa lower than the outside pressure. Figure 2 diagrams the pressure difference between a building shaft and the outside. A positive pressure difference indicates that the shaft pressure is higher than the outside pressure, and a negative pressure difference indicates the opposite. Figure 3 illustrates the air movement in buildings caused by both normal and reverse stack effect.

Figure 4 can be used to determine the pressure difference due to stack effect. For normal stack effect, $\Delta p/h$ is positive, and the pressure difference is positive above the neutral plane and negative below it. For reverse stack effect, $\Delta p/h$ is negative, and the pressure difference is negative above the neutral plane and positive below it.

In unusually tight buildings with exterior stairwells, Klote (1980) observed reverse stack effect even with low outside air temperatures. In this situation, the exterior stairwell temperature is considerably lower than the building temperature. The stairwell represents the cold column of air, and other shafts within the building represent the warm columns of air.

If the leakage paths are uniform with height, the neutral plane is near the midheight of the building. However, when the leakage
paths are not uniform, the location of the neutral plane can vary considerably, as in the case of vented shafts. McGuire and Tamura (1975) provide methods for calculating the location of the neutral plane for some vented conditions.

Smoke movement from a building fire can be dominated by stack effect. In a building with normal stack effect, the existing air currents (as shown in Figure 3) can move smoke considerable distances from the fire origin. If the fire is below the neutral plane, smoke moves with the building air into and up the shafts. This upward smoke flow is enhanced by buoyancy forces due to the temperature of the smoke. Once above the neutral plane, the smoke flows from the shafts into the upper floors of the building. If the leakage between floors is negligible, the floors below the neutral plane (except the fire floor) remain relatively smoke-free until the quantity of smoke produced is greater than can be handled by stack effect flows.

Smoke from a fire located above the neutral plane is carried by the building airflow to the outside through exterior openings in the building. If the leakage between floors is negligible, all floors other than the fire floor remain relatively smoke-free until the quantity of smoke produced is greater than can be handled by stack effect flows. When the leakage between floors is considerable, the smoke flows to the floor above the fire floor.

The air currents caused by reverse stack effect (Figure 3) tend to move relatively cool smoke down. In the case of hot smoke, buoyancy forces can cause smoke to flow upward, even during reverse stack effect conditions.

**Buoyancy**

High-temperature smoke from a fire has a buoyancy force due to its reduced density. At sea level, the pressure difference between a fire compartment and its surroundings can be expressed as follows:

$$\Delta p = 3460 \left( \frac{1}{T_s} - \frac{1}{T_f} \right) h$$  \hspace{1cm} (2)

where

- $\Delta p$ = pressure difference, Pa
- $T_s$ = absolute temperature of surroundings, K
- $T_f$ = average absolute temperature of fire compartment, K
- $h$ = distance above neutral plane, m

The pressure difference due to buoyancy can be obtained from Figure 5 for the surroundings at 20°C (293 K). The neutral plane is the plane of equal hydrostatic pressure between the fire compartment and its surroundings. For a fire with a fire compartment temperature at 800°C (1073 K), the pressure difference 1.5 m above the neutral plane is 13 Pa. Fang (1980) studied pressures caused by room fires during a series of full-scale fire tests. During these tests, the maximum pressure difference reached was 16 Pa across the burn room wall at the ceiling.

Much larger pressure differences are possible for tall fire compartments where the distance $h$ from the neutral plane can be larger. If the fire compartment temperature is 700°C (993 K), the pressure difference 10 m above the neutral plane is 83 Pa. This is a large fire, and the pressures it produces are beyond present smoke control methods. However, the example illustrates the extent to which Equation (2) can be applied.

In sprinkler-controlled fires, the temperature in the fire room remains at that of the surroundings except for a short time before sprinkler activation. Sprinklers are activated by a thin (50 to 100 mm) layer of hot gas under the ceiling. This layer is called the ceiling jet. The maximum temperature of the ceiling jet depends on the location of the fire, the activation temperature of the sprinkler, and the thermal lag of the sprinkler heat-responsive element. For most residential and commercial applications, the ceiling jet is between 80 and 150°C. In Equation (2), $T_j$ is the average temperature of the fire compartment. For a sprinkler-controlled fire,

$$T_j = \frac{T_f(H - H_j) + T_j H_j}{H} \hspace{1cm} (3)$$

where

- $H$ = floor to ceiling height, m
- $H_j$ = thickness of ceiling jet, m
- $T_j$ = absolute temperature of ceiling jet, K

For example, for $H = 2.5$ m, $H_j = 0.1$ m, $T_f = 20 + 273 = 293$ K, and $T_j = 150 + 273 = 423$ K,

$$T_j = \frac{293(2.5 - 0.1) + 423 \times 0.1}{2.5} = 298 \text{ K or } 25^\circ \text{C}$$

In Equation (2), this results in a pressure difference of 0.5 Pa, which is insignificant for smoke control applications.

**Expansion**

The energy released by a fire can also move smoke by expansion. In a fire compartment with only one opening to the building, building air will flow in, and hot smoke will flow out. Neglecting the added mass of the fuel, which is small compared to the airflow, the ratio of volumetric flows can be expressed as a ratio of absolute temperatures:

$$\frac{Q_{out}}{Q_{in}} = \frac{T_{out}}{T_{in}} \hspace{1cm} (4)$$

where

- $Q_{out}$ = volumetric flow rate of smoke out of fire compartment, m³/s
- $Q_{in}$ = volumetric flow rate of air into fire compartment, m³/s
- $T_{out}$ = absolute temperature of smoke leaving fire compartment, K
- $T_{in}$ = absolute temperature of air into fire compartment, K

For a smoke temperature of 700°C (973 K) and an entering air temperature of 20°C (293 K), the ratio of volumetric flows is 3.32. Note that absolute temperatures are used in the calculation. In such a case, if the air flowing into the fire compartment is 1.5 m³/s, the smoke flowing out of the fire compartment would be 5.0 m³/s, with the gas expanding to more than three times its original volume.
For a fire compartment with open doors or windows, the pressure difference across these openings due to expansion is negligible. However, for a tightly sealed fire compartment, the pressure differences due to expansion may be important.

Wind

In many instances, wind can have a pronounced effect on smoke movement within a building. The pressure the wind exerts on a surface can be expressed as

\[ p_w = 0.5 C_w \rho_o V^2 \]  

where

- \( p_w \) = pressure exerted by wind, Pa
- \( C_w \) = dimensionless pressure coefficient
- \( \rho_o \) = outside air density, kg/m\(^3\)
- \( V \) = wind velocity, m/s

The pressure coefficients \( C_w \) are in the range of \(-0.8\) to \(0.8\), with positive values for windward walls and negative values for leeward walls. The pressure coefficient depends on building geometry and varies locally over the wall surface. In general, wind velocity increases with height from the surface of the earth. Sachs (1972), Houghton and Carruther (1976), Simiu and Scanlan (1978), and MacDonald (1975) give detailed information concerning wind velocity variations and pressure coefficients. Shaw and Tamura (1977) have developed specific information about wind data with respect to air infiltration in buildings.

With a pressure coefficient of \(0.8\) and air density of \(1.20\) kg/m\(^3\), a 15 m/s wind produces a pressure on a structure of 110 Pa. The effect of wind on air movement within tightly constructed buildings with all exterior doors and windows closed is slight. However, the effects of wind can be important for loosely constructed buildings or for buildings with open doors or windows. Usually, the resulting airflows are complicated, and computer analysis is required.

Frequently in fire situations, a window breaks in the fire compartment. If the window is on the leeward side of the building, the negative pressure caused by the wind vents the smoke from the fire compartment. This reduces smoke movement throughout the building. However, if the broken window is on the windward side, the wind forces the smoke throughout the fire floor and to other floors, which endangers the lives of building occupants and hampers fire fighting. Pressure induced by the wind in this situation can be large and can dominate air movement throughout the building.

HVAC Systems

Before methods of smoke control were developed, HVAC systems were shut down when fires were discovered because the systems frequently transported smoke during fires.

In the early stages of a fire, the HVAC system can aid in fire detection. When a fire starts in an unoccupied portion of a building, the system can transport the smoke to a space where people can smell it and be alerted to the fire. However, as the fire progresses, the system transports smoke to every area it serves, thus endangering life in all those spaces. The system also supplies air to the fire space, which aids combustion. Although shutting the system down prevents it from supplying air to the fire, it does not prevent smoke movement through the supply and return air ducts, air shafts, and other building openings due to stack effect, buoyancy, or wind.

SMOKE MANAGEMENT

In this chapter, smoke management includes all methods that can be used singly or in combination to modify smoke movement for the benefit of occupants or fire fighters or for the reduction of property damage. Barriers, smoke vents, and smoke shafts are traditional methods of smoke management. The effectiveness of barriers is limited by the extent to which they are free of leakage paths. Smoke vents and smoke shafts are limited by the fact that smoke must be sufficiently buoyant to overcome any other driving forces that could be present. In the last few decades, fans have been used with the intent of overcoming the limitations of traditional approaches. The mechanisms of compartmentation, dilution, pressurization, airflow, and buoyancy are used by themselves or in combination to manage smoke conditions in fire situations. These mechanisms are discussed in the following sections.

Compartmentation

Barriers with sufficient fire endurance to remain effective throughout a fire exposure have a long history of providing protection against fire spread. In such fire compartmentation, walls, partitions, floors, doors, and other barriers provide some level of smoke protection to spaces remote from the fire. This section refers to passive compartmentation. The use of compartmentation with pressurization is discussed in the section on Pressurization (Smoke Control). Many codes, such as NFPA Standard 101, provide specific criteria for the construction of smoke barriers (including doors) and smoke dampers in these barriers. The extent to which smoke leaks through such barriers depends on the size and shape of the leakage paths in the barriers and the pressure difference across the paths.

Dilution Remote from Fire

Dilution of smoke is sometimes referred to as smoke purging, smoke removal, smoke exhaust, or smoke extraction. Dilution can be used to maintain acceptable gas and particulate concentrations in a compartment subject to smoke infiltration from an adjacent space. It can be effective if the rate of smoke leakage is small compared to either the total volume of the safeguarded space or the rate of purging air supplied to and removed from the space. Also, dilution can be beneficial to the fire service for removing smoke after a fire has been extinguished. Sometimes, when doors are opened, smoke flows into areas intended to be protected. Ideally, the doors are only open for short periods during evacuation. Smoke that has entered spaces remote from the fire can be purged by supplying outside air to dilute the smoke.

The following is a simple analysis of smoke dilution for spaces in which there is no fire. Assume that at time zero (\( \theta = 0 \)), a compartment is contaminated with some concentration of smoke and that no more smoke flows into the compartment or is generated within it. Also, assume that the contaminant is uniformly distributed throughout the space. The concentration of contaminant in the space can be expressed as

\[ \frac{C}{C_o} = e^{a t} \]  

where

- \( C_o \) = initial concentration of contaminant
- \( C \) = concentration of contaminant at time \( \theta \)
- \( a \) = dilution rate, air changes per minute
- \( t \) = time after smoke stops entering space or time after which smoke production has stopped, min
- \( e \) = base of natural logarithm (approximately 2.718)

The dilution rate can be determined from the following equation:

\[ a = \frac{1}{t} \ln \left( \frac{C_o}{C} \right) \]
Fire and Smoke Management

McGuire et al. (1970) evaluated the maximum levels of smoke obscuration from a number of fire tests and a number of proposed criteria for tolerable levels of smoke obscuration. Based on this evaluation, they state that the maximum levels of smoke obscuration are greater by a factor of 100 than those relating to the limit of tolerance. Thus, they indicate that a space can be considered “reasonably safe” with respect to smoke obscuration if the concentration of contaminants in the space is less than about 1% of the concentration in the immediate fire area. This level of dilution increases visibility by about a factor of 100 (for example from 0.15 m to 15 m) and reduces the concentrations of toxic smoke components. Toxicity is a more complex problem, and no parallel statement has been made regarding dilution needed to obtain a safe atmosphere with respect to toxic gases.

In reality, it is impossible to ensure that the concentration of the contaminant is uniform throughout the compartment. Because of buoyancy, it is likely that higher concentrations are near the ceiling. Therefore, exhausting smoke near the ceiling and supplying air near the floor probably dilutes smoke even faster than indicated by Equation (6). The supply and exhaust points should be placed to prevent the supply air from blowing into the exhaust inlet, thereby short-circuiting the dilution.

Example 1. A space is isolated from a fire by smoke barriers and self-closing doors, so that no smoke enters the compartment when the doors are closed. When a door is opened, smoke flows through the open doorway into the space. If the door is closed when the contaminant in the space is 20% of the burn room concentration, what dilution rate is required to reduce the concentration to 1% of that in the burn room in 6 min?

The time t = 6 min and C /C = 20. From Equation (7), the dilution rate is about 0.5 air changes per minute or 30 air changes per hour.

Caution about Dilution near Fire

Many people have unrealistic expectations about what dilution can accomplish in the fire space. Neither theoretical nor experimental evidence indicates that using a building's HVAC system for smoke dilution will significantly improve tenable conditions in a fire space. The exception is an unusual space where the fuel is such that fire size can not grow above a specific limit; this occurs in some tunnels and underground transit situations. Because HVAC systems promote a considerable degree of air mixing within the spaces they serve and because very large quantities of smoke can be produced by building fires, it is generally believed that dilution of smoke by an HVAC system in the fire space will not improve the tenable conditions in that space. Thus, any attempt to improve hazard conditions within the fire space, or in spaces connected to the fire space by large openings, with smoke purging will be ineffective.

Pressurization (Smoke Control)

Systems that pressurize an area using mechanical fans are referred to as smoke control in this chapter and in NFPA Standard 92A. A pressure difference across a barrier can control smoke movement, as illustrated in Figure 6. Within the barrier is a door. The high-pressure side of the door can be either a refuge area or an egress route. The low-pressure side is exposed to smoke from a fire. Airflow through the gaps around the door and through construction cracks prevents smoke infiltration to the high-pressure side.

For smoke control analysis, the orifice equation can be used to estimate the flow through building flow paths:

\[ Q = CA^2 \Delta p / \rho \]  

where

- \( Q \) = volumetric airflow rate, m³/s
- \( C \) = flow coefficient
- \( A \) = flow area (leakage area), m²
- \( \Delta p \) = pressure difference across flow path, Pa
- \( \rho \) = density of air entering flow path, kg/m³

\[ V_k = 0.0292 \left( \frac{q_c}{W} \right)^{1/3} \]  

where

- \( V_k \) = critical air velocity to prevent smoke backflow, m/s
- \( q_c \) = heat release rate into corridor, W
- \( W \) = corridor width, m

The flow coefficient depends on the geometry of the flow path, as well as on turbulence and friction. In the present context, the flow coefficient is generally in the range of 0.6 to 0.7. For \( \rho = 1.2 \) kg/m³ and \( C = 0.65 \), the flow equation above can be expressed as

\[ Q = 0.839A \sqrt{\Delta p} \]  

The flow area is frequently the same as the cross-sectional area of the flow path. A closed door with a crack area of 0.01 m² and a pressure difference of 2.5 Pa has an air leakage rate of approximately 0.013 m³/s. If the pressure difference across the door is increased to 75 Pa, the flow is 0.073 m³/s.

Frequently, in field tests of smoke control systems, pressure differences across partitions or closed doors have fluctuated by as much as 5 Pa. These fluctuations have generally been attributed to wind, although they could have been due to the HVAC system or some other source. To control smoke movement, the pressure difference produced by a smoke control system must be sufficiently large to overcome pressure fluctuations, stack effect, smoke buoyancy, and wind pressure. However, the pressure difference should not be so large that the door is difficult to open.

Airflow

Airflow has been used extensively to manage smoke from fires in subway, railroad, and highway tunnels (see Chapter 12). Large airflow rates are needed to control smoke flow, and these flow rates can supply additional oxygen to the fire. Because of the need for complex controls, airflow is not used as extensively in buildings. The control problem consists of having very small flows when a door is closed and then significantly increased flows when that door is open. Furthermore, it is a major concern that the airflow supplies oxygen to the fire. This section presents the basics of smoke control by airflow and demonstrates why this technique is rarely recommended.

Thomas (1970) determined that in a corridor in which there is a fire, airflow can almost totally prevent smoke from flowing upstream of the fire. Molecular diffusion is believed to transfer trace amounts of smoke, which are not hazardous but which are detectable as the smell of smoke upstream. Based on work by Thomas, the critical air velocity for most applications can be approximated as
This relation can be used when the fire is located in the corridor or when the smoke enters the corridor through an open doorway, air transfer grille, or other opening. While the critical velocities calculated from Equation (10) are general and approximate, they are indicative of the kind of air velocities required to prevent smoke backflow from fires of different sizes. For specific applications, other equations may be more appropriate. For the critical velocity for tunnel applications, see Chapter 12. For the critical velocity for smoke management in atriums and other large spaces see Klote and Milke (1992) and NFPA Standard 92B.

Although Equation (10) can be used to estimate the airflow rate necessary to prevent smoke backflow through an open door, the oxygen supplied is a concern. Huggett (1980) evaluated the oxygen consumed in the combustion of numerous natural and synthetic solids. He found that for most materials involved in building fires, the energy released is approximately 13.1 MJ per kilogram of oxygen. Air is 23.3% oxygen by mass. Thus, if all the oxygen in a kilogram of air is consumed, 3.0 MJ is liberated. If all the oxygen in 1 m$^3$ of air with a density of 1.2 kg/m$^3$ is consumed by fire, 3.6 MW will be liberated.

Examples 2 and 3 demonstrate that the air needed to prevent smoke backflow can support an extremely large fire. In most commercial and residential buildings, sufficient fuel (paper, cardboard, furniture, etc.) is present to support very large fires. Even when the amount of fuel is normally very small, short-term fuel loads (during building renovation, material delivery, etc.) can be significant. Therefore, the use of airflow for smoke control is not recommended, except when the fire is suppressed or in the rare cases when fuel can be restricted with confidence.

**Example 2.** What airflow at a doorway is needed to stop smoke backflow from a room fully involved in fire, and how large a fire can this airflow support?

A room fully involved in fire can have an energy release rate on the order of 2.4 MW. Assume the door is 0.9 m wide and 2.1 m high. From Equation (10), $V_c = 0.0292(2.4 \times 10^6/0.9)^{1/3} = 4.0$ m/s. A flow through the doorway of $4.0 \times 0.9 \times 2.1 = 7.6$ m$^3$/s is needed to prevent smoke backflow.

If all the oxygen in this airflow is consumed in the fire, the heat liberated is $7.6$ m$^3$/s $\times 3.6$ MW per m$^3$/s of air = 27 MW. This is over 10 times more than the heat generated by the fully involved room fire and indicates why airflow is generally not recommended for smoke control in buildings.

**Example 3.** What airflow is needed to stop smoke backflow from a wastebasket fire, and how large a fire can this airflow support?

A wastebasket fire can have an energy release rate on the order of 150 kW. As in Example 2, $V_c = 0.0292(150 \times 10^6/0.9)^{1/3} = 1.6$ m/s. A flow through the doorway of $1.6 \times 0.9 \times 2.1 = 3.0$ m$^3$/s is needed to prevent smoke backflow.

If all the oxygen in this airflow is consumed in the fire, the heat liberated is $3$ m$^3$/s $\times 3.6$ MW per m$^3$/s of air = 10.8 MW. This is still many times greater than the fully involved room fire and further indicates why airflow is generally not recommended for smoke control in buildings.

**Buoyancy**

The buoyancy of hot combustion gases is employed in both fan-powered and non-fan-powered ventilation systems. Fan-powered ventilation for large spaces is commonly employed for atriums and covered shopping malls, and non-fan-powered ventilation is commonly used for large industrial and storage buildings. There is a concern that the sprinkler flow will cool the smoke, reducing buoyancy and thus the system effectiveness. Research is needed in this area. Refer to Klote and Milke (1992) and NFPA Standards 92B and 204 for detailed design information about these systems.
door that is 0.9 m by 2.1 m with an average crack width of 3 mm has a leakage area of 0.018 m². However, if this door is installed with a 20 mm undercut, the leakage area is 0.033 m²—a significant difference. The leakage area of elevator doors is in the range of 0.051 to 0.065 m² per door.

For open stairwell doorways, Cresci (1973) found that complex flow patterns exist and that the resulting flow through open doorways was considerably below the flow calculated using the geometric area as the flow area in Equation (8). Based on this research, it is recommended that the design flow area of an open stairwell doorway be half the geometric area (door height times width) of the doorway. An alternate approach for open stairwell doorways is to use the geometric area as the flow area and use a reduced flow coefficient. Because it does not allow the direct use of Equation (8), this alternate approach is not used here.

Typical leakage areas for walls and floors of commercial buildings are tabulated as area ratios in Table 1. These data are based on a relatively small number of tests performed by the National Research Council of Canada (Tamura and Shaw 1976a, 1976b, 1978; Tamura and Wilson 1966). Actual leakage areas depend primarily on workmanship rather than on construction materials, and in some cases, the flow areas in particular buildings may vary from the values listed. Data concerning air leakage through building penetrations are also provided in Chapter 25, Ventilation and Infiltration, of the 1997 ASHRAE Handbook—Fundamentals.

Because a vent surface is usually covered by a louver and screen, the flow area of a vent is less than its area (vent height times width). Calculation of the flow area is further complicated by the fact that the slats in louvers are frequently slanted. Manufacturer’s data should be used for specific information.

Effective Flow Areas

The concept of effective flow areas is useful for analyzing smoke control systems. The paths in a system can be in parallel with one another, in series, or a combination of parallel and series. The effective area of a system of flow areas is the area that gives the same flow as the system when it is subjected to the same pressure difference over the total system of flow paths. This is similar to the effective resistance of a system of electrical resistances. The effective flow area $A_e$ for parallel leakage areas is the sum of the individual leakage paths:

$$A_e = \sum_{i=1}^{n} A_i$$

(12)

where $n$ is the number of flow areas $A_i$ in parallel.

For example, the effective area $A_e$ for the three parallel leakage areas in Figure 8 is

$$A_e = A_1 + A_2 + A_3$$

(13)

If $A_1$ is 0.10 m² and $A_2$ and $A_3$ are each 0.05 m², then the effective flow area $A_e$ is 0.20 m².

The general rule for any number of leakage areas in series is

$$A_e = \left(\sum_{i=1}^{n} \frac{1}{A_i^2}\right)^{-0.5}$$

(14)

where $n$ is the number of leakage areas $A_i$ in series.

Three leakage areas in series from a pressurized space are illustrated in Figure 9. The effective flow area of these paths is

$$A_e = \left(\frac{1}{A_1^2} + \frac{1}{A_2^2} + \frac{1}{A_3^2}\right)^{-0.5}$$

(15)
In smoke control analysis, there are frequently only two paths in series, and the effective leakage area is

\[ A_e = \frac{A_1 A_2}{\sqrt{A_1^2 + A_2^2}} \]  

\text{(16)}

**Example 4.** Calculate the effective leakage area of two equal flow paths in series.

Let \( A_1 = A_2 = 0.02 \text{ m}^2 \). From Equation (16),

\[ A_e = \frac{A_1^2}{\sqrt{2A_1^2}} = 0.014 \text{ m}^2 \]

**Example 5.** Calculate the effective flow area of two flow paths in series, where \( A_1 = 0.02 \text{ m}^2 \) and \( A_2 = 0.2 \text{ m}^2 \). From Equation (16),

\[ A_e = \frac{A_1 A_2}{\sqrt{A_1^2 + A_2^2}} = 0.0199 \text{ m}^2 \]

Example 5 illustrates that when two paths are in series, and one is much larger than the other, the effective flow area is approximately equal to the smaller area.

The method of developing an effective area for a system of both parallel and series paths is to combine groups of parallel paths and series paths systematically. The system illustrated in Figure 10 is analyzed as an example. The figure shows that \( A_2 \) and \( A_3 \) are in parallel; therefore, their effective area is

\[ (A_{23})_e = A_2 + A_3 \]

Areas \( A_4, A_5, \) and \( A_6 \) are also in parallel, so their effective area is

\[ (A_{456})_e = A_4 + A_5 + A_6 \]

These two effective areas are in series with \( A_1 \). Therefore, the effective flow area of the system is given by

**Example 6.** Calculate the effective area of the system in Figure 10, if the leakage areas are \( A_1 = A_2 = A_3 = 0.02 \text{ m}^2 \) and \( A_4 = A_5 = A_6 = 0.01 \text{ m}^2 \).

\[
\begin{align*}
(A_{23})_e &= 0.04 \text{ m}^2 \\
(A_{456})_e &= 0.03 \text{ m}^2 \\
A_e &= 0.015 \text{ m}^2
\end{align*}
\]

**Symmetry**

The concept of symmetry is useful in simplifying problems. Figure 11 illustrates the floor plan of a multistory building that can be divided in half by a plane of symmetry. Flow areas on one side of the plane of symmetry are equal to corresponding flow areas on the other side. For a building to be treated in this manner, every floor of the building must be such that it can be divided in the same manner by the plane of symmetry. If wind effects are not considered in the analysis, or if the wind direction is parallel to the plane of symmetry, the airflow is only one-half the total for the building analyzed. It is not necessary that the building be geometrically symmetric, as shown in Figure 11; it must be symmetric only with respect to flow.

**Design Weather Data**

Little weather data has been developed specifically for the design of smoke control systems. A designer may use the design temperatures for heating and cooling found in Chapter 26 of the 1997 ASHRAE Handbook—Fundamentals. Extreme temperatures can be considerably lower than the winter design temperatures. For example, the 99% design temperature for Tallahassee, Florida, is \(-2.1^\circ\text{C}\), but the lowest temperature observed there was \(-19^\circ\text{C}\) (NOAA 1979).

Temperatures are generally below the design values for short periods, and because of the thermal lag of building materials, these short intervals of low temperature usually do not cause problems with heating. However, there is no time lag for a smoke control system; it is therefore subjected to all the extreme forces of stack effect that exist the moment it is operated. If the outside temperature is below the winter design temperature for which the smoke control system was designed, problems from stack effect may result. A similar situation can occur with respect to summer design temperatures and reverse stack effect.

Extreme wind data for smoke management design are listed in Chapter 26 of the 1997 ASHRAE Handbook—Fundamentals.

**Design Pressure Differences**

Both the maximum and minimum allowable pressure differences across the boundaries of smoke control should be considered. The maximum allowable pressure difference should not cause excessive door-opening forces.
The minimum allowable pressure difference across a boundary of a smoke control system might be the difference such that no smoke leakage occurs during building evacuation. In this case, the smoke control system must produce sufficient pressure differences to overcome forces of wind, stack effect, or buoyancy of hot smoke. The pressure differences due to wind and stack effect can be large in the event of a broken window in the fire compartment. Evaluation of these pressure differences depends on evacuation time, rate of fire growth, building configuration, and the presence of a fire suppression system. NFPA Standard 92A suggests values of minimum and maximum design pressure difference.

Open Doors
Another design concern is the number of doors that could be opened simultaneously when the smoke control system is operating. A design that allows all doors to be open simultaneously may ensure that the system always works, but it probably adds to the cost of the system.

The number of doors that may be open simultaneously depends largely on building occupancy. For example, in a densely populated building, it is likely that all doors will be open during evacuation. However, if a staged evacuation plan or refuge area concept is incorporated in the building fire emergency plan, or if the building is sparsely occupied, only a few of the doors may be open during a fire.

FIRE AND SMOKE DAMPERS
Opening for ducts in walls and floors with fire resistance ratings should be protected by fire dampers and ceiling dampers, as required by local codes. Air transfer openings should also be protected. These dampers should be classified and labeled in accordance with Underwriters Laboratories (UL) Standard 555. Figure 12 shows recommended damper positions for smoke control.

A smoke damper can be used for either traditional smoke management (smoke containment) or smoke control. In smoke management, a smoke damper inhibits the passage of smoke under the forces of buoyancy, stack effect, and wind. However, smoke dampers are only one of many elements (partitions, floors, doors) intended to inhibit smoke flow. In smoke management applications, the leakage characteristics of smoke dampers should be selected to be appropriate with the leakage of the other system elements.

In a smoke control system, a smoke damper inhibits the passage of air that may or may not contain smoke. A damper does not need low leakage characteristics when outside (fresh) air is on the high-pressure side of the damper, as is the case for dampers that shut off supply air from a smoke zone or that shut off exhaust air from a non-smoke zone. In these cases, moderate leakage of smoke-free air through the damper does not adversely affect the control of smoke movement. It is best to design smoke control systems so that only smoke-free air is on the high-pressure side of a closed smoke damper.

Smoke dampers should be classified and listed in accordance with UL Standard 555S for temperature, leakage, and operating velocity. The velocity rating of a smoke damper is the velocity at which the actuator will open and close the damper.

At locations requiring both smoke and fire dampers, combination dampers meeting the requirements of both UL Standard 555 and UL Standard 555S can be used. The combination fire/smoke dampers must close when they reach their UL Standard 555S temperature rating to maintain the integrity of the firewall.

Fire, ceiling, and smoke dampers should be installed in accordance with the manufacturers’ instructions. NFPA Standard 90A gives general guidelines regarding locations requiring these dampers.

The supply and return/smoke dampers should be a minimum of Class II leakage at 120°C. The return air damper should be a minimum of Class I leakage at 120°C to prevent recirculation of smoke exhaust. The operating velocity of the dampers should be evaluated when the dampers are in a smoke control mode. To minimize the velocity buildup, only zones adjacent to the fire need to be pressurized.

The exhaust ductwork and fan must be designed to handle the temperature of the exhaust smoke. The temperature of the exhaust smoke can be lowered by making the smoke control zones large or by pressurizing only the zones adjacent to the fire zone and leaving all the other zones operating normally.

PRESSURIZED STAIRWELLS
Many pressurized stairwells have been designed and built to provide a smoke-free escape route in the event of a building fire. They also provide a smoke-free staging area for fire fighters. On the fire floor, a pressurized stairwell must maintain a positive pressure difference across a closed stairwell door to prevent smoke infiltration. During building fire situations, some stairwell doors are opened intermittently during evacuation and fire fighting, and some doors may even be blocked open. Ideally, when the stairwell door is opened on the fire floor, airflow through the door should be sufficient to prevent smoke backflow. Designing a system to achieve this goal is difficult because of the many combinations of open stairwell doors and weather conditions affecting airflow.

Stairwell pressurization systems may be single- or multiple-injection systems. A single-injection system supplies pressurized air to the stairwell at one location—usually at the top. Associated with this system is the potential for smoke to enter the stairwell through the pressurization fan intake. Therefore, automatic shutdown during such an event should be considered.

For tall stairwells, single-injection systems can fail when a few doors are open near the air supply injection point. Such a failure is especially likely in bottom injection systems when a ground-level stairwell door is open.

For tall stairwells, supply air can be supplied at a number of locations over the height of the stairwell. Figures 13 and 14 show two examples of multiple-injection systems that can be used to overcome the limitations of single-injection systems. In these figures, the supply duct is shown in a separate shaft. However, systems have been built that have eliminated the expense of a separate duct shaft by locating the supply duct in the stairwell itself. In such a case, care must be taken that the duct does not become an obstruction to orderly building evacuation.
Compartmentation of the stairwell into a number of sections is one alternative to multiple injection (Figure 15). When the doors between compartments are open, the effect of compartmentation is lost. For this reason, compartmentation is inappropriate for densely populated buildings where total building evacuation by the stairwell is planned in the event of fire. However, when a staged evacuation plan is used and when the system is designed to operate successfully with the maximum number of doors between compartments open, compartmentation can provide stairwell pressurization for tall stairwells effectively.

Stairwell Analysis

This section presents an analysis for a pressurized stairwell in a building without vertical leakage. This method closely approximates the performance of pressurized stairwells in buildings without elevators. It is also useful for buildings with vertical leakage because it yields conservative results. Only one stairwell is considered in the building; however, the analysis can be extended to any number of stairwells by the concept of symmetry. For evaluation of vertical leakage through the building or with open stairwell doors, computer analysis is recommended. The analysis is for buildings where the leakage areas are the same for each floor of the building and where the only significant driving forces are the stairwell pressurization system and the indoor-outdoor temperature difference.

The pressure difference $\Delta p_{sb}$ between the stairwell and the building can be expressed as

$$\Delta p_{sb} = \Delta p_{sbb} + \frac{B y}{1 + (A_{sb}/A_{bo})^2}$$

where

- $\Delta p_{sbb} =$ pressure difference between stairwell and building at stairwell bottom, Pa
- $B = 3460(1/T_o - 1/T_s)$ at sea level standard pressure
- $y =$ distance above stairwell bottom, m
- $A_{sb} =$ flow area between stairwell and building (per floor), m$^2$
- $A_{bo} =$ flow area between building and outside (per floor), m$^2$
- $T_o =$ temperature of outside air, K
- $T_s =$ temperature of stairwell air, K

For a stairwell with no leakage directly to the outside, the flow rate of pressurization air is

$$Q = 0.559N A_{sb} \left( \frac{\Delta p_{sbt}^{1/2} - \Delta p_{sbb}^{1/2}}{\Delta p_{sbt} - \Delta p_{sbb}} \right)$$

where

- $Q =$ volumetric flow rate, m$^3$/s
- $N =$ number of floors
- $\Delta p_{sbt} =$ pressure difference from stairwell to building at stairwell top, Pa

Example 7. Each story of a 20-story stairwell is 3.3 m high. The stairwell has a single-leaf door at each floor leading to the occupant space and one ground-level door to the outside. The exterior of the building has a wall area of 560 m$^2$ per floor. The exterior building walls and stairwell walls are of average leakiness. The stairwell wall area is 52 m$^2$ per floor. The area of the gap around each stairwell door to the building is 0.024 m$^2$. The exterior door is well gasketed, and its leakage can be neglected when it is closed.

For this example, outside design temperature $T_o = 263$ K; stairwell temperature $T_s = 294$ K; maximum design pressure differences when all stairwell doors are closed is 137 Pa; the minimum allowable pressure difference is 13 Pa.

Using the leakage ratio for an exterior building wall of average tightness from Table 1, $A_{bo} = 560(0.21 \times 10^{-3}) = 0.118$ m$^2$. Using the leakage ratio for a stairwell wall of average tightness from Table 1, the
leakage area of the stairwell wall is $52(0.11 \times 10^{-3}) = 0.006 \text{ m}^2$. The value of $A_g$ equals the leakage area of the stairwell wall plus the gaps around the closed doors: $A_g = 0.006 + 0.024 = 0.030 \text{ m}^2$. The temperature factor $B$ is calculated at 1.39 Pa/m. The pressure difference at the stairwell bottom is selected as $\Delta p_{\text{sb}} = 20 \text{ Pa}$ to provide an extra degree of protection above the minimum allowable value of 13 Pa. The pressure difference $\Delta p_{\text{sb}}$ is calculated from Equation (17) at 106 Pa, using $y = 20(3.3) = 66 \text{ m}$. Thus, $\Delta p_{\text{sb}}$ does not exceed the maximum allowable pressure. The flow rate of pressurization air is calculated from Equation (18) at 3.9 m$^3$/s.

The flow rate depends strongly on the leakage area around the closed doors and on the leakage area in the stairwell walls. In practice, these areas are difficult to evaluate and even more difficult to control. If the flow area $A_g$ in Example 7 were 0.050 m$^2$ rather than 0.030 m$^2$, a flow rate of pressurization air of 6.5 m$^3$/s would be calculated from Equation (18). A fan with a sheave allows adjustment of supply air to offset for variations in actual leakage from the values used in design calculations.

Stairwell Pressurization and Open Doors

The simple pressurization system discussed in the previous section has two limitations regarding open doors. First, when a stairwell door to the outside and building doors are open, the simple system cannot provide sufficient airflow through building doorways to prevent smoke backflow. Second, when stairwell doors are open, the pressure difference across the closed doors can drop to low levels. Two systems used to overcome these problems are over-pressure relief (Tamura 1990) and supply fan bypass.

**Overpressure Relief.** The total airflow rate is selected to provide the minimum air velocity when a specific number of doors is open. When all the doors are closed, part of this air is relieved through a vent to prevent excessive pressure buildup, which could cause excessive door-opening forces. This excess air can be vented either to the building or to the outside. Because exterior vents can be subject to adverse wind effects, wind shields are recommended.

**Barometric dampers** that close when the pressure drops below a specified value can minimize air loss through the vent when doors are open. Figure 16 illustrates a pressurized stairwell with overpressure relief vents to the building at each floor. In systems with vents between the stairwell and the building, the vents typically have a fire damper in series with the barometric damper. As an energy conservation feature, these fire dampers are normally closed, but they open when the pressurization system is activated. This arrangement also reduces the possibility of the annoying damper chatter that frequently occurs with barometric dampers.

An exhaust duct can provide overpressure relief in a pressurized stairwell. The system is designed so that the normal resistance of a nonpowered exhaust duct maintains pressure differences within the design limits. Exhaust fans can also relieve excess pressure when all stairwell doors are closed. An exhaust fan should be controlled by a differential pressure sensor, so that it will not operate when the pressure difference between the stairwell and the building falls below a specified level. This control should prevent the fan from pulling smoke into the stairwell when a number of open doors have reduced stairwell pressurization. Such an exhaust fan should be specifically sized so that the pressurization system will perform within design limits. A wind shield is recommended because an exhaust fan can be adversely affected by the wind.

An alternate method of venting a stairwell is through an automatically opening stairwell door to the outside at ground level. Under normal conditions, this door would be closed and, in most cases, locked for security reasons. Provisions need to be made to prevent this lock from conflicting with the automatic operation of the system. Possible adverse wind effects are also a concern with a system that uses an open outside door as a vent. Occasionally, high local wind velocities develop near the exterior stairwell door; such winds are difficult to estimate without expensive modeling. Nearby obstructions can act as wind breaks or wind shields.

**Supply Fan Bypass.** In this system, the supply fan is sized to provide at least the minimum air velocity when the design number of doors are open. Figure 17 illustrates such a system. The flow rate of air into the stairwell is varied by modulating bypass dampers, which are controlled by one or more static pressure sensors that sense the pressure difference between the stairwell and the building.
When all the stairwell doors are closed, the pressure difference increases and the bypass damper opens to increase the bypass air and decrease the flow of supply air to the stairwell. In this manner, excessive stairwell pressures and excessive pressure differences between the stairwell and the building are prevented.

ELEVATORS

Elevator smoke control systems intended for use by fire fighters should keep elevator cars, elevator shafts, and elevator machinery rooms smoke-free. Small amounts of smoke in these spaces are acceptable, provided that the smoke is nontoxic and that the operation of the elevator equipment is not affected. Elevator smoke control systems intended for fire evacuation of the handicapped or other building occupants should also keep elevator lobbies smoke-free or nearly smoke-free. The long-standing obstacles to fire evacuation by elevators include:

- Logistics of evacuation
- Reliability of electrical power
- Jamming of elevator doors
- Fire and smoke protection

All these obstacles, except smoke protection, can be addressed by existing technology (Klote 1984).

Klote and Tamura (1986) studied conceptual elevator smoke control systems for the evacuation of handicapped individuals. The major problem was maintaining pressurization with open building doors, especially doors on the ground floor. Of the systems evaluated, only one with a supply fan bypass with feedback control maintained adequate pressurization with any combination of open or closed doors. There are probably other systems capable of providing adequate smoke control; the procedure used by Klote and Tamura can be viewed as an example of a method of evaluating the performance of a system to determine whether it suits the particular characteristics of a building under construction.

The transient pressures due to piston effect when an elevator car moves in a shaft have been a concern with regard to elevator smoke control. Piston effect is not a concern for slow-moving cars in multiple-car shafts. However, for fast cars in single-car shafts, the piston effect can be considerable.

ZONE SMOKE CONTROL

Klote (1990) conducted a series of tests on full-scale fires that demonstrated that zone smoke control can restrict smoke movement to the zone where a fire starts.

Pressurized stairwells are intended to prevent smoke infiltration into stairwells. However, in a building with only stairwell pressurization, smoke can flow through cracks in floors and partitions and through shafts to damage property and threaten life at locations remote from the fire. Zone smoke control is intended to limit such smoke movement.

A building is divided into a number of smoke control zones, each separated from the others by partitions, floors, and doors that can be closed to inhibit smoke movement. In the event of a fire, pressure differences and airflows produced by mechanical fans limit the spread of smoke from the zone in which the fire started. The concentration of smoke in this zone goes unchecked; thus, in zone smoke control systems, the occupants should evacuate the smoke zone as soon as possible after fire detection.

A smoke control zone can consist of one floor, more than one floor, or part of a floor. Sprinkler zones and smoke control zones should be coordinated so that sprinkler water flow activates the zone’s smoke control system. Some arrangements of smoke control zones are illustrated in Figure 18. All the nonsmoke zones in the building may be pressurized. The term pressure sandwich describes cases where only zones adjacent to the smoke zone are pressurized, as in Figures 18B and 18D.

Computer Analysis for Pressurization Systems

Because of the complexity of airflow in buildings, network computer programs were developed to model the airflow with pressurization systems. These models represent rooms and shafts by nodes; airflow is from nodes of high pressure to nodes of lower pressure. Some programs calculate steady-state airflow and pressures throughout a building (Sander 1974, Sander and Tamura 1973). Other programs go beyond this to calculate the smoke concentrations that would be produced throughout a building in the event of a fire (Yoshida et al. 1979, Evers and Waterhouse 1978, Wakamatsu 1977, and Rilling 1978).

The ASCOS program was developed specifically for analysis of pressurization smoke control systems (Klote 1982). ASCOS was the most widely used program for smoke control analysis.
Fire growth is the rate of change of the heat release rate and is sometimes expressed as a growth constant that identifies the time required for the fire to attain a particular rate of heat release. Designs may be based on either steady fires or unsteady fires.

It is the nature of fires to be unsteady, but the steady fire is a very useful idealization. Steady fires have a constant heat release rate. In many applications, use of a steady design fire leads to straightforward and conservative design.

Morgan (1979) suggests 500 kW/m² as a typical rate of heat release per unit floor area for mercantile occupancies. Fang and Breeze (1980) determined about the same rate of heat release for residential occupancies. Morgan and Hansell (1987) and Law (1982) suggest a heat release rate per unit floor area for office buildings of 225 kW/m².

In many atriums, the fuel loading is severely restricted with the intent of restricting fire size. Such atriums are characterized by interior finishes of metal, brick, stone, or gypsum board and furnished with objects made of similar materials plus plants. Even in such a fuel-restricted atrium, many combustible objects are present for short periods. Packing materials, holiday decorations, displays, and furniture being moved into another part of the building are a few examples of transient fuels.

This chapter uses a heat release rate per floor area of 225 kW/m² for a fuel-restricted atrium, and 500 kW/m² for atriums containing furniture, wood, or other combustible materials.

Transient fuels must not be overlooked when selecting a design fire. Klote and Milke (1992) suggest incorporating transient fuels in a design fire by considering the fire occurring over 9.3 m² of floor space. This results in a design fire of 2100 kW for fuel-restricted atriums. In an atrium with combustibles, the design fire would be 4600 kW. However, the area involved in fire may be much greater; flame spread considerations must be taken into account (NFP A Standard 92B; Klote and Milke 1992). A large atrium fire of 25 000 kW would involve an area of 50 m² at 500 kW/m².

These unsteady fires are often characterized by the following equation:

\[
q = 1055 \left( \frac{t}{t_g} \right)^{1/2}
\]  

where
\(q\) = heat release rate of fire, kW
\(t\) = time, s
\(t_g\) = growth time, s

These unsteady fires are called \(t\)-squared fires; typical growth times are listed in Table 3.
Zone Fire Models

Atrium smoke management design is based on the zone fire model concept. This concept has been applied to several computer models, which can be used for atrium smoke management design analysis. These computer models include the Harvard Code (Mitler and Emmons 1981), ASET (Cooper 1985), the BRI Model (Tanaka 1983), CCFM (Cooper and Forney 1987), and CFAST (Peacock et al. 1993). The University of Maryland has modified CCFM specifically for atrium smoke management design (Milke and Mowrer 1994). Although each of these models has unique features, they all share the same basic two-zone model concept.

For more information about zone models, see Mitler and Rockett (1986), Mitler (1984), and Quintiere (1989). The ASET-B model (Walton 1985) is a good starting point for learning about zone models.

Zone models were originally developed for room fires. In a room fire, hot gases rise above the fire, forming a plume. As the plume rises, it entrains air from the room so that the diameter and mass flow rate of the plume increase with elevation. Accordingly, the plume temperature decreases with elevation. The fire gases from the plume flow up to the ceiling and form a hot stratified layer under the ceiling. The hot gases can flow through openings in walls to other spaces; such flow is referred to as a door jet. A door jet is similar to a plume, except that it flows through an opening in a wall.

Figure 20A is a sketch of a room fire. Zone modeling is an idealization of the room fire conditions, as illustrated in Figure 20B. For this idealization, the temperature of the hot upper layer of the room is uniform, and the temperature of the lower layer is also uniform. The height of the discontinuity between these layers is the same everywhere. The dynamic effects on pressure are considered negligible, so pressures are treated as hydrostatic. Other properties are considered uniform for each layer. Algebraic equations are used to calculate the mass flows due to plumes and door jets.

Many computer zone models allow exhaust from the upper layer, which is essential for simulation of atrium smoke exhaust systems. Many of the computer models estimate heat transfer by methods ranging from a simple allowance as a fraction of the heat released by the fire to a complicated simulation including the effects of conduction, convection, and radiation.

Atrium Smoke Filling by a Steady Fire

The following experimental correlation of the accumulation of smoke in a space due to a steady fire is the steady filling equation:

\[
\frac{z}{H} = 1.11 - 0.28 \ln \left( \frac{tq^{1/3}H^{-4/3}}{A/H^2} \right)
\]

Equation (20) is conservative in that it estimates the height of the first indication of smoke above the fire rather than the smoke interface, as illustrated in Figure 21. In the idealized zone model, the smoke interface is considered to be a height where there is smoke above and none below. In actual fires, there is a gradual transition zone between the lower cool layer and upper hot layer. The first indication of smoke can be thought of as the bottom of the transition zone. Another factor making Equation (20) conservative is that it is based on a plume that has no contact with the walls, which would reduce entrainment of air.

Equation (20) is for a constant cross-sectional area with respect to height. For other atrium shapes, physical modeling or computational fluid dynamics can be used. Alternatively, a sensitivity analysis can be made using Equation (20) to set bounds on the filling time for an atrium of complex shape. The equation is appropriate for \(A/H^2\) from 0.9 to 14 and for values of \(z/H\) greater than or equal to 20% of \(H\). A value of \(z/H\) greater than 1 means that the smoke layer under the ceiling has not yet begun to descend. These conditions can be expressed as

\[
0.2 \leq \frac{z}{H} < 1.0
\]

\[
0.9 \leq \frac{A}{H^2} \leq 14
\]
When Equation (20) is solved for $z/H$, $z/H$ is often outside the acceptable range. Equation (20) can be solved for time.

\[
   t = \frac{A H^{4/3}}{q^{1/3}} \exp \left[ \frac{1}{0.28} \left( 1.11 - \frac{z}{H} \right) \right]
\]

(21)

### Atrium Smoke Filling by an Unsteady Fire

For a $t$-squared fire, the location of the smoke layer interface can be estimated by the unsteady filling equation:

\[
   \frac{z}{H} = 0.91 \left[ \frac{t}{t_g} \right]^{2/5} H^{4/5} \left( \frac{A}{H^2} \right)^{3/5} \left( \frac{z}{H} \right)^{-1.45}
\]

(22)

This equation is based on experimental data and is conservative in that it estimates the height of the first indication of smoke and is for a plume that has no wall contact. The conditions can be expressed as

\[
   A = \text{Constant with respect to } H
\]

\[
   0.2 \leq \frac{z}{H} < 1.0
\]

\[
   1 \leq \frac{A}{H^2} \leq 23
\]

Values of $t_g$ for various characteristic fire growths are listed in Table 2. Like the steady filling equation, the unsteady filling equation can be solved for time:

\[
   t = 0.937 t_g^{2/5} H^{4/5} \left( \frac{A}{H^2} \right)^{3/5} \left( \frac{z}{H} \right)^{-0.69}
\]

(23)

### Steady Clear Height with Upper Layer Exhaust

Figure 18 illustrates smoke exhaust from the hot smoke layer at the top of an atrium to maintain a steady clear height. The smoke flow into the upper layer from the fire plume depends on the heat release rate of the fire, clear height, fuel type, and fuel orientation. The following is a generalized plume approximation that does not take into account the specifics of the material being burned.

\[
   m = 0.071 q_c^{1/3} z^{5/3} + 0.0018 q_c
\]

(24)

where

- $m$ = mass flow of plume, kg/s
- $q_c$ = convective heat release rate of fire, kW
- $z$ = clear height above top of fuel, m

The clear height $z$ is the distance from the top of the fuel to the interface between the “clear” space and the smoke layer. Because a smoke management system generally must protect against a fire at any location, it is suggested that the top of the fuel be considered at the floor level.

Equation (27) is not applicable when the mean flame height is greater than the clear height. An approximate relationship for the mean flame height is

\[
   z_f = 0.166 q_c^{2/5}
\]

(25)

where $z_f$ = mean flame height, m.

The convective portion $q_c$ of the heat release rate can be expressed as

\[
   q_c = \xi q
\]

(26)

where $\xi$ is the convective fraction of heat release. The convective fraction depends on the material being burned, heat conduction through the fuel, and the radiative heat transfer of the flames, but a value of 0.7 is often used.

The temperature of the smoke entering the upper smoke layer is

\[
   T_p = T_a + \frac{q_c}{m c_p}
\]

(27)

where

- $T_p$ = plume temperature at clear height, K
- $T_a$ = ambient temperature, K
- $m$ = mass flow of plume, kg/s
- $q_c$ = convective heat release rate of fire, kW
- $c_p$ = specific heat of plume gases, kJ/(kg·K)

Figure 22 shows plume temperature as a function of height above the fuel as calculated from Equations (24) and (27). Smoke plumes consist primarily of air mixed with the products of combustion, and the specific heat of plume gases is generally taken to be the same as that of air [$c_p = 1.00$ kJ/(kg·K)]. Equation (24) was developed for strongly buoyant plumes. For small temperature differences between the plume and ambient, errors due to low buoyancy could be significant. This topic needs study, and, in the absence of better data, it is recommended that the plume equations not be used when this temperature difference is small (less than 2 K).

The density of smoke gases can be calculated from the perfect gas law:

\[
   \rho = \frac{p}{R T}
\]

(28)

where

- $\rho$ = density, kg/m$^3$
- $p$ = absolute pressure, Pa
- $R$ = gas constant, J/(kg·K)
- $T$ = absolute temperature of smoke gases, K

Volumetric flow is expressed as

\[
   Q = \frac{m}{\rho}
\]

(29)
where

\[ m = \text{mass flow of plume or exhaust gas, kg/s} \]
\[ Q = \text{volumetric flow of exhaust gases, m}^3/\text{s} \]
\[ \rho = \text{density of plume or exhaust gas, kg/m}^3 \]

The atrium exhaust should equal the mass flow of the plume plus any leakage flow into the atrium above the clear height.

For an atrium with negligible heat loss from the smoke layer and negligible air leakage into the smoke layer from the outside, the exhaust equals the mass flow rate of the plume from Equation (24) at the same temperature as the plume from Equation (27). Figures 23 and 24 show the exhaust rate needed to maintain a constant clear height for an atrium with negligible heat loss from the smoke layer and negligible air leakage into the smoke layer from the outside.

The major assumptions of the analysis plotted in Figures 23 and 24 are as follows:

1. The plume has space to flow to the top of the atrium without obstructions.
2. The heat release rate of the fire is constant.
3. The clear height is greater than the mean flame height.
4. The smoke layer is adiabatic.
5. The plume flow and the exhaust are the only significant mass flows into or out of the smoke layer (i.e., outside airflow, either as leakage or as makeup air, into the smoke layer is insignificant).

**Minimum Smoke Layer Depth**

When the smoke layer depth below an exhaust inlet is relatively shallow, a high exhaust rate can lead to entrainment of cold air from the clear layer. This phenomenon is called plugholing. Accordingly, more than one exhaust point may be needed. The maximum volumetric flow rate that can be extracted through an exhaust line is

\[
Q_{\text{max}} = 0.0089 \beta d^{5/2} \frac{T^3}{T} (T_s - T_o) \tag{30}
\]

where

\[ Q_{\text{max}} = \text{maximum volumetric flow rate at } T_o, \text{ m}^3/\text{s} \]
\[ T = \text{absolute temperature of smoke layer, K} \]
\[ T_s = \text{absolute ambient temperature, K} \]
\[ d = \text{depth of smoke layer below exhaust inlet, m} \]
\[ \beta = \text{exhaust location factor, dimensionless} \]

Based on limited information, suggested values of \( \beta \) are 2.0 for a ceiling exhaust inlet near a wall, 2.0 for a wall exhaust inlet near the ceiling, and 2.8 for a ceiling exhaust inlet far from any walls. The inlet velocity should not exceed 10 m/s and \( d/D \) should not exceed 2, where \( D \) is the diameter of the inlet. For exhaust inlets, use \( D = 2ab/(a + b) \), where \( a \) and \( b \) are the length and width of the inlet.

**Prestratification and Detection**

A hot layer of air often forms under the ceiling of an atrium due to solar radiation on the atrium roof. Although no studies have been made of this prestratification layer, building designers indicate that the temperature of such a layer can exceed 50°C. Temperatures below this layer are controlled by the building’s heating and cooling system; the temperature can be considered to increase significantly over a small increase in elevation, as shown in Figure 25. The analysis of smoke stratification given in NFPA Standard 92B is not appropriate for the temperature profile addressed in this section because it is for a constant temperature increase per unit elevation.

When the average temperature of the plume is lower than that of the prestratification layer, the smoke will form a stratified layer beneath the prestratification layer, as shown in Figure 26. Average plume temperatures can be calculated from Equations (24) and (27); they are plotted in Figure 22, which shows that the average plume temperature is usually less than expected temperatures of the hot air layer. Thus, when there is a hot prestratified air layer, smoke cannot be expected to reach the ceiling of the atrium, and smoke detectors mounted on that ceiling cannot be expected to go into alarm.

Beam smoke detectors oriented horizontally to detect smoke in the plume can overcome the limitations of ceiling-mounted detectors in atriums. Beam detectors are often mounted on balconies, where they are generally easier to reach for maintenance than are ceiling-mounted detectors. The light beams must be below the hot prestratified layer, and the space between beams must be small enough that plumes will be detected regardless of the location of the fire. The visible plume diameter is approximately half the clear height, with an estimated uncertainty in the range of +5% to −40%. Therefore, it is suggested that the spacing between beams be
where

\[ x = \frac{H_b}{4} \]  

The height \( H_b \) of beams above the floor must be well below the prestratification layer so that the plume will reach the level of the beams and be detected. Figure 27 is an example arrangement of beam detectors in an atrium.

ACCEPTANCE TESTING

Regardless of the care, skill, and attention to detail with which a smoke control system is designed, an acceptance test is needed as assurance that the system, as built, operates as intended.

An acceptance test should be composed of two levels of testing. The first is of a functional nature, that is, an initial check of the system components. The importance of the initial check has become apparent because of the problems encountered during tests of smoke control systems. These problems include fans operating backward, fans to which no electrical power was supplied, and controls that did not work properly.

The second level of testing is of a performance nature to determine whether the system performs adequately under all required modes of operation. This can consist of measuring pressure differences across barriers under various modes of smoke control system operation. If airflows through open doors are important, these should be measured. Chemical smoke from smoke candles (sometimes called smoke bombs) is not recommended for performance testing because it normally lacks the buoyancy of hot smoke from a real building fire. Smoke near a flaming fire has a temperature in the range of 500 to 1100°C. Heating chemical smoke to such temperatures to emulate smoke from a real fire is not recommended unless precautions are taken to protect life and property. The same comments about buoyancy apply to tracer gases. Thus, pressure difference testing is the most practical performance test. However, chemical smoke can be used to aid flow visualization.

ASHRAE Guideline 5 covers the commissioning of smoke management systems.

Radiant heating and cooling applications are classified as panel heating or cooling if the surface temperature is below 150°C and are classified as low-, medium-, or high-intensity if the surface or source temperature range exceeds 150°C. Radiant energy is transmitted by electromagnetic waves that travel in straight lines, can be reflected, and heat solid objects but do not heat the air through which the energy is transmitted. Because of these characteristics, radiant systems are effective for both spot heating and space heating or cooling requirements for an entire building.

LOW-, MEDIUM-, AND HIGH-INTENSITY INFRARED HEATING

Low-, medium-, and high-intensity infrared heaters are compact, self-contained direct-heating devices used in hangars, warehouses, factories, greenhouses, and gymnasiums, as well as in areas such as loading docks, racetrack stands, outdoor restaurants, animal breeding areas, swimming pool lounge areas, and areas under marquees. Infrared heating is also used for snow melting (e.g., on stairs and ramps) and process heating (e.g., paint baking and drying). An infrared heater may be electric, gas-fired, or oil-fired and is classified by the source temperature as follows:

• Low intensity for source temperatures to 650°C
• Medium intensity for source temperatures to 980°C
• High intensity for source temperatures to 2800°C

The source temperature is determined by such factors as the source of energy, the configuration, and the size. Reflectors can be used to direct the distribution of radiation in specific patterns [Chapter 15] of the 2000 ASHRAE Handbook—Systems and Equipment covers radiant equipment in detail.

PANEL HEATING AND COOLING

Panel heating and cooling systems provide a comfortable environment by controlling surface temperatures and minimizing air motion within a space. They include the following designs:

• Metal ceiling panels
• Embedded hydronic tubing or attached piping in ceilings, walls, or floors
• Air-heated floors or ceilings
• Electric ceiling or wall panels
• Electric heating cable in ceilings or floors
• Deep heat, a modified storage system using electric heating cable or embedded hydronic tubing in ceilings or floors

In these systems, generally more than 50% of the heat transfer from the controlled temperature surface to other surfaces is by radiation. Panel heating and cooling systems are used in residences, office buildings (for perimeter heating), classrooms, hospital patient rooms, swimming pool areas, repair garages, and in industrial and warehouse applications. Additional information is available in Chapter 6 of the 2000 ASHRAE Handbook—Systems and Equipment.

Some radiant panel systems combine controlled heating and cooling with central air conditioning and are referred to as hybrid conditioning systems. They are used more for cooling than for heating (Wilkins and Kosonen 1992). The controlled temperature surfaces may be in the floor, walls, or ceiling, with the temperature maintained by electric resistance or circulation of water or air. The central station can be a basic, one-zone, constant-temperature, or constant-volume system, or it can incorporate some or all the features of dual-duct, reheat, multitzone, or variable-volume systems. When used in combination with other water/air systems, radiant panels provide zone control of temperature and humidity.

Metal ceiling panels may be integrated into the central heating and cooling system to provide individual room or zone heating and cooling. These panels can be designed as small units to fit the building module, or they can be arranged as large continuous areas for economy. Room thermal conditions are maintained primarily by direct transfer of radiant energy, normally using four-pipe hot and chilled water. These metal ceiling panel systems have generally been used in hospital patient rooms.

The application of metal ceiling panel systems is discussed in Chapter 6 of the 2000 ASHRAE Handbook—Systems and Equipment.

ELEMENTARY DESIGN RELATIONSHIPS

When considering radiant heating or cooling for human comfort, the following terms describe the temperature and energy characteristics of the total radiant environment:

• Mean radiant temperature (MRT) $t_r$ is the temperature of an imaginary isothermal black enclosure in which an occupant would exchange the same amount of heat by radiation as in the actual nonuniform environment.
• Ambient temperature $t_a$ is the temperature of the air surrounding the occupant.
• Operative temperature $t_o$ is the temperature of a uniform isothermal black enclosure in which the occupant would exchange the same amount of heat by radiation and convection as in the actual nonuniform environment.

For air velocities less than 0.4 m/s and mean radiant temperatures less than 50°C, the operative temperature is approximately equal to the adjusted dry-bulb temperature, which is the average of the air and mean radiant temperatures.

• Adjusted dry-bulb temperature is the average of the air temperature and the mean radiant temperature at a given location. The adjusted dry-bulb temperature is approximately equivalent to the operative temperature for air motions less than 0.4 m/s and mean radiant temperatures less than 50°C.
• Effective radiant flux (ERF) is defined as the net radiant heat exchanged at the ambient temperature $t_a$ between an occupant, whose surface is hypothetical, and all enclosing surfaces and directional heat sources and sinks. Thus, ERF is the net radiant energy received by the occupant from all surfaces and sources.
whose temperatures differ from \( t_{ta} \), ERF is particularly useful in high-intensity radiant heating applications.

The relationship between these terms can be shown for an occupant at surface temperature \( t_{sf} \), exchanging sensible heat \( H_m \) in a room with ambient air temperature \( t_a \) and mean radiant temperature \( \bar{t}_r \). The linear radiative and convective heat transfer coefficients are \( h_r \) and \( h_c \), respectively; the latter coefficient is a function of the air movement \( V \). The heat balance equation is

\[
H_m = h_r (t_{sf} - \bar{t}_r) + h_c (t_{sf} - t_a)
\]

During thermal equilibrium, \( H_m \) is equal to metabolic heat minus work and evaporative cooling by sweating. By definition of operative temperature,

\[
H_m = (h_r + h_c)(t_{sf} - t_a)
\]

Using Equations (1) and (2) to solve for \( t_{sf} \) yields

\[
t_{sf} = \frac{h_r \bar{t}_r + h_c t_a}{h_r + h_c}
\]

Thus, \( t_{sf} \) is an average of \( \bar{t}_r \) and \( t_a \), weighted by their respective heat transfer coefficients; it represents how people sense the thermal level of their total environment as a single temperature.

The combined heat transfer coefficient is \( h_t \), where \( h = h_r + h_c \). Rearranging Equation (1) and substituting \( h - h_t \) for \( h_t \),

\[
H_m = h_t (t_{sf} - t_a) = h(t_{sf} - t_a)
\]

where \( h_t(t_{sf} - t_a) \) is, by definition, the effective radiant flux (ERF) and represents the radiant energy absorbed by the occupant from all sources whose temperatures differ from \( t_{sf} \).

The principal relationships between \( \bar{t}_r \), \( t_{sr} \), \( t_a \), and ERF are as follows:

\[
ERF = h_t(\bar{t}_r - t_a)
\]

\[
ERF = h(t_o - t_a)
\]

\[
\bar{t}_r = t_a + ERF/h_t
\]

\[
t_o = t_a + ERF/h
\]

\[
\bar{t}_r = t_a + (h/h_t)(t_o - t_a)
\]

\[
t_o = t_a + (h_c/h)(\bar{t}_r - t_a)
\]

In Equations (1) through (10), the radiant environment is treated as a blackbody with temperature \( \bar{t}_r \). The effect of the emittance of the source, radiating at absolute temperature in kelvins, and the absorptance of the skin and clothed surfaces is reflected in the effective values of \( \bar{t}_r \) or ERF and not in the coefficient \( h_r \), which is generally given by

\[
h_r = 4\sigma f_\text{off} \left( \frac{\bar{t}_r + t_a}{2} + 273 \right)^3
\]

where

\[
h_r = \text{linear radiative heat transfer coefficient, W/(m}^2 \cdot \text{K)}
\]

\[
f_\text{off} = \text{ratio of radiating surface of the human body to its total DuBois surface area, } A_D = 0.71
\]

\[
\sigma = \text{Stefan-Boltzmann constant} = 5.67 \times 10^{-8} \text{ W/(m}^2 \cdot \text{K}^4)
\]

\[\text{1999 ASHRAE Applications Handbook (SI)}\]

Fig. 1 Relative Absorptance and Reflectance of Skin and Typical Clothing Surfaces at Various Color Temperatures

The convective heat transfer coefficient for an occupant is

\[
h_c = 8.5 V^{0.5}
\]

where \( h_c \) is in W/(m\(^2\) \cdot K) and \( V \) is air movement in m/s.

When \( \bar{t}_r > t_{sr} \), ERF adds heat to the body system; when \( t_{sr} > \bar{t}_r \), heat is lost from the body due to radiant cooling. ERF is independent of the surface temperature of the occupant and can be measured directly by a black globe thermometer or any blackbody radiometer or flux meter using the ambient air \( t_a \) as its heat sink.

In the above definitions and for radiators below 925°C (1200 K), the body clothing and skin surface are treated as blackbodies, exchanging radiation with an imaginary blackbody surface at temperature \( \bar{t}_r \). The effectiveness of a radiating source on human occupants is governed by the absorptance \( \alpha \) of the skin and clothing surface for the color temperature (in K) of that radiating source. The relationship between \( \alpha \) and temperature is illustrated in Figure 1. The values for \( \alpha \) are those expected relative to the matte black surface normally found on globe thermometers or radiometers measuring radiant energy. A gas radiator usually operates at 925°C (1200 K); a quartz lamp, for example, radiates at 2200°C (2475 K) with 240 V; and the sun’s radiating temperature is 5500°C (5800 K). The use of \( \alpha \) in estimating the ERF and \( t_{sr} \) caused by sources radiating at temperatures above 925°C (1200 K) is discussed in the section on Testing Instruments for Radiant Heating.

**DESIGN CRITERIA FOR ACCEPTABLE RADIANT HEATING**

Perceptions of comfort, temperature, and thermal acceptability are related to activity, the transfer of body heat from the skin to the environment, and the resulting physiological adjustments and body temperature. Heat transfer is affected by the ambient air temperature, thermal radiation, air movement, humidity, and clothing worn. Thermal sensation is described as feelings of hot, warm, slightly warm, neutral, slightly cool, cool, and cold. An acceptable environment is defined as one in which at least 80% of the occupants perceive a thermal sensation between “slightly cool” and “slightly warm.” Comfort is associated with a neutral thermal sensation during which the human body regulates its internal temperature with minimal physiological effort for the activity concerned. In contrast, warm discomfort is primarily related to the physiological strain necessary to maintain the body’s thermal equilibrium rather than to the temperature sensation experienced. For a full discussion on the interrelation of physical, psychological, and physiological factors, refer to Chapter 8 of the 1997 ASHRAE Handbook—Fundamentals.
ASHRAE Standard 55 shows a linear relationship between the clothing insulation worn and the operative temperature for comfort (Figure 2). Figure 3, which is adapted from the standard, shows the effect of both activity and clothing on the operative temperature for comfort. Figure 4 shows the slight effect humidity has on the comfort of a sedentary person wearing average clothing.

A comfortable to at 50% rh is perceived as slightly warmer as the humidity increases or is perceived as slightly cooler as the humidity decreases. Changes in humidity have a much greater effect on “warm” and “hot” discomfort. In contrast, “cold” discomfort is only slightly affected by humidity and is very closely related to a “cold” thermal sensation.

Determining the specifications for a radiant heating installation designed for human occupancy and acceptability involves the following steps:

1. Define the probable activity (metabolism) level of, and clothing worn by, the occupant and the air movement in the occupied space. The following are two examples:
   - **Case 1:** Sedentary (65 W/m²)
     - Clothing insulation = 0.09 m²·K/W; air movement = 0.15 m/s
   - **Case 2:** Light work (116 W/m²)
     - Clothing insulation = 0.14 m²·K/W; air movement = 0.5 m/s

2. From Figure 2 or 3, determine the optimum operative temperature for comfort:
   - **Case 1:** To = 23.5°C
   - **Case 2:** To = 17°C

3. For the ambient air temperature ta, calculate the mean radiant temperature tre and/or ERF necessary for comfort and thermal acceptability.
   - **Case 1:** For ta = 15°C and assuming re = 30°C,
     - Solve for hr from Equation (11):
     
     \[
     h_r = 4 \times 5.67 \times 10^{-8} \times 0.71(30 + 10)/2 + 273)^{1/4} = 4.15
     \]
     - Solve for hc from Equation (12):
     
     \[
     h_c = 0.15 \times 0.5 = 0.075
     \]

     Then,
     
     \[
     h = h_r + h_c = 4.15 + 0.075 = 4.225 \text{ W/(m}^2\cdot\text{K)}
     \]

   - From Equation (6) for comfort,
     
     \[
     \text{ERF} = 7.45(23.5 - 15) = 63.3 \text{ W/m}^2
     \]

   - From Equation (9),
     
     \[
     t_r = 15 + (7.45/4.15)(23.5 - 15) = 30.2°C
     \]
Case 2: For $t_a = 10\, ^\circ C$ at 50% rh and assuming $T_r = 25\, ^\circ C$.

\[
h_r = 4 \times 5.67 \times 10^{-8} \times 0.71\left[(25 + 10)/2 + 273\right]^3 = 3.95
\]

\[
h_c = 8.5(0.5)^{0.5} = 6.01
\]

\[
h = 3.95 + 6.01 = 9.96 \text{ W/(m}^2\cdot \text{K)}
\]

ERF = 9.96(17 – 10) = 69.7 W/m\(^2\)

From Equation (7):

\[
T_r = 10 + 69.7/3.95 = 27.6\, ^\circ C
\]

The $t_o$ for comfort, predicted by Figure 2, is on the “slightly cool” side when the humidity is low; for very high humidities, the predicted $t_o$ for comfort is “slightly warm.” This small effect of humidity on comfort can be seen in Figure 4. For example, for high humidity at $t_{ph} = 13\, ^\circ C$, the $t_o$ for comfort is

Case 1: $t_o = 22\, ^\circ C$, compared to $23\, ^\circ C$ at 50% rh

Case 2: $t_o = 16\, ^\circ C$, compared to $17\, ^\circ C$ at 50% rh

When thermal acceptability is the primary consideration in an installation, humidity can sometimes be ignored in preliminary design specifications. However, for conditions where radiant heating and the work level cause sweating and high heat stress, humidity is a major consideration.

Equations (3) through (12) can also be used to determine the ambient air temperature $t_a$ required when the mean radiant temperature MRT is maintained by a specified radiant system.

When calculating heat loss, $t_u$ must be determined. For a radiant system that is to maintain a MRT of $T_r$, the operative temperature $t_o$ can be determined from Figure 4. Then, $t_o$ can be calculated by recalling that $t_o$ is approximately equal to the average of $t_a$ and $t_r$. For example, for a $t_a$ of $23\, ^\circ C$ and a radiant system designed to maintain an MRT of $26\, ^\circ C$, the $t_o$ would be $20\, ^\circ C$.

When the surface temperature of outside walls, particularly those with large areas of glass, deviates too much from the room air temperature and from the temperature of other surfaces, simplified calculations for the load and the operative temperature may lead to errors in sizing and locating the panels. In such cases, more detailed radiant exchange calculations may be required, with separate estimation of heat exchange between the panels and each surface. A large window area may lead to significantly lower mean radiant temperatures than expected. For example, Athienitis and Dale (1987) reported an MRT 3 K lower than room air temperature for a room with a glass area equivalent to 22% of its floor area.

**DESIGN FOR BEAM RADIANT HEATING**

Spot beam radiant heat can improve comfort at a specific location in a large, poorly heated work area. The design problem is specifying the type, capacity, and orientation of the beam heater.

Using the same reasoning as in Equations (1) through (10), the effective radiant flux ERF that must be added to an unheated work space with an operative temperature $t_{u0}$ to result in a $t_o$, for comfort (as given by Equation 2 or 3) is

\[
\text{ERF} = h(t_o - t_{u0})
\]

where $h = h_r + h_c$.

or

\[
t_o = t_{u0} + \text{ERF}/h
\]

This equation is unaffected by air movement. The heat transfer coefficient $h$ for the occupant in Equation (13) is given by Equations (11) and (12), with $h = h_r + h_c$. For additional information on radiant flux distribution patterns and sample calculations of radiation intensity $I_k$ and ERF, refer to Chapter 15 of the 2000 ASHRAE Handbook—Systems and Equipment.
Floor Reradiation

In most low-, medium-, and high-intensity radiant heater installations, local floor areas are strongly irradiated. The floor absorbs most of this energy and warms to an equilibrium temperature $t_r$, which is higher than that of the ambient air temperature $t_a$ and the unheated room enclosure surfaces. Part of the energy directly absorbed by the floor is transmitted by conduction to the cooler underside (or, for slabs-on-grade, to the ground), part is transferred by natural convection to room air, and the remainder is reradiated. The warmer floor will raise $E_R$ or $t_r$ over that caused by the heater alone.

For a person standing on a large, flat floor that has a temperature raised by direct radiation $t_r$, the linearized $t_r$ due to the floor and unheated walls is

$$t_{rf} = F_p t_r (1 - F_p) t_a$$  \hspace{1cm} (16)

where the unheated walls, ceiling, and ambient air are assumed to be at $t_a$, and $F_p$ is the angle factor governing the radiation exchange between the heated floor and the person.

The $E_R f$ from the floor affecting the occupant, which is due to the $(t_r - t_a)$ difference, is

$$E_R f = h_r (t_{rf} - t_a) \hspace{1cm} (17)$$

where $h_r$ is the linear radiative heat transfer coefficient for a person as given by Equation (11). For a standing or sitting subject when the walls are farther than 5 m away, $F_p$ is 0.44 (Fanger 1973). For an average-sized 5 m by 5 m room, a value of 0.35 for $F_p$ is suggested. For detailed information on floor reradiation, see Chapter 15 in the 2000 ASHRAE Handbook—Systems and Equipment.

In summary, when radiant heaters warm occupants in a selected area of a poorly heated space, the radiation heat necessary for comfort consists of two additive components: (1) $E_R$ directly caused by the heater and (2) reradiation $E_R f$ from the floor. The effectiveness of floor reradiation can be improved by choosing flooring with a low specific conductivity. Flooring with high thermal inertia may be desirable during radiant transients, which may occur as the heaters are cycled by a thermostat set to the desired operative temperature $t_o$.

Asymmetric Radiant Fields

In the past, comfort heating has required flux distribution in occupied areas to be uniform, which is not possible with beam radiant heaters. Asymmetric radiation fields, such as those experienced when lying in the sun on a cool day or when standing in front of a warm fire, can be pleasant. Therefore, a limited amount of asymmetry is allowable for comfort heating, is referred to as “reasonable uniform radiation distribution” and is used as a design requirement.

To develop criteria for judging the degree of asymmetry allowable for comfort heating, Fanger et al. (1980) proposed defining radiant temperature asymmetry as the difference in the plane radiant temperature between two opposing surfaces. Plane radiant temperature is the equivalent $t_{1,2}$ caused by radiation on one side of the subject, compared with the equivalent $t_{2,1}$ caused by radiation on the opposite side. Gagge et al. (1967) conducted a study of subjects (eight clothed and eight unclothed) seated in a chair and heated by two lamps. Unclothed subjects found a $(t_r - t_a)$ asymmetry of 11 K to be comfortable, but clothed subjects were comfortable with an asymmetry as high as 17 K.

For an unclothed subject lying on an insulated bed under a horizontal bank of lamps, neutral temperature sensation occurred for a $t_o$ of 22°C, which corresponds to a $(t_o - t_a)$ asymmetry of 11 K or a $(t_r - t_a)$ asymmetry of 15 K, both averaged for eight subjects (Stevens et al. 1969). In studies of heated ceilings, 80% of eight male and eight female clothed subjects voted conditions as comfortable and acceptable for asymmetries as high as 11 K. The study compared the floor and heated ceilings. The asymmetry in the MRWs for direct radiation from three lamps and for floor reradiation is about 0.5 K, which is negligible.

In general, the human body has a great ability to sum sensations from many hot and cold sources. For example, Australian aborigines sleep unclothed next to open fires in the desert at night, where $t_a$ is 6°C. The $t_r$ caused directly by three fires alone is 77°C, and the cold sky $t_r$ is −1°C; the resulting $t_r$ is 28°C, which is acceptable for human comfort (Scholander 1958).

According to the limited field and laboratory data available, an allowable design radiant asymmetry of 12 ± 3 K should cause little discomfort over the comfortable $t_r$ range used by ASHRAE Standard 55 and in Figures 2 and 3. Increased clothing insulation allows increases in the acceptable asymmetry, but increased air movement reduces it. Increased activity also reduces human sensitivity to changing $t_r$ or $t_o$ and, consequently, increases the allowable asymmetry. The design engineer should use caution with an asymmetry greater than 15 K, as measured by a direct beam radiometer or estimated by calculation.

RADIATION PATTERNS

Figure 5 indicates the basic radiation patterns commonly used in design for radiation from point or line sources (Boyd 1962). A point source radiates over an area that is proportional to the square of the distance from the source. The area for a (short) line source also varies substantially as the square of the distance, with about the same area as the circle actually radiated at that distance. For line sources, the width of the pattern is determined by the reflector shape and position of the element within the reflector. The rectangular area used for installation purposes as the pattern of radiation from a line source assumes a length equal to the width plus the fixture length. This assumed length is satisfactory for design, but is often two or three times the pattern width.

Electric infrared fixtures are often identified by their beam pattern (Rapp and Gagge 1967), which is the radiation distribution normal to the line source element. The beam of a high-intensity infrared fixture may be defined as that area in which the intensity is at least 80% of the maximum intensity encountered anywhere within the beam. This intensity is measured in the plane in which maximum control of energy distribution is exercised.

The beam size is usually designated in angular degrees and may be symmetrical or asymmetrical in shape. For adaptation to their design specifications, some manufacturers indicate beam characteristics based on 50% maximum intensity.

The control used for an electric system affects the desirable maximum end-to-end fixture spacing. Actual pattern length is about three times the design pattern length, so control in three equal stages is achieved by placing every third fixture on the same circuit. If all fixtures are controlled by input controllers or variable voltage to electric units, end-to-end fixture spacing can be nearly three times the design pattern length. Side-to-side minimum spacing is determined by the distribution pattern of the fixture and is not influenced by the method of control.

Low-intensity equipment typically consists of a steel tube hung near the ceiling and parallel to the outside wall. Circulation of combustion products inside the tube elevates the tube temperature and radiant energy is emitted. The tube is normally provided with a reflector to direct the radiant energy down into the space to be conditioned.

Radiant ceiling panels for heating only are installed in a narrow band around the perimeter of an occupied space and are usually the primary heat source for the space. The radiant source is (long)
DESIGN FOR TOTAL SPACE HEATING

Radiant heating differs from conventional heating by a moderately elevated ERF, \( t_r \), over the ambient temperature \( t_a \). Standard methods of design are normally used, although informal studies indicate that radiant heating requires a lower heating capacity than convection heating (Zmeureanu et al. 1987). Buckley and Seel (1987) demonstrated that a combination of elevated floor temperature, higher mean radiant temperature, and reduced ambient temperature results in lower thermostat settings, reduced temperature differential across the building envelope, and thus, lower heat loss and heating load for the structure. In addition, the peak load may be decreased due to heat (cool) stored in the structure (Kilkis 1990, 1992).

Most gas radiation systems for full-building heating concentrate the bulk of capacity at mounting heights of 3 to 5 m at the perimeter, directed at the floor near the walls. Units can be mounted considerably higher. Successful application depends on supplying the proper amount of heat in the occupied area. Heaters should be located to take maximum advantage of the pattern of radiation produced. Exceptions to perimeter placement include walls with high transmission losses and extreme height, as well as large roof areas where roof heat losses exceed perimeter and other heat losses.

Electric infrared systems installed indoors for complete building heating have used layouts that uniformly distribute the radiation throughout the area used by people, as well as layouts that emphasize perimeter placement, such as in ice hockey rinks. Some electric radiant heaters emit a significant amount of visible radiation and provide both heating and illumination.

The orientation of equipment and people is less important for general area heating (large areas within larger areas) than it is for spot heating. With reasonably uniform radiation distribution in work or living areas, the exact orientation of the units is not important. Higher intensities of radiation may be desirable near walls with outside exposure. Radiation shields (reflective to infrared) fastened a few centimetres from the wall to allow free air circulation between the wall and shield are effective for frequently occupied work locations close to outside walls.

In full-building heating, units should be placed where their radiant and convective output best compensates for the structure’s heat loss. The objective of a complete heating system is to provide a warm floor with low conductance to the heat sink beneath the floor. This thermal storage may permit cycling of units with standard controls.

TESTING INSTRUMENTS FOR RADIANT HEATING

In designing a radiant heating system, the calculation of radiant heat exchange may involve some untested assumptions. During field installation of the radiant heating equipment, the designer must test and adjust the equipment to ensure that it provides acceptable comfort conditions. The black globe thermometer and the directional radiometer can be used to evaluate the installation.

Black Globe Thermometer

The classic (Bedford) globe thermometer is a thin-walled, matte-black, hollow sphere with a thermocouple, thermistor, or thermometer placed at the center. It can directly measure \( t_g \), ERF, and \( t_r \). When a black globe is in thermal equilibrium with its environment, the gain in radiant heat from various sources is balanced by the convective loss to ambient air. Thus, in terms of the globe’s linear radiative and convective heat transfer coefficients, \( h_{rg} \) and \( h_{cg} \), respectively, the heat balance at equilibrium is

\[
 h_{rg} (t_r - t_g) = h_{cg} (t_g - t_a)
\]

where \( t_r \) is the mean radiant temperature measured by the globe and \( t_g \) is the temperature in the globe.
Radiant Heating and Cooling

In general, the $T_r$ of Equation (18) equals the $T_r$ affecting a person when the globe is placed at the center of the occupied space and when the radiant sources are distant from the globe.

The effective radiant flux measured by a black globe is

$$ERF_g = h_{rg}(T_{rg} - t_a)$$  \hspace{1cm} (19)

which is analogous to Equation (5) for occupants. From Equations (18) and (19) it follows that

$$ERF_g = (h_{rg} + h_{rc})(t_g - t_a)$$  \hspace{1cm} (20)

If the $ERF_g$ of Equation (20) is modified by the skin-clothing absorptance $\alpha_k$ and the shape $f_{eff}$ of an occupant relative to the black globe, the corresponding $ERF$ affecting the occupant is

$$ERF\text{ (for a person)} = f_{eff} \alpha_k ERF_g$$  \hspace{1cm} (21)

where $\alpha_k$ is defined in the section on Geometry of Beam Heating and $f_{eff}$, which is defined after Equation (11), is approximately 0.71 and equals the ratio $h_r/h_{rg}$. The $t_g$ affecting a person, in terms of $t_g$ and $t_a$, is given by

$$t_o = Kt_g + (1 - K)t_a$$  \hspace{1cm} (22)

where the coefficient $K$ is

$$K = \alpha_k f_{eff}(h_{rg} + h_{rc})/(h_r + h_c)$$  \hspace{1cm} (23)

Ideally, when $K$ is unity, the $t_g$ of the globe would equal the $t_o$ affecting a person.

For an average comfortable equilibrium temperature of 25°C and noting that $f_{eff}$ for the globe is unity, Equation (11) yields

$$h_{rg} = 6.01 \text{ W/(m}^2\cdot\text{K})$$  \hspace{1cm} (24)

and Equation (12) yields

$$h_{rc} = 6.32D^{-0.4}V^{0.5}$$  \hspace{1cm} (25)

where

- $D$ = globe diameter, m
- $V$ = air velocity, m/s

Equation (25) is Bedford’s convective heat transfer coefficient for a 150 mm globe’s convective loss, modified for $D$. For any radiating source below 1200 K, the ideal diameter of a sphere that makes $K = 1$ and that is independent of air movement is 200 mm (see Table 1). Table 1 shows the value of $K$ for various values of globe diameter $D$ and ambient air movement $V$. The table shows that the uncorrected temperature of the traditional 150 mm globe would overestimate the true $(t_o - t_g)$ difference by 6% for velocities up to 1 m/s, and the probable error of overestimating $t_o$ by $t_g$ uncorrected would be less than 0.5 K. Globe diameters between 150 and 200 mm are optimum for using the uncorrected $t_o$ measurement for $t_o$. The exact value for $K$ may be used for the smaller-sized globes when estimating $t_o$ from $t_g$ and $t_a$ measurements. The value of $t_g$ may be found by substituting Equations (24) and (25) in Equation (18), because $t_g$ (person) is equal to $t_g$. The smaller the globe, the greater the variation in $ERF$ caused by air movement. Globes with $D$ greater than 200 mm will overestimate the importance of radiation gain versus convection loss.

For sources radiating at high temperatures (1000 to 5800 K), the ratio $\alpha_k/\alpha_k$ may be set near unity by using a pink-colored globe surface, whose absorptance for the sun is 0.7, a value similar to that of human skin and normal clothing (Madsen 1976).

In summary, the black globe thermometer is simple and inexpensive and may be used to determine $T_r$ [Equation (18)] and the $ERF$.

Directional Radiometer

The angle of acceptance (in steradians) in commercial radiometers allows the engineer to point the radiometer directly at a wall, floor, or high-temperature source and read the average temperature of that surface. Directional radiometers are calibrated to measure either the radiative flux accepted by the radiometer or the equivalent blackbody radiation temperature of the emitting surface. Many are collimated to sense small areas of body, clothing, wall, or floor surfaces. A directional radiometer allows rapid surveys and analyses of important radiant heating factors such as the temperature of skin, clothing surfaces, and walls and floors, as well as the radiation intensity $I_k$ of heaters on the occupants. One radiometer for direct measurement of the equivalent radiant temperature has an angle of acceptance of 2.8° or 0.098 sr, so that at 1 m, it measures the average temperature over a projected circle about 30 mm in diameter.

APPLICATIONS

When installing radiant heaters in specific applications, consider the following factors:

- Gas and electric high-temperature infrared heaters must not be placed where they could ignite flammable dust or vapors, or decompose vapors into toxic gases.
- Fixtures must be located with recommended clearances to ensure proper heat distribution. Stored materials must be kept far enough from the fixtures to avoid hot spots. Manufacturers’ recommendations must be followed.
- Unvented gas heaters inside tight, poorly insulated buildings may cause excessive humidity with condensation on cold surfaces. Proper insulation, vapor barriers, and ventilation prevent these problems.
- Combustion-type heaters in tight buildings may require makeup air to ensure proper venting of combustion gases. Some infrared heaters are equipped with induced draft fans to relieve this problem.
- Some transparent materials may break due to uneven application of high-intensity infrared. Infrared energy is transmitted without loss from the radiator to the absorbing surfaces. The system must produce the proper temperature distribution at the absorbing surfaces. Problems are rarely encountered with glass 6 mm or less in thickness.
• Comfort heating with infrared heaters requires a reasonably uniform flux distribution in the occupied area. While thermal discomfort can be relieved in warm areas with high air velocity, such as on loading docks, the full effectiveness of a radiant heater installation is reduced by the presence of high air velocity.
• Radiant spot heating and zoning in large undivided areas with variable occupancy patterns provides localized heating just where and when people are working, which reduces the heating cost.

Low-, Medium-, and High-Intensity Infrared Applications

Low-, medium-, and high-intensity infrared equipment is used extensively in industrial, commercial, and military applications. This equipment is particularly effective in large areas with high ceilings, such as in buildings with large air volumes and in areas with high infiltration rates, large access doors, or large ventilation requirements.

Factories. Low-intensity radiant equipment suspended near the ceiling around the perimeter of facilities with high ceilings enhances the comfort of employees because it warms floors and equipment in the work area. For older uninsulated buildings, the energy cost for low-intensity radiant equipment is less than that of other heating systems. High-intensity infrared for spot heating and low-intensity infrared for zone temperature control effectively heat large unheated facilities.

Warehouses. Low- and high-intensity infrared are used for heating warehouses, which usually have a large volume of air, are often poorly insulated, and have high infiltration. Low-intensity infrared equipment is installed near the ceiling around the perimeter of the building. High-level mounting near the ceiling leaves floor space available for product storage. Both low- and high-intensity infrared are arranged to control radiant intensity and provide uniform heating at the working level and frost protection areas, which is essential for perishable goods storage.

Garages. Low-intensity infrared provides comfort for mechanics working near or on the floor. With elevated MRT in the work area, comfort is provided at a lower ambient temperature.

In winter, opening the large overhead doors to admit equipment for service causes a substantial entry of cold outdoor air. On closing the doors, the combination of reradiation from the warm floor and radiant heat warming the occupants (not the air) provides rapid recovery of comfort. Radiant energy rapidly warms the cold (perhaps snow-covered) vehicles. Radiant floor panel heating systems are also effective in garages.

Low-intensity equipment is suspended near the ceiling around the perimeter, often with greater concentration near overhead doors. High-intensity equipment is also used to provide additional heat near doors.

Aircraft Hangars. Equipment suspended near the roofs of hangars, which have high ceilings and large access doors, provides uniform radiant intensity throughout the working area. A heated floor is particularly effective in restoring comfort after an aircraft has been admitted. As in garages, the combination of reradiation from the warm floor and radiation from the radiant heating system provides rapid regain of comfort. Radiant energy also heats aircraft moved into the work area.

Greenhouses. In greenhouse applications, a uniform flux density must be maintained throughout the facility to provide acceptable growing conditions. In a typical application, low-intensity units are suspended near, and run parallel to, the peak of the greenhouse.

Outdoor Applications. Applications include loading docks, racetrack stands, outdoor restaurants, and under marquees. Low-, medium-, and high-intensity infrared are used in these facilities, depending on their layout and requirements.

Other Applications. Radiant heat may be used in a variety of large facilities with high ceilings, including churches, gymnasiums, swimming pools, enclosed stadiums, and facilities that are open to the outdoors. Radiant energy is also used to control condensation on surfaces such as large glass exposures. One example is at the Chicago/O’Hare Airport.

Low-, medium-, and high-intensity infrared are also used for other industrial applications, including process heating for component or paint drying ovens, humidity control for corrosive metal storage, and snow control for parking or loading areas.

Panel Heating and Cooling

Residences. Embedded pipe coil systems, electric resistance panels, and forced warm-air panel systems have all been used in residences. The embedded pipe coil system is most common, using plastic or rubber tubing in the floor slab or copper tubing in older plaster ceilings. These systems are suitable for conventionally constructed residences with normal amounts of glass. Light hydronic metal panel ceiling systems have also been applied to residences, and prefabricated electric panels are advantageous, particularly in rooms that have been added on.

Office Buildings. A panel system is usually applied as a perimeter heating system. Panels are typically piped to provide exposure control with one riser on each exposure and all horizontal piping incorporated in the panel piping. In these applications, the air system provides individual room control. Perimeter radiant panel systems have also been installed with individual zone controls. However, this type of installation is usually more expensive and, at best, provides minimal energy savings and limited additional occupant comfort. Radiant panels can be used for cooling as well as heating. Cooling installations are generally limited to retrofit or renovation jobs where ceiling space is insufficient for the required duct sizes. In these installations, the central air supply system provides ventilation air, dehumidification, and some sensible cooling. Water distribution systems using the two- and four-pipe concept may be used. Hot water supply temperatures are commonly reset by outside temperature, with additional offset or flow control to compensate for solar load. Panel systems are readily adaptable to accommodate most changes in partitioning. Electric panels in lay-in ceilings have been used for full perimeter heating.

Schools. In all areas except gymnasiums and auditoriums, panels are usually selected for heating only, and may be used with any type of approved ventilation system. The panel system is usually sized to offset the transmission loads plus any reheating of the air. If the school is air conditioned by a central air system and has perimeter heating panels, single-zone piping may be used to control the panel heating output, and the room thermostat modulates the supply air temperature or volume. Heating and cooling panel applications are similar to those in office buildings. Panel heating and cooling for classroom areas has no mechanical equipment noise to interfere with instructional activities.

Hospitals. The principal application of heating and cooling radiant panels has been for hospital patient rooms. Perimeter radiant heating panels are typically applied in other areas of hospitals. Compared to conventional systems, radiant heating and cooling systems are well suited to hospital patient rooms because they (1) provide a draft-free, thermally stable environment, (2) have no mechanical equipment or bacteria and virus collectors, and (3) do not take up space in the room. Individual room control is usually achieved by throttling the water flow through the panel. The supply air system is often 100% outdoor air; minimum air quantities delivered to the room are those required for ventilation and exhaust of the toilet room and soiled linen closet. The piping system is typically a four-pipe design. Water control valves should be installed in corridors so that they can be adjusted or serviced without entering the patient rooms. All piping connections above the ceiling should be soldered or welded and thoroughly tested. If cubicle tracks are applied to the ceiling surface, track installation should be coordinated with the radiant ceiling. Security panel ceilings are often used in areas occupied by mentally disturbed patients so that equipment cannot be damaged by a patient or used to inflict injury.
Swimming Pools. A partially clothed person emerging from a pool is very sensitive to the thermal environment. Panel heating systems are well suited to swimming pool areas. Floor panel temperatures must be controlled so they do not cause foot discomfort. Ceiling panels are generally located around the perimeter of the pool, not directly over the water. Panel surface temperatures are higher to compensate for the increased ceiling height and to produce a greater radiant effect on partially clothed bodies. Ceiling panels may also be placed over windows to reduce condensation.

Apartment Buildings. For heating, pipe coils are embedded in the masonry slab. The coils must be carefully positioned so as not to overheat one apartment while maintaining the desired temperature in another. The slow response of embedded pipe coils in buildings with large glass areas may be unsatisfactory. Installations for heating and cooling have been made with pipes embedded in hung plaster ceilings. A separate minimum-volume dehumidified air system provides the necessary dehumidification and ventilation for each apartment. The application of electric resistance elements embedded in floors or behind a skim coat of plaster at the ceiling has increased. Electric panels are easy to install and simplify individual room control.

Industrial Applications. Panel systems are widely used for general space conditioning of industrial buildings in Europe. For example, the walls and ceilings of an internal combustion engine test cell are cooled with chilled water. Although the ambient air temperature in the space reaches up to 35°C, the occupants work in relative comfort when 13°C water is circulated through the ceiling and wall panels.

Other Buildings. Metal panel ceiling systems can be operated as heating systems at elevated water temperatures and have been used in airport terminals, convention halls, lobbies, and museums, especially those with large glass areas. Cooling may also be applied. Because radiant energy travels through the air without warming it, ceilings can be installed at any height and remain effective. One particularly high ceiling installed for a comfort application is 15 m above the floor, with a panel surface temperature of approximately 140°C for heating. The ceiling panels offset the heat loss from a single-glazed, all-glass wall.

The high lighting levels in television studios make them well suited to panels that are installed for cooling only and are placed above lighting to absorb the radiation and convection heat from the lights and normal heat gains from the space. The panel ceiling also improves the acoustical properties of the studio.

Metal panel ceiling systems are also installed in minimum and medium security jail cells and in facilities where disturbed occupants are housed. The ceiling is strengthened by increasing the gage of the ceiling panels, and security clips are installed so that the ceiling panels cannot be removed. Part of the perforated metal ceiling can be used for air distribution.

New Techniques. The introduction of thermoplastic and rubber tubing and new design techniques have improved radiant panel heating and cooling equipment. The systems are energy-efficient and use low water temperatures available from solar collectors and heat pumps (Kilkis 1993). Metal radiant panels can be integrated into the ceiling design to provide a narrow band of radiant heating around the perimeter of the building. These new radiant systems are more attractive, provide more comfortable conditions, operate more efficiently, and have a longer life than some baseboard or overhead air systems.

SEISMIC AND WIND RESTRAINT DESIGN

Almost all inhabited areas of the world are susceptible to the damaging effects of either earthquakes or wind. Restraints that are designed to resist one may not be adequate to resist the other. Consequently, when exposure to either earthquake or wind loading is a possibility, strength of equipment and attachments should be evaluated for both conditions.

Earthquake damage to inadequately restrained HVAC&R equipment can be extensive. Mechanical equipment that is blown off the support structure can become a projectile, threatening life and property. The cost of properly restraining the equipment is small compared to the high costs of replacing or repairing damaged equipment, or compared to the cost of building down-time due to damaged facilities.

Design and installation of seismic and wind restraints has the following primary objectives:

- Life safety to reduce the threat to life
- Reduce long-term costs due to equipment damage and the resultant down time

This chapter covers the design of restraints to limit the movement of equipment and to keep the equipment captive during an earthquake or during extreme wind loading. Seismic restraints and seismic isolators do not reduce the forces transmitted to the equipment to be restrained. Instead, properly designed and installed seismic restraints and seismic isolators have the necessary strength to withstand the imposed forces. However, equipment that is to be restrained must also have the necessary strength to remain attached to the restraint. Equipment manufacturers should review structural aspects of the design in the areas of attachment to ensure the equipment will remain attached to the restraint.

For mechanical systems, analysis of seismic and wind loading conditions is typically a static analysis, and conservative safety factors are applied to reduce the complexity of earthquake and wind loading response analysis and evaluation. Three aspects are considered in a properly designed restraint system.

1. Attachment of equipment to restraint. The equipment must be positively attached to the restraint, and must have sufficient strength to withstand the imposed forces, and to transfer the forces to the restraint.
2. Restraint design. Strength of the restraint must also be sufficient to withstand the imposed forces. This should be determined by the manufacturer by tests and/or analyses.
3. Attachment of restraint to substructure. Attachment may be by means of bolts, welds or concrete anchors. The substructure must be capable of surviving the imposed forces.

The preparation of this chapter is assigned to TC 2.7, Seismic Restraint Design.

Seismic Restraint Design

Most seismic requirements adopted by local jurisdictions in North America are based on model codes developed by the International Conference of Building Officials (ICBO), Building Officials and Code Administrators International (BOCA), the Southern Building Code Conference, Inc. (SBCCI), and the National Building Code of Canada (NBCC); or on the requirements of the National Earthquake Hazards Reduction Program (NEHRP). The model code bodies are working through the International Code Council (ICC) to unify their model codes into the International Building Code (IBC) by the year 2000. Local building officials must be contacted for specific requirements that may be more stringent than those presented in this chapter and to determine if the unified specification has been invoked.

Other sources of seismic restraint information include:

- Seismic Restraint Manual: Guidelines for Mechanical Systems, published by SMACNA (1998), includes seismic restraint information for mechanical equipment subjected to seismic forces of up to 4.7 m/s² (0.48g).
- The National Fire Protection Association (NFPA) has developed standards on restraint design for fire protection systems.
- U.S. Department of Energy DOE 6430.1A and ASME AG-1 cover restraint design for nuclear facilities.

In seismically active areas where governmental agencies regulate the earthquake-resistive design of buildings (e.g., California), the HVAC engineer usually does not prepare the code-required seismic restraint calculations. The HVAC engineer selects all the heating and cooling equipment and, with the assistance of the acoustical engineer (if the project has one), selects the required vibration isolation devices. The HVAC engineer specifies these devices and calls for shop drawing submittals from the contractors, but the manufacturer employs a registered engineer to design and detail the installation. The HVAC engineer reviews the shop design and details the installation, reviews the shop drawings and calculations, and obtains the approval of the architect and structural engineer before issuance to the contractors for installation.

Anchors for tanks, brackets, and other equipment supports that do not require vibration isolation are designed by the building’s structural engineer, or by the supplier of the seismic restraints, based on layout drawings prepared by the HVAC engineer. The building officials maintain the code-required quality control over the design by requiring that all building design professionals are registered (licensed) engineers. Upon completion of installation, the supplier of the seismic restraints, or a qualified representative, should inspect the installation and verify that all restraints are installed properly and in compliance with specifications.
### TERMINOLOGY

**Base plate thickness.** Thickness of the equipment bracket fastened to the floor.

**Effective shear force** \((V_{ep})\). Maximum shear force of one seismic restraint or tie-down bolt.

**Effective tension force** \((T_{ep})\). Maximum tension force or pullout force on one seismic restraint or tie-down bolt.

**Equipment.** Any HVAC&R component that must be restrained from movement during an earthquake.

**Fragility level.** Maximum lateral acceleration force that the equipment is able to withstand. This data may be available from the equipment manufacturer and is generally on the order of four times the acceleration of gravity \((4g)\) for mechanical equipment.

**Resilient support.** An active seismic device (such as a spring with a bumper) to prevent equipment from moving more than a specified amount.

**Response spectra.** Relationship between the acceleration response of the ground and the peak acceleration of the earthquake. The ground motion response spectrum varies with soil conditions.

**Rigid support.** Passive seismic device used to restrict any movement.

**Shear force** \((V)\). Force generated at the plane of the seismic restraints, acting to cut the restraint at the base.

**Seismic restraint.** Device designed to withstand an earthquake.

**Seismic zones.** The geographical location of a facility determines its seismic zone, as given in the Uniform Building Code or International Building Code.

**Snubber.** Device made of steel-housed resilient bushings arranged to prevent equipment from moving beyond an established gap.

**Tension force** \((T)\). Force generated by overturning moments at the plane of the seismic restraints, acting to pull out the bolt.

### CALCULATIONS

The calculations presented here assume that the equipment support is an integrated resilient support and restraint device. When the two functions of resilient support and motion restraint are separate or act separately, additional spring loads may need to be added to the anchor load calculation for the restraint device. Internal loads within integrated devices are not addressed in this chapter. Such devices must be designed to withstand the full anchorage loads plus any internal spring loads.

Both static and dynamic analyses reduce the force generated by an earthquake to an equivalent static force, which acts in a horizontal direction at the component’s center of mass. The resulting overturning moment is resisted by shear and tension (pullout) forces on the tie-down bolts. Static analysis is used for both rigid-mounted and resilient-mounted equipment.

### Dynamic Analysis

A dynamic analysis is based on site-specific ground motions developed by a geotechnical or soils engineer. A common approach assumes an elastic response spectrum. The results of the dynamic analysis are then scaled up or down as a percentage of the total lateral force obtained from the static analysis performed on the building. The scaling coefficient is established by the UBC or by the governing building official. The scaled acceleration calculated by the structural engineer at any level in the structure can be determined and compared to the force calculated in Equation (1). The greater of the two should be used in the anchor design. The horizontal force factor \(C_h\) should be multiplied by a factor of two in either case, as shown in Table 1.

### Static Analysis as Defined in the International Building Code

The final draft of the International Building Code (ICC 1998) specifies a design lateral force \(F_p\) for nonstructural components as

\[
F_p = \frac{0.4a_p S_{DS} W_p}{I_p} \left(1 + \frac{2\zeta}{h}\right)
\]

but \(F_p\) need not be greater than

\[
F_p = 1.6 S_{DS} I_p W_p
\]

nor less than

\[
F_p = 0.35 S_{DS} I_p W_p
\]

A vertical force is specified as

\[
F_v = 0.2 S_{DS} W_p
\]

where

- \(a_p\) = component amplification factor in accordance with \(\text{Table 1}\)
- \(S_{DS}\) = design spectral response acceleration at short periods as determined by \(S_{DS} = 2F_p S/S.\) \(S_s\) is the mapped spectral accelerations from \(\text{Figure 1}\) and \(0.8 \leq F_s \leq 2.5.\) \(F_p\) is a function of the site soil characteristics and must be determined in consultation with either the project geotechnical (soils) or structural engineer. Values for \(F_p\) are given in \(\text{Table 2}\).
- \(I_p\) = component response modification factor in accordance with \(\text{Table 1}\).
- \(R_p\) = component response modification factor in accordance with \(\text{Table 2}\).
- \(1 + 2\zeta/h\) = height amplification factor where \(\zeta\) is the height of attachment in the structure and \(h\) is the average height of the roof above grade. The value of \(\zeta\) should not be taken as less than 0.
- \(W_p\) = mass of equipment, which includes all items attached or contained in the equipment.

Seismic and Wind Restraint Design

53.3

The total design lateral seismic force is given as

\[ F_p = Z I_p C_p W_p \]  

where

- \( F_p \) = total design lateral seismic force
- \( Z \) = seismic zone factor
- \( I_p \) = importance factor (set equal to 1.5 for equipment)
- \( C_p \) = horizontal force factor
- \( W_p \) = weight of equipment in newtons = mass in kilograms times standard acceleration of gravity (9.807 m/s²)

The seismic zone factor \( Z \) can then be determined from Table 4.

Seismic Design for Buildings (Army, Navy, and Air Force 1992) can also be used to determine the seismic zone.

The importance factor \( I_p \) from the UBC (ICBO 1994) ranges from 1 to 1.5, depending on the building occupancy and hazard level. For equipment, \( I_p \) should be conservatively set at 1.5.

The horizontal force factor \( C_p \) is determined from Table 5 based on the type of equipment, the tie-down configuration, and the type of base.

The weight \( W_p \) of the equipment should include all the items attached or contained in the equipment.

Note: Stacks and tanks should be evaluated for compliance with the applicable codes by a qualified engineer.

**Static Analysis as Defined in 1994 Uniform Building Code**

The forces acting on the equipment are the lateral and vertical forces resulting from the earthquake, the force of gravity, and the forces of the restraint holding the equipment in place. The analysis assumes the equipment does not move during an earthquake, thus, the sum of the forces and moments must be zero. When calculating the overturning moment, the vertical component \( F_p V \) at the center of mass is given as

\[ F_p V = F_p / 3 \]  

The forces of the restraint holding the equipment in position include shear and tension forces. It is important to determine the number of bolts that are affected by the earthquake forces. The direction of the lateral force should be evaluated in both horizontal directions as shown in Figure 3. All bolts or as few as a single bolt may be affected.

\[ 0 = F_p - V \]  

The effective shear force \( V_{eff} \) is

\[ V_{eff} = F_p / N_{bolt} \]  

where \( N_{bolt} \) = the number of bolts in shear.

</tbody>
</table>
The restraints shown in Figure 3 have two bolts on each side, so that four bolts are in shear. To calculate the tension force, the sum of the moments for overturning are as follows:

\[
T = \frac{F_p h_{cg} - \left(W_p - F_p/3\right)D_1/2}{D_1}
\] (9)

Thus, the effective tension force is

\[
T_{eff} = TN_{bolts}
\] (10)

For the example shown in Figure 3, two bolts are in tension. The shear and tension forces \(V\) and \(T\) should be calculated independently for both axes as shown in the front and side views. The worst case governs seismic restraint design; however, the direction of seismic loading that governs the design in not always obvious. For example, if three bolts were installed on each side, the lateral force applied as shown in the side view affects six bolts in shear and a minimum of two in tension. The lateral force applied as shown on the front view results in six bolts affected in shear and three in tension. Also, \(D_1\) and \(D_2\) are different for each axis.

Equations (6), (7), and (8) may be applied to ceiling-mounted equipment. Equation (9) must be modified to Equation (11) because the mass of the equipment adds to the overturning moment. Summing the moments determines the effective tension force as

\[
T = \frac{D_1 F_p h_{cg} + \left(W_p + \frac{F_p}{3}\right)D_2/2}{D_1}
\] (11)

### Interaction Formula

To evaluate the combined effective tension and shear forces that act simultaneously on the bolt, the following equation applies:

\[
\left(\frac{T_{eff}}{T_{allow}}\right)^{5/3} + \left(\frac{V_{eff}}{V_{allow}}\right)^{5/3} \leq 1.0
\] (12)

### Table 7  Typical Allowable Loads for Wedge-Type Anchors

**Notes**:
1. The allowable tensile forces are for installations without special inspection (torque test) and may be doubled if the installation is inspected.
2. Additional tension and shear values may be obtained from published ICBO reports.
ANCHOR BOLTS

Several types of anchor bolts for insertion in concrete are manufactured. Wedge and sleeve anchors perform better than self-drilling or drop-in types. Epoxy-type anchors are stronger than other anchors, but lose their strength at elevated temperatures (i.e., on rooftops and in areas damaged by fire).

Wedge-type anchors have a wedge on the end with a small clip around the wedge. After a hole is drilled, the bolt is inserted and the external nut tightened. The wedge expands the small clip, which bites into the concrete.

A self-drilling anchor is basically a hollow drill bit. The anchor is used to drill the hole and is then removed. A wedge is then inserted on the end of the anchor, and the assembly is drilled back into place; the drill twists the assembly fully in place. The self-drilling anchor is weaker than other types because it forms a rough hole.

Drop-in expansion anchors are hollow cylinders with a tapered end. After they are inserted in a hole, a small rod is driven through the hollow portion, expanding the tapered end. These anchors are only for shallow installations because they have no reserve expansion capacity.

A sleeve anchor is a bolt covered by a threaded, thin-wall, split tube. As the bolt is tightened, the thin wall expands. Additional load tends to further expand the thin wall. The bolt must be properly pre-loaded or friction force will not develop the required holding force.

Adhesive anchors may be in glass capsules or installed with various tools. Pure epoxy, polyester, or vinyl ester resin adhesives are used with a threaded rod supplied by the contractor or the adhesive manufacturer. Some adhesives have a problem with shrinkage; others are degraded by heat. However, some adhesives have been tested without protection to 590°C before they fail (all mechanical anchors will fail at this temperature). Where required, or if there is a concern, anchors should be protected with fire retardants similar to those applied to steel decks in high-rise buildings.

The manufacturer’s instructions for installing the anchor bolts should be followed. Performance test data published by manufacturers should include shock, fatigue, and seismic resistance. IBEC reports have further information on allowable forces for design. Add a safety factor of two if the installation has not been inspected by a qualified firm or individual.

WELD CAPACITIES

Weld capacities may be calculated to determine the size of welds needed to attach equipment to a steel plate or to evaluate raised support legs and attachments. A static analysis provides the effective tension and shear forces. The capacity of a weld is given per unit length of weld based on the shear strength of the weld material. For steel welds, the allowable shear strength capacity if 110 MPa on the throat section of the weld. The section length is 0.707 times the specified weld size.

For a 1.5 mm weld, the length of shear in the weld is 0.707 × 1.5 = 1.06 mm. The allowable weld force \( F_{w, allow} \) for a 1.5 mm weld is

\[
F_{w, allow} = 1.06 \times 110 = 117 \text{ N per millimetre of weld}
\]

For a 3 mm weld, the capacity is 233 N/mm.

The effective weld force is the sum of the vectors calculated in Equations (8) and (10). Because the vectors are perpendicular, they are added by the method of the square root of the sum of the squares (SRSS), or:

\[
(F_w)_{eff} = \sqrt{(T_{eff})^2 + (V_{eff})^2}
\]

The length of weld required is given by the following equation:

\[
\text{Length} = \frac{(F_w)_{eff}}{(F_w)_{allow}}
\]

SEISMIC SNUBBERS

Several types of snubbers are manufactured or field fabricated. All snubber assemblies should meet the following minimum requirements to avoid imparting excessive accelerations to the HVAC&R equipment:

- Impact surface should have a high-quality elastomeric surface that is not cemented in place
- Resilient material should be easy to inspect for damage and be replaceable if necessary
- Assembly must provide restraint in all directions
- Snubbers should be tested by an independent test laboratory (and analyzed by a registered engineer to ensure the stated load capacity and) to avoid serious design flaws.

Typical snubbers are classified as Types A through J (see Figure). Many devices are presently approved with Office of Statewide Health Planning Development (OSHPD) ratings.

Type A. Snubber built into a resilient mounting. All-directional, molded bridge-bearing quality neoprene element is a minimum of 3.2 mm thick. Mounting must have a minimum of two anchor bolt holes.

Type B. Isolator/Restraint. Stable isolation spring bears on the base plate of the fixed restraining member. Earthquake motion of the isolated equipment is restrained close to the base plate, minimizing pullout force to the base plate anchorage.

Type C. Spring isolator with built-in all directional restraints. Restraints have molded neoprene elements with a minimum thickness of 3.2 mm. A neoprene sound pad should be included between the spring and the base plate. Sound pads below the base plate are not recommended for seismic installations. The base plate should have a minimum of four anchor bolt holes.

Type D. Integral all directional snubber/restrained spring isolator with AASHTO quality replaceable neoprene element. The all welded housing has a minimum of two anchor bolt holes for attachment to the structure.

Type E. Fully bonded neoprene mount capable of withstanding seismic loads in all directions with no metal-to-metal contact. Outer hosing must be ductile iron and have a minimum of two anchor bolt holes.

Type F. All-directional with molded, replaceable neoprene element. Neoprene element of bridge-bearing quality is a minimum of 4.8 mm. Snubber must have a minimum of two anchor bolt holes.

Type G. All-directional lateral snubber. Reinforced AASHTO quality neoprene element is a minimum of 6.4 mm thick. Upper bracket is welded to the equipment and the base plate has a minimum of two anchor bolt holes.

Type H. Restriction for floor mounted equipment consisting of interlocking steel assemblies lined with resilient elastomer. Bolt to equipment and anchored to structure through slotted holes to allow field adjustment of restraint for 6.4 mm clearance in the horizontal and vertical directions. After final adjustment, weld anchor to floor bracket and angle clip to equipment to assure no slip can occur. Alternately, fill slots with epoxy grout to prevent slip. The restraint assembly rating is certified by independent laboratory test.

Type I. Single axis, single direction lateral snubber, ribbed AASHTO quality neoprene element is a minimum of 6.4 mm thick. Minimum floor mounting is with two anchor bolts. Must be used in sets of 4 or more.

Type J. Prestretched aircraft wire rope with galvanized end connections that avoid bending the wire rope across sharp edges. This type of snubber is mainly used with suspended pipe duct and equipment.
EXAMPLES

The following examples are provided to assist in the design of equipment anchorage to resist seismic forces. Assume seismic zone 4 for all examples.

Example 1. Anchorage design for equipment rigidly mounted to the structure (see Figure 5).

From Equations (5) and (6), calculate the lateral seismic force and its vertical component:

\[ F_p = 0.4 \times 1.5 \times 0.75 \times 4500 = 2025 \text{ N} \]
\[ F_{pv} = F_p / 3 = 2025 / 3 = 675 \text{ N} \]

Calculate the overturning moment (OTM):

\[ \text{OTM} = F_p h_{cg} = (2025 \times 1.0) = 2025 \text{ N} \cdot \text{m} \quad (14) \]
Calculate the resisting moment (RM):
\[
RM = \frac{(W_p + F_p) d_{min}}{2}
\]
\[
= \frac{(4500 + 675) \times 0.70}{2} = 1811 \text{ or } 1339 \text{ N} \cdot \text{m}
\]
(15)

Calculate the tension force \( T \), using \( RM_{min} \) to determine the maximum tension force:
\[
T = \frac{(OTM - RM_{min})}{d_{min}} = \frac{(2025 - 1339)}{0.70} = 980 \text{ N}
\]
(16)

This force is the same as that obtained using Equation (9).

Calculate \( T_{eff} \) per bolt from Equation (10):
\[
T_{eff} = 980 / 2 = 490 \text{ N/bolt}
\]
Calculate shear force per bolt from Equation (8):
\[
V_{eff} = 2025 / 4 = 506 \text{ N/bolt}
\]

**Case 1. Equipment attached to a timber structure**

From the National Design Specification for Wood Construction (NDS) (AFPA 1997). Selected fasteners must be secured to solid lumber, not to plywood or other similar material. The following calculations are made to determine whether a 13 mm diameter, 100 mm long post drill-in anchors can be used.

Therefore, a 13 mm diameter, 100 mm long lag screw will hold the required load.

From Table 8.1A in the NDS, which is inch-pound units, for Group IV (mixed species), \( G = 0.35 \), and from Table 8.6A, the allowable withdrawal load is 203 lb/ln. \( \times 4.45 \text{ N/lb/(25.4 mm/m)} = 35.6 \text{ N/mm} \), and in the NDS,
\[
T_{allow} = (35.6 \text{ N/mm} \times 88 \text{ mm penetration})/2/3 = 2090 \text{ N}
\]
where the factor 2/3 accounts for the fact that about one-third of the length of a lag screw or bolt has no threads on the shank.

From Table 8.6C in the NDS,
\[
V_{allow} = 800 \text{ N}
\]

Other types of wood may be used with appropriate factors from Table 8 and/or other reductions as specified in Part II of the NDS.

In timber construction, the interaction formula given in Equation (12) does not apply to steel-to-steel connections. Instead, the allowable tension load must be modified as in the following equation:
\[
(T_{allow})_{mod} = F_a A_b
\]

where
\[
F_a = 116 - 1.8(V/N_{bob} A_b) \leq 140(4/3) = 187
\]

\( V/N_{bob} \) is in kilonewtons and \( F_a \) is in kilopascals. The 33% stress increase (4/3) is allowed for short-term loads such as wind or earthquakes.

**Example 2. Anchorage design for equipment supported by external spring mounts**

A mechanical or acoustical consultant should choose the type of isolator or snubber or combination of the two. Then the product vendor should select the actual spring snubber.

Assume that the center of mass, which is abbreviated \( cg \) (center of gravity) in this chapter, (cg) of the equipment coincides with the center of mass of the isolator group.

If \( T \) = maximum tension on isolator,
\[
C = \text{maximum compression on isolator},
\]
\[
F_{pv} = F_p/3,
\]
then
\[
W_p + F_{pv} h_{cg} \cos \theta + F_p h_{cg} \sin \theta
\]
\[
= \frac{W_p + F_{pv}}{4} + \frac{F_p h_{cg}}{2} \left( \cos \frac{\theta_{max}}{a} + \sin \frac{\theta_{max}}{a} \right)
\]

To find maximum \( T \) or \( C \), set \( dT/d\theta = 0 \):
\[
\frac{dT}{d\theta} = \frac{F_p h_{cg}}{2} \left( - \sin \theta + \cos \frac{\theta}{a} \right) = 0
\]
\[
\theta_{max} = \tan^{-1}(b/a) = \tan^{-1}(0.7/1.2) = 30.26^\circ
\]
(17)

\[
T = \frac{W_p + F_{pv}}{4} + \frac{F_p h_{cg}}{2} \left( \cos \frac{\theta_{max}}{b} + \sin \frac{\theta_{max}}{a} \right)
\]
(18)

\[
C = \frac{W_p - F_{pv}}{4} - \frac{F_p h_{cg}}{2} \left( \cos \frac{\theta_{max}}{b} + \sin \frac{\theta_{max}}{a} \right)
\]
(19)

**Table 8 Allowable Loads for A307 Bolts**

<table>
<thead>
<tr>
<th>Diameter, mm</th>
<th>( T_{allow}, \text{kN} )</th>
<th>( V_{allow}, \text{kN} )</th>
<th>( A_b, \text{mm}^2 )</th>

<td>506</td>
</tr>
</tbody>
</table>

The interaction formula given in Equation (12) does not apply to steel-to-steel connections. Instead, the allowable tension load must be modified as in the following equation:

\[
(T_{allow})_{mod} = F_a A_b
\]

**Fig. 6 Equipment Supported by External Spring Mounts**
Seismic and Wind Restraint Design

From Equations (5) and (6),
\[ F_p = 0.4 \times 1.5 \times 2 \times 0.75 \times 12 = 10.8 \text{ kN} \]
\[ F_{pv} = F_p / 3 = 10.8 / 3 = 3.6 \text{ kN} \]

From Equations (18) and (19),
\[ T = -2.10 + 8.93 = 6.83 \text{ kN} \]
\[ C = -3.90 - 8.93 = -12.83 \text{ kN} \]

Calculate the shear force per isolator:
\[ V = F_p / N_{iso} = 10.8 / 4 = 2.70 \text{ kN} \] (20)

This shear force is applied at the operating height of the isolator. Uplift tension \( T \) on the vibration isolator is the worst condition for the design of the anchor bolts. The compression force \( C \) must be evaluated to check the adequacy of the structure to resist the loads [Figure 7].

The value of \( (T_2)_{eff} \) per bolt due to overturning on the isolator is
\[ (T_2)_{eff} = \frac{V \times \text{Optimum height}}{0.85d/N_{bolts}} \]

where \( d \) = distance from edge of isolator base plate to center of bolt hole.

\[ (T_2)_{eff} = \frac{2.7 \times 200}{0.85 \times 75 \times 2} = 4.24 \text{ kN} \]

\[ (T_{max})_{eff} = (T_1)_{eff} + (T_2)_{eff} = 3.42 + 4.24 = 7.66 \text{ kN} \]

\[ V_{eff} = 2.70 / 2 = 1.35 \text{ kN} \]

Determine whether 16 mm post drill-in anchors with special inspection will handle this load. From Equation (12) and Table 7,
\[ \left( \frac{7.66}{2 \times 4.0} \right)^{5/3} + \left( \frac{1.35}{9.8} \right)^{5/3} = 0.97 < 1.0 \]

Therefore, 16 mm post drill-in anchors will carry the load.

Example 3. Anchorage design for equipment with a center of mass different from that of the isolator group (see Figure 8).

Anchor properties: \( I_x = 4B^2 \); \( I_y = 4L^2 \)

Angles:
\[ \theta = \tan^{-1}(B/L) \] (21)
\[ \alpha = \tan^{-1}(e_y/e_x) \] (22)
\[ \beta = 180 - |\alpha - \theta| \] (23)

Vertical reactions:
\[ (W_n)_{max/min} = W_p \pm F_{pv} \] (25)

Vertical reaction due to overturning moment:
\[ T_m = F_p h_c g \left( \frac{B}{I_y} \cos \phi + \frac{L}{I_y} \sin \phi \right) \] (26)

Vertical reaction due to eccentricity:
\[ (T_e)_{max/min} = (W_n)_{max/min} \left( \frac{B e_x}{I_x} + \frac{L e_y}{I_y} \right) \] (27)

Vertical reaction due to \( W_p \):
\[ (T_w)_{max/min} = (W_n)_{max/min} / 4 \] (28)

\[ T_{max} = T_m + (T_e)_{max} + (T_w)_{max} \] (29)

\[ T_{min} = T_m + (T_e)_{min} + (T_w)_{min} \] (tension if positive) (30)

Horizontal reactions:

Horizontal reaction due to rotation:
\[ V_{rot} = F_p \left[ \frac{e_y^2 + e_x^2}{16(B^2 + L^2)} \right]^{0.5} \] (31)

\[ V_{dir} = F_p / 4 \] (32)

\[ V_{max} = (V_{rot}^2 + V_{dir}^2 - 2V_{rot}V_{dir} \cos \beta)^{0.5} \] (33)

From Equations (5) and (6),
\[ F_p = 0.4 \times 1.5 \times 2 \times 0.75 \times 11 = 9.9 \text{ kN} \]
\[ F_{pv} = 9.9 / 3 = 3.3 \text{ kN} \]

\[ I_x = 4(0.51)^2 = 1.04 \text{ m}^2; \quad I_y = 4(0.76)^2 = 2.31 \text{ m}^2 \]

From Equations (21) through (24),
\[ \theta = 33.86^\circ \quad \alpha = 63.43^\circ \]
\[ \beta = 150.43^\circ \quad \phi = 33.86^\circ \]
From Equation (25),
\[(W_n)_{max/min} = 14.3 \text{ or } 7.7 \text{ kN}\]

From Equation (26),
\[T_m = 9.9(0.407 + 0.183) = 5.84 \text{ kN}\]

From Equation (27),
\[(T_e)_{max/min} = 0.1148 \times (W_n)_{max/min} = 1.64 \text{ kN or } 0.88 \text{ kN}\]

From Equation (28),
\[(T_e)_{max/min} = 3.58 \text{ kN or } 1.93 \text{ kN}\]

From Equation (29),
\[T_{max} = 5.84 + 1.64 + 3.58 = 11.06 \text{ kN}\]

From Equation (30),
\[T_{min} = 5.84 + 0.88 - 1.93 = 4.79 \text{ kN (tension)}\]

From Equations (31), (32), and (33),
\[V_{rot} = 9.9 \times 0.061 = 0.60 \text{ kN}\]
\[V_{dir} = 9.9 \times \frac{4}{2} = 2.48 \text{ kN}\]
\[V_{max} = 3.02 \text{ kN}\]

The values of \(T_{max}\) and \(V_{max}\) are used to design the anchorage of the isolators and/or snubbers, and \(T_{max}\) is used to verify the adequacy of the structure to resist the vertical loads.

**Example 4.** Anchorage design for equipment with supports and bracing for suspended equipment (see Figure 9). Equipment weight \(W_p = 2200 \text{ N}\).

Because post drill-in anchors may not withstand published allowable static loads when subjected to vibratory loads, vibration isolators should be used between the equipment and the structure to dampen vibrations generated by the equipment.

From Equations (5) and (6),
\[F_p = 0.4 \times 1.5 \times 2 \times 0.75 \times 2200 = 1980 \text{ N}\]
\[F_{pv} = 1980 \times \frac{3}{3} = 660 \text{ N}\]

From Equation (14),
\[\text{OTM} = 1980 \times 0.30 = 594 \text{ N} \cdot \text{m}\]

From Equation (10),
\[\text{RM} = (2200 \pm 660) \times 0.90/2 = 1287 \text{ or } 693 \text{ N} \cdot \text{m}\]

Because RM is greater than OTM, overturning is not critical.

Force to the hanger rods:
\[T_{eff} = (W_p + F_{pv})/4 = (2200 + 660)/4 = 715 \text{ N}\]

Force in the splay brace = \(\sqrt{2} \times F_p = 2800 \text{ N at a 1:1 slope}\)

Due to the force being applied at the critical angle, as in Example 2, only one splay brace is effective in resisting the lateral load \(F_p\). If eccentricities occur, as in Example 3, a similar method of analysis must be done to obtain the design forces.

**Design of hanger rod/vibration isolator and connection to structure**

When installing post drill-in anchors in the underside of a concrete beam or slab, the allowable tension loads on the anchors must be reduced to account for the cracking of the concrete. A general rule is to use half the allowable load.

Determine whether a 13 mm wedge anchor with special inspection provisions will hold the required load.

Note: The splay braces are prestretched aircraft cables with enough slack so that the isolators can fully function vertically.

**Fig. 9 Supports and Bracing for Suspended Equipment**

\[T_{allow} = 2600 \times 0.5 = 1300 \text{ N} > T_{eff} = 715 \text{ N}\]

Therefore, a 13 mm rod and post drill-in anchor should be used at each corner of the unit.

For anchors installed without special inspection,
\[T_{allow} = 1300 \times 0.5 = 650 \text{ N} < T_{eff} = 715 \text{ N}\]

Therefore, a larger anchor would have to be chosen.

**Design of splay brace and connection to structure**

Force in the slack cable = 2800 N

Force in the connection to the structure:
\[V_{max} = 2800/ \sqrt{2} = 1980 \text{ N}\]
\[V_{max} = 3.02 \text{ kN}\]

Design of splay brace and connection to structure

Force in the hanger rod = 2800 N at a 1:1 slope

Due to the force being applied at the critical angle, as in Example 2, only one splay brace is effective in resisting the lateral load \(F_p\). If eccentricities occur, as in Example 3, a similar method of analysis must be done to obtain the design forces.

Determine whether a 19 mm wedge-type anchor will hold the required load. From Table 7,
\[T_{allow} = 6000/2 = 3000 \text{ N}\]
\[V_{allow} = 13 \times 300 = 3900 \text{ N}\]

Therefore, it is permissible to use a 19 mm anchor or multiple anchors of a smaller size bolted through a clip and to the structure.

Because the cable forces are relatively small, a 9.5 mm aircraft cable attached to clips with cable clamps should be used. The clips, in turn, may be attached to either the structure or the equipment.
Seismic and Wind Restraint Design

INSTALLATION PROBLEMS

The following should be considered when installing seismic restraints.

- Anchor location affects the required strengths. Concrete anchors should be located away from edges, stress joints, or existing fractures. ASTM Standard E488 should be followed as a guide for edge distances and center-to-center spacing.
- Concrete anchors should not be too close together. Epoxy-type anchors can be closer together than expansion-type anchors. Expansion-type anchors (self-drilling and drop-in) can crush the concrete where they expand and impose internal stresses in the concrete. Spacing of all anchor bolts should be carefully reviewed. (See manufacturer’s recommendations.)
- Supplementary steel bases and frames, concrete bases, or equipment modifications may void some manufacturer’s warranties. Snubbers, for example, should be properly attached to a subbase. Bumpers may be used with springs.
- Static analysis does not account for the effects of resonant conditions within a piece of equipment or its components. Because all equipment has different resonant frequencies during operation and nonoperation, the equipment itself might fail even if the restraints do not. Equipment mounted inside a housing should be seismically restrained to meet the same criteria as the exterior restraints.
- Snubbers used with spring mounts should withstand motion in all directions. Some snubbers are only designed for restraint in one direction; sets of snubbers or snubbers designed for multidirectional purposes should be used.
- Equipment must be strong enough to withstand the high deceleration forces developed by resilient restraints.
- Flexible connections should be provided between equipment that is braced and piping and ductwork that need not be braced.
- Flexible connections should be provided between isolated equipment and braced piping and ductwork.
- Bumpers installed to limit horizontal motion should be outfitted with resilient neoprene pads to soften the potential impact loads of the equipment.
- Anchor installations should be inspected; in many cases, damage occurs because bolts were not properly installed. To develop the rated restraint, bolts should be installed according to manufacturer’s recommendations.
- Brackets in structural steel attachments should be matched to reduce bending and internal stresses at the joint. Rigid seismic restraints should not have slotted holes.

WIND RESTRAINT DESIGN

Damage done to HVAC&R equipment by both sustained and gusting wind forces has increased concern about the adequacy of the equipment protection that is defined in design documents. The following calculative procedure generates the same type of total design lateral force that is used in the static analysis of the seismic restraint. This means that the value that is determined for the design wind force $F_w$ can be substituted for the total design lateral seismic force $F_s$ when evaluating and choosing restraint devices.

ASCE Standard 7-93, Minimum Design Loads for Buildings and Other Structures, includes design guidelines for wind, snow, rain and earthquake loads. The equations, guidelines, and data presented here are from an earlier version of this standard and only cover non-structural components. The current standard includes more comprehensive and rigorous procedures for evaluating wind forces and wind restraint.

TERMINOLOGY

Classification. Buildings and other structures are classified for wind load design according to [Table 9].

Basic wind speed. The fastest metre-per-second wind speed at 10 m above the ground of Terrain Exposure C (see [Table 10]) having an annual probability of occurrence of 0.02. Data in ASCE Standard 7 or regional climatic data may be used to determine basic wind speeds. ASCE data does not include all special wind regions (such as mountainous terrains, gorges, and ocean promontories) where records or experience indicate that the wind speeds are higher than what is shown in appropriate wind data tables. For these circumstances, regional climatic data may be used provided that both acceptable extreme-value statistical-analysis procedures were used in reducing the data and due regard was given to the

Table 9 Classification of Buildings and Other Structures for Wind Loads

Table 10 Definition of Exposure Categories

<table>
<thead>
<tr>
<th>Exposure Category</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Exposure A</td>
<td>Large city centers with at least 50% of the buildings having a height in excess of 21 m. Use of this exposure category is limited to those areas for which terrain representative of Exposure A prevails in the upwind direction for a distance of at least 800 m or 10 times the height of the building or structure, whichever is greater. Possible channeling effects or increased velocity pressures due to the building or structure being located in the wake of adjacent buildings needs to be considered.</td>
</tr>
<tr>
<td>Exposure B</td>
<td>Urban and suburban areas, wooded areas, or other terrain with numerous closely spaced obstructions having the size of single-family dwellings or larger. Use of this exposure category should be limited to those areas for which terrain representative of Exposure B prevails in the upwind direction for a distance of at least 450 m or 10 times the height of the building or structure, whichever is greater.</td>
</tr>
<tr>
<td>Exposure C</td>
<td>Open terrain with scattered obstructions having heights generally less than 9 m. This category includes flat open country and grasslands.</td>
</tr>
<tr>
<td>Exposure D</td>
<td>Flat, unobstructed areas exposed to wind flowing over large bodies of water. This exposure shall apply only to those buildings and other structures exposed to the wind coming from over the water.</td>
</tr>
</tbody>
</table>

Notes:
1. HVAC components for buildings with a mean roof height of 18 m or less are designed on the basis of Exposure C.
2. HVAC components on buildings with a mean roof height greater than 18 m and other structures are designed on the basis of the exposure categories defined in this table except assume Exposure B for buildings and other structures sited in terrain representative of Exposure A.

</table>

Notes:
1. The design wind force is calculated based on the area of the structure projected on a plane normal to the wind direction. The force is assumed to act parallel to the wind direction.
2. Linear interpolation may be used for $h/D$ values other than shown.
3. Nomenclature:
   - $D$ = diameter or least horizontal dimension, m
   - $D'$ = depth of protruding elements such as ribs and spoilers, m
   - $h$ = height of structure, m
   - $Q_z = velocity pressure evaluated at height $z$ above ground level, Pa

</tbody>
</table>

Note: See Table 11 for definitions of Exposure Categories.

$$Q_z = \rho K_z (I_w V)^2 / 2 = 0.61 K_z (I_w V)^2$$

where

- $\rho = air mass density. At 15°C and 101.325 kPa the density of dry air is 1.22 kg/m³.
- $K_z = velocity pressure exposure coefficient evaluated at height $z$ above ground level. The value of $K_z$ is determined by the following equation that uses data from Table 13.

$$K_z = 2.58(z/z_g)^{2\alpha}$$

Values for $K_z$, from $0 \leq z \leq 150$ m, are given in Table 14. The definitions of Exposure A through D categories are shown in Table 10.

$I_w = importance factor. Values are given in Table 11. Definitions for categories I, II, III, and IV are found in Table 9. $V = basic wind speed determined from data in ASCE Standard 7 or appropriate regional data. The basic wind speed used should be at least 31.3 m/s.

**Gust response factor.** The values of $G_z$ are determined by the following equations, Table 15 lists values for $G_z$ for $0 \leq z \leq 150$ m.

$$G_z = 0.65 + 3.65T_z$$

where

$$T_z = 2.35 \left( \frac{D_o}{z/9} \right)^{1/2}$$

**CALCULATIONS**

Two procedures are used to determine the design wind load on HVAC components. The analytical procedure, which is described here, is the most common analysis method for standard component shapes. The second method, the wind-tunnel procedure, is incorporated in the analysis of complex and unusual shaped components or equipment that are located on sites that produce wind channeling or buffeting due to upwind obstructions. The analytical procedure produces design wind forces that are expected to act on HVAC components for durations of 1 to 10 s. The various factors, pressure, and force coefficients incorporated in this procedure are based on a mean wind speed that corresponds to the fastest meter-per-second wind speed.

**Analytical Procedure**

The design wind force is determined by the following equation:

$$F_w = Q_z G_z C_f A_f$$

where

- $F_w = design wind force, N$
- $Q_z = velocity pressure evaluated at height $z$ above ground level, Pa$
- $G_z = gust response factor for HVAC components evaluated at height $z$ above ground level$
- $C_f = force coefficient [Table 12]$
- $A_f = area of HVAC component projected on a plane normal to wind direction, m²$

Certain of the above factors must be calculated from equations that incorporate site-specific conditions that are defined as follows:

**Velocity Pressure.** The design wind speed must be converted to a velocity pressure that is acting on an HVAC component at a height $z$ above the ground. The equation is
Example Calculations: Analytical Procedure

The following example calculations are for a 1400 kW cooling tower with dimensions shown in Figure 10:

Tower height = \( h = 3 \) m

Tower width = \( D = 3 \) m

Tower length = \( l = 6 \) m

Tower operating mass = \( W_p = 8650 \) kg

Tower diagonal dimension = \((3^2 + 6^2)^{0.5} = 6.71 \) m

Area normal to wind direction = \( A_f = 3 \times 6.71 = 20.1 \) m²

From Table 12; \( C_f = 1.0 \) for wind acting along diagonal with \( h/D = 3/3 = 1 \).

Example 5. Suburban hospital in Omaha, Nebraska. The top of the cooling tower is 30 m. above ground level.

Solution:

From appropriate wind data tables, the design wind speed is found to be 40 m/s.

From Table 9, use Category III

From Table 10, use Exposure B

From Table 11, \( I_w = 1.07 \)

Substitution into Equation (35) yields:

\[ Q_z = 0.61 \times 0.86 \times (1.07 \times 40)^2 = 961 \text{ Pa} = 0.961 \text{ kPa} \]

From Table 15 or Equations (37) and (38); \( G_z = 1.31 \). Substitution into Equation (34) yields the design wind force as

\[ F_w = 0.961 \times 1.31 \times 1.0 \times 20.1 = 25.3 \text{ kN} \]

Example 6. Office building in New York City. Top of tower is 180 m. above ground level.

Solution:

From wind data tables, the design wind speed is 54 m/s.

From Table 9, use Category I.

From Table 10, use Exposure A

From Table 11, \( V_e = 1.05 \)

Because \( z > 150 \) m, use Equations (36), (37), (38), and Table 15 to determine \( K_z \) and \( G_z \).

From Table 13, \( \alpha = 3.0 \), \( z_g = 450 \), and \( D_o = 0.025 \)

From Equation (36): \( K_z = 2.58(180/450)^{0.5} = 1.40 \)

From Equation (35):

\[ Q_z = 0.61 \times 1.40 \times (1.05 \times 54)^2 = 2746 \text{ Pa} = 2.746 \text{ kPa} \]
Determine the gust response factor for \( z = 180 \text{ m} \) using Equations [37] and [38]

\[
T_z = \frac{2.35(0.025)}{(180/9)^{1/3}} = 0.137
\]

\[
G_z = 0.65 + 3.65(0.137) = 1.15
\]

**Equation (34)** yields the design wind force as

\[
F_w = 2.746 \times 1.15 \times 1.0 \times 20.1 = 63.5 \text{ kN}
\]

**Example 7.** Church in Key West, Florida. The top of the tower is 15 m above ground level.

**Solution:**

- From Table 9, use Category II
- From Table 10, use Exposure D
- From Table 11, \( I_z = 1.11 \)
- From Table 14, \( K_z = 1.52 \)

From appropriate wind data, the design wind speed is found to be 67 m/s.

- From Equation (35)
  \[
  Q_z = 0.61 \times 1.52 (1.11 \times 67)^2 = 5128 \text{ Pa} = 5.128 \text{ kPa}
  \]

From Table 15, \( G_z = 1.10 \).

Again using **Equation (34)** the design wind force is

\[
F_w = 5.128 \times 1.10 \times 1.0 \times 20.1 = 113.4 \text{ kN}
\]
