1999 HVAC Applications

Contributors and Preface

- A1 Residences
- A2 Retail Facilities
- A3 Commercial and Public Buildings
- A4 Places of Assembly
- A5 Hotels, Motels, and Dormitories
- A6 Educational Facilities
- A7 Health Care Facilities
- A8 Surface Transportation
- A9 Aircraft
- A10 Ships
- A11 Industrial Air Conditioning
- A12 Enclosed Vehicular Facilities
- A13 Laboratories
- A14 Engine Test Facilities
- A15 Clean Spaces
- A16 Data Processing and Elec. Office Areas
- A17 Printing Plants
- A18 Textile Processing Plants
- A19 Photographic Materials
- A20 Museums, Libraries, and Archives
- A21 Environ. Control for Animals and Plants
- A22 Drying and Storing Selected Farm Crops
- A23 AC of Wood and Paper Product Facilities
- A24 Power Plants
- A25 Nuclear Facilities
- A26 Mine Air Conditioning and Ventilation
- A27 Industrial Drying Systems
- A28 Ventilation of the Industrial Environment
- A29 Industrial Local Exhaust Systems
- A30 Kitchen Ventilation
- A31 Geothermal Energy
- A32 Solar Energy Use
- A33 Thermal Storage
- A34 Energy Management
- A35 Owning and Operating Costs
- A36 Testing, Adjusting, and Balancing
- A37 Operation and Maintenance Management
- A38 Computer Applications
- A39 Building Energy Monitoring
- A40 Control Strategies and Optimization
- A41 Building Commissioning
- A42 Building Envelopes
- A43 Building Air Intake and Exhaust Design
- A44 Gaseous Indoor Air Contaminant Control
- A45 Design and Application of Controls
- A46 Sound and Vibration Control
- A47 Water Treatment
- A48 Service Water Heating
- A49 Snow Melting
- A50 Evaporative Cooling Applications
- A51 Fire and Smoke Management
- A52 Radiant Heating and Cooling
- A53 Seismic and Wind Restraint Design
- A54 Codes and Standards

1999 ASHRAE Handbook Preface

This handbook describes heating, ventilating, and air conditioning for a broad range of applications. Most of the chapters from the 1995 *ASHRAE Handbook* have been revised for this volume to reflect current requirements and design approaches. New chapters on HVAC for museums and power plants, information on air quality in aircraft, additional information on maintaining a proper environment for indoor swimming pools and new information on sound control and building operation make this a particularly useful reference. Because this book focuses on specific applications for HVAC, it provides background information to designers new to the application as well as to those needing a refresher on the topic. In addition, many chapters include valuable data for design. Some of the revisions that have been made are as follows.

- Chapter 4, Places of Assembly, provides more comprehensive design information on natatoriums.
- Chapter 5, Hotels, Motels, and Dormitories, includes more information on hotels and motels, which is reflected in a change in the title of the chapter.
- Chapter 8, Surface Transportation, has been substantially revised. It now includes information about European bus air conditioning and the state of the art in railcar air conditioning.
- Chapter 9, Aircraft, has been completely rewritten. It describes the environmental control systems used in commercial aircraft today and their operation during a typical flight. Applicable regulations are summarized and the section on air quality has been expanded. Information on air-cycle equipment has been deleted.
- Chapter 12, Enclosed Vehicular Facilities, includes more ventilation design information. Research from a tunnel fire test has provided new ventilation design criteria for tunnel ventilation. The chapter now covers ventilation for toll booths, railroad tunnels, and areas with vehicles that use alternative fuels.
- Chapter 13, Laboratories, has additional information on scale-up laboratories and compressed gas storage. The sections on internal heat load and Biosafety Level 3 have been expanded.
- Chapter 15, Clean Spaces, greatly expands on pharmaceutical and biomanufacturing cleanrooms. A new section covers high bay cleanrooms.
- Chapter 20, Museums, Libraries, and Archives, is a new chapter. It discusses in detail the importance of relative humidity on collections and suggests the degree of environmental control for various types of collections and historic buildings.
- Chapter 21, Environmental Control for Animals and Plants, provides new information on levels of contaminants in livestock buildings and suggests several methods of control. It includes new findings on ventilation for laboratory animals.
- Chapter 24, Power Plants, is a new chapter that introduces HVAC design criteria for the various facilities in electrical generating stations and in facilities that produce process heat and power.
- Chapter 29, Industrial Local Exhaust Systems, has been greatly expanded with much more information about specific types of hoods and their design and application.
- Chapter 30, Kitchen Ventilation, is updated to reflect code changes including changed terminology for nonlisted hoods and new information on exhaust system effluent control.
- Chapter 33, Thermal Storage, has an expanded discussion of control strategies.
- Chapter 34, Energy Management, has new and more comprehensive energy consumption data for commercial and residential buildings in the United States.
- Chapter 35, Owning and Operating Costs, has updated information of the impact of refrigerant phaseouts. New information is included on financing alternatives, on district energy service and on-site electric generation in view of deregulation, and on computer analysis.
- Chapter 39, Building Energy Monitoring, reflects the new direction in this field and focuses on monitoring designed to answer specific questions rather than broad-based research-oriented programs. The section on accuracy and uncertainty is rewritten.
- Chapter 40, Supervisory Control Strategies and Optimization, has a new title to reflect its reorganization and the significant amount of new material. The first section defines systems and control variables. The second section, which is intended for practitioners, presents computerized control strategies. The third section presents basic optimization methods and is for researchers and developers of advanced control strategies.
- Chapter 41, Building Commissioning, has expanded the information on the various phases of commissioning.
- Chapter 42, Building Envelopes, is moved from the 1997 *ASHRAE Handbook—Fundamentals* with minor editing.
- Chapter 43, Building Air Intake and Exhaust Design, is a revision of the last half of Chapter 15 in the 1997 *ASHRAE Handbook*.
- Chapter 44, Control of Gaseous Indoor Air Contaminants, has a greatly expanded section on air cleaning. It includes more information on the equipment used and on its design, energy use, startup procedures, operation, maintenance, and testing procedures.
- Chapter 45, Design and Application of Controls, is slightly reorganized because the information on control fundamentals was moved to the 1997 *ASHRAE Handbook*.
- Chapter 46, Sound and Vibration Control, describes all currently recognized criteria methods—dBA, NC, RC, RC Mark II, and NCB. New sections include information on: (1) uncertainties that can reasonably be expected from the data in the chapter, (2) chiller and air-cooled condenser noise, and (3) data for estimating ceiling plenum insertion loss.
- Chapter 47, Water Treatment, is reorganized and has added information on biological growth control. A new section covers startup and shutdown procedures.
- Chapter 49, Snow Melting, includes expanded equations for heating requirements and new load data including maps. Information on piping materials for hydronic systems has been updated.
- Chapter 51, Fire and Smoke Management, includes new sections on fire management (i.e., through-penetration fire stopping) and on smoke management in large spaces.
- Chapter 53, Seismic and Wind Restraint Design, introduces the proposed International Building Code seismic design equations and describes several new seismic snubbers. The chapter also includes a new section on wind restraint design.

Each Handbook is published in two editions. One edition contains inch-pound (I-P) units of measurement, and the other contains the International System of Units (SI).

Look for corrections to the 1996, 1997, and 1998 volumes of the Handbook on the Internet at http://www.ashrae.org. Any changes to this volume will be reported in the 2000 *ASHRAE Handbook* and on the Internet.

If you have suggestions for improving a chapter or you would like more information on how you can help revise a chapter, e-mail bparsons@ashrae.org; write to Handbook Editor, ASHRAE, 1791 Tullie Circle, Atlanta, GA 30329; or fax (404) 321-5478.

Robert A. Parsons
ASHRAE Handbook Editor

CHAPTER 1

RESIDENCES

Single-Family Residences 1.2
Multifamily Residences 1.5
Manufactured Homes 1.6

SPACE-CONDITIONING systems for residential use vary with both local and application factors. Local factors include energy source availability (both present and projected) and price; climate; socioeconomic circumstances; and the availability of installation and maintenance skills. Application factors include housing type, construction characteristics, and building codes. As a result, many different systems are selected to provide combinations of heating, cooling, humidification, dehumidification, and air filtering. This chapter emphasizes the more common systems for space conditioning of both single-family (i.e., traditional site-built and modular or manufactured homes) and multifamily residences. Low-rise multifamily buildings generally follow single-family practice because constraints favor compact designs. Retrofit and remodeling construction also adopt the same systems as those for new construction, but site-specific circumstances may call for unique designs.

Systems

The common residential heating systems are listed in Table 1. Three generally recognized groups are central forced air, central hydronic, and zoned systems. System selection and design involve such key decisions as (1) source(s) of energy, (2) means of distribution and delivery, and (3) terminal device(s).

Climate determines the services needed. Heating and cooling are generally required. Air cleaning (by filtration or electrostatic devices) can be added to most systems. Humidification, which can also be added to most systems, is generally provided in heating systems only when psychrometric conditions make it necessary for comfort and health (as defined in ASHRAE *Standard* 55). Cooling systems dehumidify as well. Typical residential installations are shown in Figures 1 and 2.

Figure 1 shows a gas furnace, a split-system air conditioner, a humidifier, and an air filter. The system functions as follows: Air returns to the equipment through a return air duct (1). It passes initially through the air filter (2). The circulating blower (3) is an integral part of the furnace (4), which supplies heat during winter.

Table 1 Residential Heating and Cooling Systems

	Forced Air	Hydronic	Zoned
Most common energy sources	Gas Oil Electricity Resistance Heat pump	Gas Oil Electricity Resistance Heat pump	Gas Electricity Resistance Heat pump
Heat distribution medium	Air	Water Steam	Air Water Refrigerant
Heat distribution system	Ducting	Piping	Ducting Piping or None
Terminal devices	Diffusers Registers Grilles	Radiators Radiant panels Fan-coil units	Included with product

The preparation of this chapter is assigned to TC 7.6, Unitary Air Conditioners and Heat Pumps

An optional humidifier (10) adds moisture to the heated air, which is distributed throughout the home from the supply duct (9). When cooling is required, the circulating air passes across the evaporator coil (5), which removes heat and moisture from the air. Refrigerant lines (6) connect the evaporator coil to a remote condensing unit (7) located outdoors. Condensate from the evaporator is removed through a drainline with a trap (8).

Figure 2 shows a split-system heat pump, supplemental electric resistance heaters, a humidifier, and an air filter. The system functions as follows: Air returns to the equipment through the return air duct (1) and passes through the air filter (2). The circulating blower (3) is an integral part of the indoor unit (or air handler) of the heat pump (4), which supplies heat via the indoor coil (6) during the heating season. Optional electric heaters (5) supplement heat from the heat pump during periods of low ambient temperature and counteract airstream cooling during the defrost cycle. An optional humidifier (10) adds moisture to the heated air, which is distributed throughout the home from the supply duct (9). When cooling is required, the circulating air passes across the indoor coil (6), which removes heat and moisture from the air. Refrigerant lines (11) connect the indoor coil to the outdoor unit (7). Condensate from the indoor coil drains away through a drainline with a trap (8).

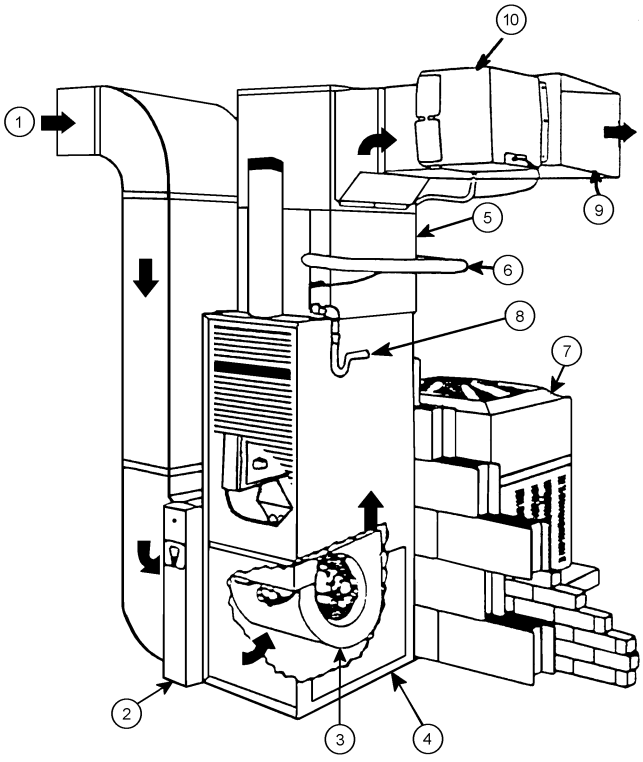

Fig. 1 Typical Residential Installation of Heating, Cooling, Humidifying, and Air Filtering System

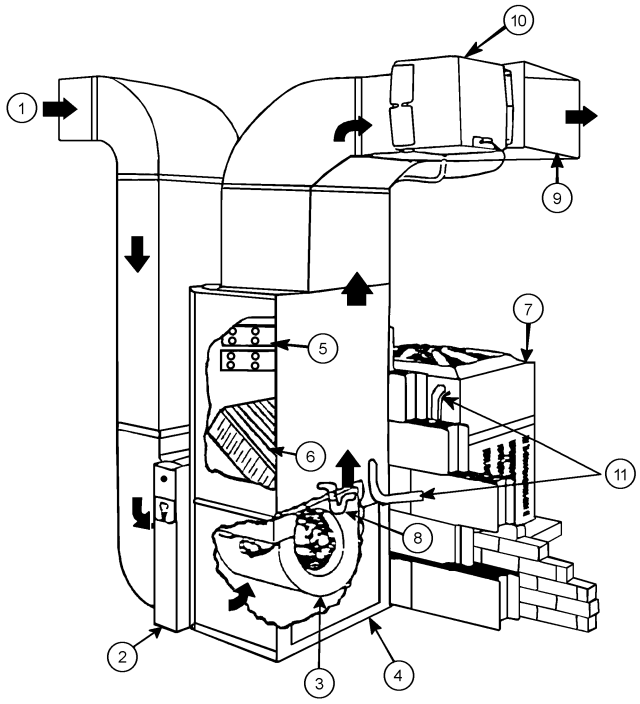

Fig. 2 Typical Residential Installation of Heat Pump

Single-package systems, where all equipment is contained in one cabinet, are also popular in the United States. They are used extensively in areas where residences have duct systems in crawlspaces beneath the main floor and in areas such as the Southwest, where they are typically rooftop-mounted and connected to an attic duct system.

Central hydronic heating systems are popular both in Europe and in parts of North America where central cooling is not normally provided. If desired, central cooling is often added through a separate cooling-only system with attic ducting.

Zoned systems are designed to condition only part of a home at any one time. They may consist of individual room units or central systems with zoned distribution networks. Multiple central systems that serve individual floors or serve sleeping and common portions of a home separately are also widely used in large single-family houses.

The source of energy is a major consideration in heating system selection. For heating, gas and electricity are most widely used, followed by oil, wood, solar energy, geothermal energy, waste heat, coal, district thermal energy, and others. Relative prices, safety, and environmental concerns (both indoor and outdoor) are further factors in heating energy source selection. Where various sources are available, economics strongly influence the selection. Electricity is the dominant energy source for cooling.

Equipment Sizing

The heat loss and gain of each conditioned room and of ductwork or piping run through unconditioned spaces in the structure must be accurately calculated in order to select equipment with the proper output and design. To determine heat loss and gain accurately, the floor plan and construction details must be known. The plan should include information on wall, ceiling, and floor construction as well as the type and thickness of insulation. Window design and exterior door details are also needed. With this information, heat loss and gain can be calculated using the Air-Conditioning Contractors of America (ACCA) *Manual* J or similar calculation procedures. To conserve energy, many jurisdictions require that the building be designed to meet or exceed the requirements of ASHRAE *Standard* 90.2, Energy-Efficient Design of New Low-Rise Residential Buildings, or similar requirements.

Proper matching of equipment capacity to the design heat loss and gain is essential. The heating capacity of air-source heat pumps is usually supplemented by auxiliary heaters, most often of the electric resistance type; in some cases, however, fossil fuel furnaces or solar systems are used.

The use of undersized equipment results in an inability to maintain indoor design temperatures at outdoor design conditions and slow recovery from setback or set-up conditions. Grossly oversized equipment can cause discomfort due to short on-times, wide indoor temperature swings, and inadequate dehumidification when cooling. Gross oversizing may also contribute to higher energy use due to an increase in cyclic thermal losses and off-cycle losses. Variable capacity equipment (heat pumps, air conditioners, and furnaces) can more closely match building loads over specific ambient temperature ranges, usually reducing these losses and improving comfort levels; in the case of heat pumps, supplemental heat needs may also be reduced.

Recent trends toward tightly constructed buildings with improved vapor retarders and low infiltration may cause high indoor humidity conditions and the buildup of indoor air contaminants in the space. Air-to-air heat-recovery equipment may be used to provide tempered ventilation air to tightly constructed houses. Outdoor air intakes connected to the return duct of central systems may also be used when lower installed costs are the most important factor. Simple exhaust systems with passive air intakes are also becoming popular. In all cases, minimum ventilation rates, as outlined in ASHRAE *Standard* 62 should be maintained.

SINGLE-FAMILY RESIDENCES

Heat Pumps

Heat pumps for single-family houses are normally unitary systems; i.e., they consist of single-package units or two or more factory-built modules as illustrated in Figure 2. These differ from applied or built-up heat pumps, which require field engineering to select compatible components for complete systems.

Most commercially available heat pumps (particularly in North America) are electrically powered air-source systems. Supplemental heat is generally required at low outdoor temperatures or during defrost. In most cases, supplemental or backup heat is provided by electric resistance heaters.

Heat pumps may be classified by thermal source and distribution medium in the heating mode as well as the type of fuel used. The most commonly used classes of heat pump equipment are air-to-air and water-to-air. Air-to-water and water-to-water types are also used.

Heat pump systems, as contrasted to the actual heat pump equipment, are generally described as air-source or ground-source. The thermal sink for cooling is generally assumed to be the same as the thermal source for heating. Air-source systems using ambient air as the heat source/sink are generally the least costly to install and thus the most commonly used. Ground-source systems usually employ water-to-air heat pumps to extract heat from the ground via groundwater or a buried heat exchanger.

Ground-Source (Geothermal) Systems. As a heat source/sink, groundwater (from individual wells or supplied as a utility from community wells) offers the following advantages over ambient air: (1) heat pump capacity is independent of ambient air temperature, reducing supplementary heating requirements; (2) no defrost cycle is required; (3) for equal equipment rating point efficiency, the seasonal efficiency is usually higher for heating and for cooling; and (4) peak heating energy consumption is usually lower. Ground-coupled or surface-water-coupled systems offer the same advantages. However, they circulate brine or water in a buried or sub-

merged heat exchanger to transfer heat from the ground. Direct expansion ground-source systems, with evaporators buried in the ground, are occasionally used. The number of ground-source systems is growing rapidly, particularly of the ground-coupled type. Water-source systems that extract heat from surface water (e.g., lakes or rivers) or city (tap) water are also used where local conditions permit.

Water supply, quality, and disposal must be considered for groundwater systems. Bose et al. (1985) provides detailed information on these subjects. Secondary coolants for ground-coupled systems are discussed in this manual and in Chapter 20 of the 1997 *ASHRAE Handbook—Fundamentals*. Buried heat exchanger configurations may be horizontal or vertical, with the vertical including both multiple-shallow- and single-deep-well configurations. Ground-coupled systems avoid water quality, quantity, and disposal concerns but are sometimes more expensive than groundwater systems. However, ground-coupled systems are usually more efficient, especially when pumping power for the groundwater system is considered.

Add-On Heat Pumps. In add-on systems, a heat pump is added—often as a retrofit—to an existing furnace or boiler system. The heat pump and combustion device are operated in one of two ways: (1) alternately, depending on which is most cost-effective, or (2) in parallel. In unitary bivalent heat pumps, the heat pump and combustion device are grouped in a common chassis and cabinets to provide similar benefits at lower installation costs.

Fuel-Fired Heat Pumps. Extensive research and development has been conducted to develop fuel-fired heat pumps. They are beginning to be marketed in North America.

Water-Heating Options. Heat pumps may be equipped with desuperheaters (either integral or field-installed) to reclaim heat for domestic water heating. Integrated space-conditioning and water-heating heat pumps with an additional full-size condenser for water heating are also available.

Furnaces

Furnaces are fueled by gas (natural or propane), electricity, oil, wood, or other combustibles. Gas, oil, and wood furnaces may draw combustion air from the house or from outdoors. If the furnace space is located such that combustion air is drawn from the outdoors, the arrangement is called an isolated combustion system (ICS). Furnaces are generally rated on an ICS basis. When outdoor air is ducted to the combustion chamber, the arrangement is called a direct vent system. This latter method is used for manufactured home applications and some mid- and high-efficiency equipment designs. Using outside air for combustion eliminates both the infiltration losses associated with the use of indoor air for combustion and the stack losses associated with atmospherically induced draft hood-equipped furnaces.

Two available types of high-efficiency gas furnaces are noncondensing and condensing. Both increase efficiency by adding or improving heat exchanger surface area and reducing heat loss during furnace off-times. The higher efficiency condensing type also recovers more energy by condensing water vapor from the combustion products. The condensate is developed in a high-grade stainless steel heat exchanger and is disposed of through a drain line. Condensing furnaces generally use PVC for vent pipes and condensate drains.

Wood-fueled furnaces are used in some areas. A recent advance in wood furnaces is the addition of catalytic converters to enhance the combustion process, increasing furnace efficiency and producing cleaner exhaust.

Chapters 28 and 29 of the 2000 *ASHRAE Handbook—Systems and Equipment* include more detailed information on furnaces and furnace efficiency.

Hydronic Heating Systems—Boilers

With the growth of demand for central cooling systems, hydronic systems have declined in popularity in new construction, but still account for a significant portion of existing systems in northern climates. The fluid is heated in a central boiler and distributed by piping to terminal units (fan coils, radiators, radiant panels, or baseboard convectors) in each room. Most recently installed residential systems use a forced circulation, multiple zone hot water system with a series-loop piping arrangement. Chapters 12, 27, and 32 of the 2000 *ASHRAE Handbook—Systems and Equipment* have more information on hydronics and hydronic.

Design water temperature is based on economic and comfort considerations. Generally, higher temperatures result in lower first costs because smaller terminal units are needed. However, losses tend to be greater, resulting in higher operating costs and reduced comfort due to the concentrated heat source. Typical design temperatures range from 80 to 95°C. For radiant panel systems, design temperatures range from 45 to 75°C. The preferred control method allows the water temperature to decrease as outdoor temperatures rise. Provisions for the expansion and contraction of the piping and heat distributing units and for the elimination of air from the hydronic system are essential for quiet, leaktight operation.

Fossil fuel systems that condense water vapor from the flue gases must be designed for return water temperatures in the range of 50 to 55°C for most of the heating season. Noncondensing systems must maintain high enough water temperatures in the boiler to prevent this condensation. If rapid heating is required, both terminal unit and boiler size must be increased, although gross oversizing should be avoided.

Zoned Heating Systems

Zoned systems offer the potential for lower operating costs, because unoccupied areas can be kept at lower temperatures in the winter and at higher temperatures in the summer. Common areas can be maintained at lower temperatures at night and sleeping areas at lower temperatures during the day.

One form of this system consists of individual heaters located in each room. These heaters are usually electric or gas-fired. Electric heaters are available in the following types: baseboard free-convection, wall insert (free-convection or forced-fan), radiant panels for walls and ceilings, and radiant cables for walls, ceilings, and floors. Matching equipment capacity to heating requirements is critical for individual room systems. Heating delivery cannot be adjusted by adjusting air or water flow, so greater precision in room-by-room sizing is needed.

Individual heat pumps for each room or group of rooms (zone) are another form of zoned electric heating. For example, two or more small unitary heat pumps can be installed in two-story or large one-story homes.

The multisplit heat pump consists of a central compressor and an outdoor heat exchanger to service up to eight indoor zones. Each zone uses one or more fan coils, with separate thermostatic control for each zone. Such systems are used in both new and retrofit construction.

A method for zoned heating in central ducted systems is the zone-damper system. This consists of individual zone dampers and thermostats combined with a zone control system. Both variable-air-volume (damper position proportional to zone demand) and on-off (damper fully open or fully closed in response to thermostat) types are available. Such systems sometimes include a provision to modulate to lower capacities when only a few zones require heating.

Solar Heating

Both active and passive solar energy systems are sometimes used to heat residences. In typical active systems, flat plate collectors

heat air or water. Air systems distribute heated air either to the living space for immediate use or to a thermal storage medium (i.e., a rock pile). Water systems pass heated water through a secondary heat exchanger and store extra heat in a water tank. Due to low delivered water temperatures, radiant floor panels requiring moderate temperatures are generally used.

Trombe walls and sunspaces are two common passive systems. Glazing facing south (with overhangs to reduce solar gains in the summer) and movable insulated panels can reduce heating requirements.

Backup heating ability is generally needed with solar energy systems. Chapter 32 has information on sizing solar heating equipment.

Unitary Air Conditioners

In forced-air systems, the same air distribution duct system can be used for both heating and cooling. Split-system central cooling, as illustrated in Figure 1, is the most widely used forced-air system. Upflow, downflow, and horizontal airflow units are available. Condensing units are installed on a noncombustible pad outside and contain a motor- or engine-driven compressor, condenser, condenser fan and fan motor, and controls. The condensing unit and evaporator coil are connected by refrigerant tubing that is normally field-supplied. However, precharged, factory-supplied tubing with quick-connect couplings is also common where the distance between components is not excessive.

A distinct advantage of split-system central cooling is that it can readily be added to existing forced-air heating systems. Airflow rates are generally set by the cooling requirements to achieve good performance, but most existing heating duct systems are adaptable to cooling. Airflow rates of 45 to 60 L/s per kilowatt of refrigeration are normally recommended for good cooling performance. As with heat pumps, these systems may be fitted with desuperheaters for domestic water heating.

Some cooling equipment includes forced-air heating as an integral part of the product. Year-round heating and cooling packages with a gas, oil, or electric furnace for heating and a vapor-compression system for cooling are available. Air-to-air and water-source heat pumps provide cooling and heating by reversing the flow of refrigerant.

Distribution. Duct systems for cooling (and heating) should be designed and installed in accordance with accepted practice. Useful information is found in ACCA *Manuals* D and G. Chapter 9 of the 2000 *ASHRAE Handbook—Systems and Equipment* also discusses air distribution design for small heating and cooling systems.

Because weather is the primary influence on the load, the cooling load in each room changes from hour to hour. Therefore, the owner or occupant should be able to make seasonal or more frequent adjustments to the air distribution system to obtain improved comfort. Such adjustments may involve opening additional outlets in second-floor rooms during the summer and throttling or closing heating outlets in some rooms during the winter. Manually adjustable balancing dampers may be provided to facilitate these adjustments. Other possible refinements are the installation of a heating and cooling system sized to meet heating requirements, with additional self-contained cooling units serving rooms with high summer loads, or of separate central systems for the upper and lower floors of a house. On deluxe applications, zone-damper systems can be used.

Operating characteristics of both heating and cooling equipment must be considered when zoning is used. For example, a reduction in the air quantity to one or more rooms may reduce the airflow across the evaporator to such a degree that frost forms on the fins. Reduced airflow on heat pumps during the heating season can cause overloading if airflow across the indoor coil is not maintained at above 45 L/s per kilowatt. Reduced air volume to a given room would reduce the air velocity from the supply outlet and could cause unsatisfactory air distribution in the room. Manufacturers of zoned systems normally provide guidelines for avoiding such situations.

Special Considerations. In split-level houses, cooling and heating are complicated by air circulation between various levels. In many such houses, the upper level tends to overheat in winter and undercool in summer. Multiple outlets, some near the floor and others near the ceiling, have been used with some success on all levels. To control airflow, the homeowner opens some outlets and closes others from season to season. Free circulation between floors can be reduced by locating returns high in each room and keeping doors closed.

In existing homes, the cooling that can be added is limited by the air-handling capacity of the existing duct system. While the existing duct system is usually satisfactory for normal occupancy, it may be inadequate during large gatherings. In all cases where new cooling (or heating) equipment is installed in existing homes, supply-air ducts and outlets must be checked for acceptable air-handling capacity and air distribution. Maintaining upward airflow at an effective velocity is important when converting existing heating systems with floor or baseboard outlets to both heat and cool. It is not necessary to change the deflection from summer to winter for registers located at the perimeter of a residence. Registers located near the floor on the inside walls of rooms may operate unsatisfactorily if the deflection is not changed from summer to winter.

Occupants of air-conditioned spaces usually prefer minimum perceptible air motion. Perimeter baseboard outlets with multiple slots or orifices directing air upwards effectively meet this requirement. Ceiling outlets with multidirectional vanes are also satisfactory.

A residence without a forced-air heating system may be cooled by one or more central systems with separate duct systems, by individual room air conditioners (window-mounted or through-the-wall), or by mini-split-room air conditioners.

Cooling equipment must be located carefully. Because cooling systems require higher indoor airflow rates than most heating systems, the sound levels generated indoors are usually higher. Thus, indoor air-handling units located near sleeping areas may require sound attenuation. Outdoor noise levels should also be considered when locating the equipment. Many communities have ordinances regulating the sound level of mechanical devices, including cooling equipment. Manufacturers of unitary air conditioners often certify the sound level of their products in an ARI program (ARI *Standard* 270). ARI *Standard* 275 gives information on how to predict the dBA sound level when the ARI sound rating number, the equipment location relative to reflective surfaces, and the distance to the property line are known.

An effective and inexpensive way to reduce noise is to put distance and natural barriers between sound source and listener. However, airflow to and from air-cooled condensing units must not be obstructed. Most manufacturers provide recommendations regarding acceptable distances between condensing units and natural barriers. Outdoor units should be placed as far as is practical from porches and patios, which may be used while the house is being cooled. Locations near bedroom windows and neighboring homes should also be avoided.

Evaporative Coolers

In dry climates, evaporative coolers can be used to cool residences. Further details on evaporative coolers can be found in Chapter 19 of the 2000 *ASHRAE Handbook—Systems and Equipment* and in Chapter 50 of this volume.

Humidifiers

For improved winter comfort, equipment that increases indoor relative humidity may be needed. In a ducted heating system, a central humidifier can be attached to or installed within a supply

plenum or main supply duct, or installed between the supply and return duct systems. When applying supply-to-return duct humidifiers on heat pump systems, care should be taken to maintain proper airflow across the indoor coil. Self-contained humidifiers can be used in any residence. Even though this type of humidifier introduces all the moisture to one area of the home, moisture will migrate and raise humidity levels in other rooms. Overhumidification, which can cause condensate to form on the coldest surfaces in the living space (usually the windows), should be avoided.

Central humidifiers may be rated in accordance with ARI *Standard* 610. This rating is expressed in the number of litres per day evaporated by 60°C entering air. Some manufacturers certify the performance of their product to the ARI standard. Selecting the proper size humidifier is important and is outlined in ARI *Guideline* F.

Since moisture migrates through all structural materials, vapor retarders should be installed near the warmer inside surface of insulated walls, ceilings, and floors in most temperature climates. Improper attention to this construction detail allows moisture to migrate from inside to outside, causing damp insulation, possible structural damage, and exterior paint blistering. Humidifier cleaning and maintenance schedules should be followed to maintain efficient operation and prevent bacteria buildup. Chapter 20 of the 2000 *ASHRAE Handbook—Systems and Equipment* contains more information on residential humidifiers.

Dehumidifiers

Many homes also use dehumidifiers to remove moisture and control indoor humidity levels. In cold climates, dehumidification is sometimes required during the summer in basement areas to control mold and mildew growth and to reduce zone humidity levels. Traditionally, portable dehumidifiers have been used to control humidity in this application. While these portable units are not always as efficient as central systems, their low first cost and the ability to serve a single zone make them appropriate in many circumstances.

In hot and humid climates, the importance of providing sufficient dehumidification with sensible cooling is increasingly recognized. While conventional air conditioning units provide some dehumidification as a consequence of sensible cooling, in some cases space humidity levels can still exceed the upper limit of 60% relative humidity specified in ASHRAE *Standard* 55.

Several dehumidification enhancements to conventional air conditioning systems are possible to improve moisture removal characteristics and lower the space humidity level. Some simple improvements include lowering the supply air flow rate and eliminating off-cycle fan operation. Additional equipment options such as condenser/reheat coils, sensible-heat-exchanger-assisted evaporators (e.g., heat pipes), and subcooling/reheat coils can further improve dehumidification performance. Desiccants—applied as either thermally-activated units or heat recovery systems (i.e., enthalpy wheels)—can also increase dehumidification capacity and lower the indoor humidity level. Some dehumidification options add heat to the conditioned zone that, in some cases, increases the load on the sensible cooling equipment.

Air Filters

Most comfort conditioning systems that circulate air incorporate some form of air filter. Usually they are disposable or cleanable filters that have relatively low air-cleaning efficiency. Higher efficiency alternatives include pleated media filters and electronic air filters. These high-efficiency filters may have high static pressure drops. The air distribution system should be carefully evaluated before the installation of such filters.

Air filters are mounted in the return air duct or plenum and operate whenever air circulates through the duct system. Air filters are rated in accordance with ARI *Standard* 680, which is based on ASHRAE *Standard* 52.1. Atmospheric dust spot efficiency levels are generally less than 20% for disposable filters and vary from 60 to 90% for electronic air filters.

To maintain optimum performance, the collector cells of electronic air filters must be cleaned periodically. Automatic indicators are often used to signal the need for cleaning. Electronic air filters have higher initial costs than disposable or pleated filters, but generally last the life of the air-conditioning system. Chapter 24 of the 2000 *ASHRAE Handbook—Systems and Equipment* covers the design of residential air filters in more detail.

Controls

Historically, residential heating and cooling equipment has been controlled by a wall thermostat. Today, simple wall thermostats with bimetallic strips are often replaced by microelectronic models that can set heating and cooling equipment at different temperature levels, depending on the time of day. This has led to night setback control to reduce energy demand and operating costs. For heat pump equipment, electronic thermostats can incorporate night setback with an appropriate scheme to limit use of resistance heat during recovery. Chapter 45 contains more details about automatic control systems.

MULTIFAMILY RESIDENCES

Attached homes and low-rise multifamily apartments generally use heating and cooling equipment comparable to that used in single-family dwellings. Separate systems for each unit allow individual control to suit the occupant and facilitate individual metering of energy use.

Central Forced-Air Systems

High-rise multifamily structures may also use unitary heating and cooling equipment comparable to that used in single-family dwellings. Equipment may be installed in a separate mechanical equipment room in the apartment, or it may be placed in a soffit or above a drop ceiling over a hallway or closet.

Small residential warm-air furnaces may also be used, but a means of providing combustion air and venting combustion products from gas- or oil-fired furnaces is required. It may be necessary to use a multiple-vent chimney or a manifold-type vent system. Local codes should be consulted. Direct vent furnaces that are placed near or on an outside wall are also available for apartments.

Another concept for multifamily residences (also applicable to single-family dwellings) is a combined water heating/space heating system that uses water from the domestic hot water storage tank to provide space heating. Water circulates from the storage tank to a hydronic coil in the system air handler. Space heating is provided by circulating indoor air across the coil. A split-system central air conditioner with the evaporator located in the system air handler can be included to provide space cooling.

Hydronic Central Systems

Individual heating and cooling units are not always possible or practical in high-rise structures. In this case, applied central systems are used. Two- or four-pipe hydronic central systems are widely used in high-rise apartments. Each dwelling unit has either individual room units located at the perimeter or interior, or ducted fan-coil units.

The most flexible hydronic system with the lowest operating costs is the four-pipe type, which provides heating or cooling for each apartment dweller. The two-pipe system is less flexible in that it cannot provide heating and cooling simultaneously. This limitation causes problems during the spring and fall when some apartments in a complex require heating while others require cooling due to solar or internal loads. This spring/fall problem may be overcome by operating the two-pipe system in a cooling mode and providing

the relatively low amount of heating that may be required by means of individual electric resistance heaters. Chapter 12 of the 2000 *ASHRAE Handbook—Systems and Equipment* discusses hydronic design in more detail.

Through-the-Wall Units

Through-the-wall room air conditioners, packaged terminal air conditioners (PTACs), and packaged terminal heat pumps (PTHPs) give the highest flexibility for conditioning single rooms. Each room with an outside wall may have such a unit. These units are used extensively in the renovation of old buildings because they are self-contained and do not require complex piping or ductwork renovation.

Room air conditioners have integral controls and may include resistance or heat pump heating. PTACs and PTHPs have special indoor and outdoor appearance treatments, making them adaptable to a wider range of architectural needs. PTACs can include gas, electric resistance, hot water, or steam heat. Integral or remote wall-mounted controls are used for both PTACs and PTHPs. Further information may be found in Chapter 46 of the 2000 *ASHRAE Handbook—Systems and Equipment* and in ARI *Standard* 310/380.

Water-Loop Heat Pumps

Any mid- or high-rise structure having interior zones with high internal heat gains that require year-round cooling can efficiently use a water-loop heat pump. Such systems have the flexibility and control of a four-pipe system while using only two pipes. Water-source heat pumps allow for the individual metering of each apartment. The building owner pays only the utility cost for the circulating pump, cooling tower, and supplemental boiler heat. Existing buildings can be retrofitted with heat flow meters and timers on fan motors for individual metering. Economics permitting, solar or ground heat energy can provide the supplementary heat in lieu of a boiler. The ground can also provide a heat sink, which in some cases can eliminate the cooling tower.

Special Concerns for Apartment Buildings

Many ventilation systems are used in apartment buildings. Local building codes generally govern air quantities. ASHRAE *Standard* 62 requires minimum outdoor air values of 25 L/s intermittent or 10 L/s continuous or operable windows for baths and toilets, and 50 L/s intermittent or 12 L/s continuous or operable windows for kitchens.

In some buildings with centrally controlled exhaust and supply systems, the systems are operated on time clocks for certain periods of the day. In other cases, the outside air is reduced or shut off during extremely cold periods. If known, these factors should be considered when estimating heating load.

Buildings using exhaust and supply air systems 24 h a day may benefit from air-to-air heat recovery devices (see Chapter 44 of the 2000 *ASHRAE Handbook—Systems and Equipment*). Such recovery devices can reduce energy consumption by transferring 40 to 80% of the sensible and latent heat between the exhaust air and supply air streams.

Infiltration loads in high-rise buildings without ventilation openings for perimeter units are not controllable on a year-round basis by general building pressurization. When outer walls are pierced to supply outdoor air to unitary or fan-coil equipment, combined wind and thermal stack effects create other infiltration problems.

Interior public corridors in apartment buildings need positive ventilation with at least two air exchanges per hour. Conditioned supply air is preferable. Some designs transfer air into the apartments through acoustically lined louvers to provide kitchen and toilet makeup air, if necessary. Supplying air to, instead of exhausting air from, corridors minimizes odor migration from apartments into corridors.

Air-conditioning equipment must be isolated to reduce noise generation or transmission. The design and location of cooling towers must be chosen to avoid disturbing occupants within the building and neighbors in adjacent buildings. An important load, frequently overlooked, is heat gain from piping for hot water services.

In large apartment houses, a central panel may allow individual apartment air-conditioning systems or units to be monitored for maintenance and operating purposes.

MANUFACTURED HOMES

Manufactured homes are constructed at a factory and constitute over 7% of all housing units and about 25% of all new single-family homes sold each year. In the United States, heating and cooling systems in manufactured homes, as well as other facets of construction such as insulation levels, are regulated by HUD Manufactured Home Construction and Safety Standards. Each complete home or home section is assembled on a transportation frame—a chassis with wheels and axles—for transport. Manufactured homes vary in size from small, single-floor section units starting at 37 m^2 to large, multiple sections, which when joined together provide over 230 m^2 and have the same appearance as site-constructed homes.

Heating systems are factory-installed and are primarily forced air downflow units feeding main supply ducts built into the subfloor, with floor registers located throughout the home. A small percentage of homes in the far South and in the Southwest use upflow units feeding overhead ducts in the attic space. Typically there is no return duct system. Air returns to the air handler from each room through hallways. The complete heating system is a reduced clearance type with the air-handling unit installed in a small closet or alcove usually located in a hallway. Sound control measures may be

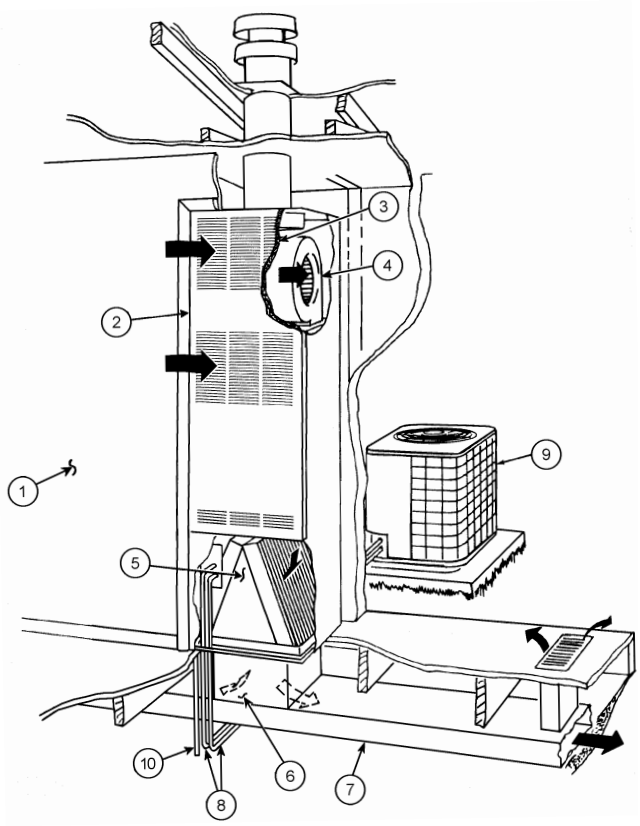

Fig. 3 Typical Installation of Heating and Cooling Equipment for a Manufactured Home

required if large forced-air systems are installed close to sleeping areas. Gas, oil and electric furnaces or heat pumps may be installed by the home manufacturer to satisfy market requirements.

Gas and oil furnaces are compact direct vent types that have been approved for installation in a manufactured home. The special venting arrangement used is a vertical through-the-roof concentric pipe-in-pipe system that draws all air for combustion directly from the outdoors and discharges the combustion products through a windproof vent terminal. Gas furnaces must be easily convertible from liquefied petroleum to natural gas and back as required at the final site.

Manufactured homes may be cooled with add-on split or single-package air-conditioning systems when the supply ducts are adequately sized and rated for that purpose according to HUD requirements. The split-system evaporator coil may be installed in the integral coil cavity provided with the furnace. A high static pressure blower is used to overcome resistance through the furnace, the evaporator coil and the compact air duct distribution system. Supply air from a single-package air conditioner is connected with flexible air ducts to feed existing factory in-floor or overhead ducts. Dampers or other means are required to prevent the cooled, conditioned air from backflowing through a furnace cabinet.

A typical installation of a downflow gas or oil furnace with a split-system air conditioner is illustrated in Figure 3. Air returns to the furnace directly through the hallway (1), passing through a louvered door (2) on the front of the furnace. The air then passes through air filters (3) and is drawn into the top-mounted blower (4), which during the winter months forces air down over the heat exchanger, where it picks up heat. For summer cooling, the blower forces air through the split-system evaporator coil (5), which removes heat and moisture from the passing air. During heating and cooling, the conditioned air then passes through a combustible floor base and duct connector (6), before flowing into the floor air distribution duct (7). The evaporator coil is connected via quick-connect refrigerant lines (8) to a remote air-cooled condensing unit (9). The condensate collected at the evaporator is drained by a flexible hose (10), which is routed to the outdoors through the floor construction and connected to a suitable drain.

CHAPTER 2

RETAIL FACILITIES

General Criteria 2.1
Small Stores 2.1
Discount and Big Box Stores 2.2
Supermarkets 2.2
Department Stores 2.5
Convenience Centers 2.6
Regional Shopping Centers 2.6
Multiple-Use Complexes 2.7

THIS chapter covers the design and application of air-conditioning and heating systems for various retail merchandising facilities. Load calculations, systems, and equipment are covered elsewhere in the Handbook series.

GENERAL CRITERIA

To apply equipment properly, it is necessary to know the construction of the space to be conditioned, its use and occupancy, the time of day in which greatest occupancy occurs, the physical building characteristics, and the lighting layout.

The following must also be considered:

- Electric power—size of service
- Heating—availability of steam, hot water, gas, oil, or electricity
- Cooling—availability of chilled water, well water, city water, and water conservation equipment
- Internal heat gains
- Rigging and delivery of equipment
- Structural considerations
- Obstructions
- Ventilation—opening through roof or wall for outdoor air duct, number of doors to sales area, and exposures
- Orientation of store
- Code requirements
- Utility rates and regulations
- Building standards

Specific design requirements, such as the increase in outdoor air required for exhaust where lunch counters exist, must be considered. The requirements of ASHRAE ventilation standards must be followed. Heavy smoking and objectionable odors may necessitate special filtering in conjunction with outdoor air intake and exhaust. Load calculations should be made using the procedure outlined in Chapter 28 of the 1997 *ASHRAE Handbook—Fundamentals*.

In almost all localities there is some form of energy code in effect that establishes strict requirements for insulation, equipment efficiencies, system designs, and so forth, and places strict limits on fenestration and lighting. The requirements of ASHRAE *Standard* 90 should be met as a minimum guideline for retail facilities.

The selection and design of the HVAC for retail facilities are normally determined by economics. First cost is usually the determining factor for small stores; for large retail facilities, operating and maintenance costs are also considered. Generally, decisions about mechanical systems for retail facilities are based on a cash flow analysis rather than on a full life-cycle analysis.

SMALL STORES

The large glass areas found at the front of many small stores may cause high peak solar heat gain unless they have northern exposures. High heat loss may be experienced on cold, cloudy days. The HVAC system for this portion of the small store should be designed to offset the greater cooling and heating requirements. Entrance vestibules and heaters may be needed in cold climates.

Many new small stores are part of a shopping center. While exterior loads will differ between stores, the internal loads will be similar; the need for proper design is important.

Design Considerations

System Design. Single-zone unitary rooftop equipment is common in store air conditioning. The use of multiple units to condition the store involves less ductwork and can maintain comfort in the event of partial equipment failure. Prefabricated and matching curbs simplify installation and ensure compatibility with roof materials.

The heat pump, offered as packaged equipment, readily adapts to small-store applications and has a low first cost. Winter design conditions, utility rates, and operating cost should be compared to those for conventional heating systems before this type of equipment is chosen.

Water-cooled unitary equipment is available for small-store air conditioning, but many communities in the United States have restrictions on the use of city and ground water for condensing purposes and require the installation of a cooling tower. Water-cooled equipment generally operates efficiently and economically.

Retail facilities often have a high sensible heat gain relative to the total heat gain. Unitary HVAC equipment should be designed and selected to provide the necessary sensible heat removal.

Air Distribution. The external static pressures available in small-store air-conditioning units are limited, and ducts should be designed to keep duct resistances low. Duct velocities should not exceed 6 m/s and pressure drop should not exceed 0.8 Pa/m. Average air quantities range from 47 to 60 L/s per kilowatt of cooling in accordance with the calculated internal sensible heat load.

Attention should be paid to suspended obstacles, such as lights and displays, that interfere with proper air distribution.

The duct system should contain enough dampers for air balancing. Dampers should be installed in the return and outdoor air duct for proper outdoor air/return air balance. Volume dampers should be installed in takeoffs from the main supply duct to balance air to the branch ducts.

Control. Controls for small stores should be kept as simple as possible while still able to perform the required functions. Unitary equipment is typically available with manufacturer-supplied controls for ease of installation and operation.

Automatic dampers should be placed in the outdoor air intake to prevent outdoor air from entering when the fan is turned off.

Heating controls vary with the nature of the heating medium. Duct heaters are generally furnished with manufacturer-installed safety controls. Steam or hot water heating coils require a motorized valve for heating control.

Time clock control can limit unnecessary HVAC operation. Unoccupied reset controls should be provided in conjunction with timed control.

Maintenance. To protect the initial investment and ensure maximum efficiency, the maintenance of air-conditioning units in small stores should be contracted out to a reliable service company on a

The preparation of this chapter is assigned to TC 9.8, Large Building Air-Conditioning Applications.

yearly basis. The contract should clearly specify responsibility for filter replacements, lubrication, belts, coil cleaning, adjustment of controls, compressor maintenance, replacement of refrigerant, pump repairs, electrical maintenance, winterizing, system startup, and extra labor required for repairs.

Improving Operating Cost. Outdoor air economizers can reduce the operating cost of cooling in most climates. They are generally available as factory options or accessories with roof-mounted units. Increased exterior insulation generally reduces operating energy requirements and may in some cases allow the size of installed equipment to be reduced. Many codes now include minimum requirements for insulation and fenestration materials.

DISCOUNT AND BIG BOX STORES

Large warehouse or big box stores attract customers with discount prices when large quantities are purchased. These stores typically have high bay fixture displays and usually store merchandise in the sales area. They feature a wide range of merchandise and may include such diverse areas as a lunch counter, an auto service area, a supermarket area, a pharmacy, and a garden shop. Some stores sell pets, including fish and birds. This variety of merchandise must be considered in designing air conditioning. The design and application suggestions for small stores also apply to discount stores.

Another type of big box facility provides both dry good and grocery areas. The grocery area is typically treated as a traditional stand-alone grocery. Conditioning of outside air into the dry goods areas must be considered to limit the introduction of excess moisture that will migrate to the freezer aisles.

Hardware, lumber and furniture, etc. is also retailed from big box facilities. An particular concern in this type of facility is ventilation for material handling equipment, such as forklift trucks.

In addition to the sales area in any of these facilities such areas as stockrooms, rest rooms, offices, and special storage rooms for perishable merchandise may require air conditioning or refrigeration.

Load Determination

Operating economics and the spaces served often dictate the indoor design conditions. Some stores may base summer load calculations on a higher inside temperature (e.g., 27ºC db) but then set the thermostats to control at 22 to 24ºC db. This reduces the installed equipment size while providing the desired inside temperature most of the time.

Special rooms for storage of perishable goods are usually designed with separate unitary air conditioners.

The heat gain from lighting will not be uniform throughout the entire area. For example, jewelry and other specialty displays have lighting heat gains as high as 65 to 85 W per square meter of floor area, while the typical sales area has an average value of 20 to 40 W/m^2. For stockrooms and receiving, marking, toilet, and rest room areas, a value of 20 W/m^2 may be used. When available, actual lighting layouts rather than average values should be used for load computation.

The store owner usually determines the population density for a store based on its location, size, and past experience.

Food preparation and service areas in discount and outlet stores range from small lunch counters having heat-producing equipment (ranges, griddles, ovens, coffee urns, toasters) in the conditioned space to large deluxe installations with kitchens separate from the conditioned space. Chapter 30 has specific information on HVAC systems for kitchen and eating spaces.

Data on the heat released by special merchandising equipment, such as amusement rides for children or equipment used for preparing speciality food items (e.g., popcorn, pizza, frankfurters, hamburgers, doughnuts, roasted chickens, cooked nuts, etc.), should be obtained from the equipment manufacturers.

Ventilation and outdoor air must be provided as required in ASHRAE standards and local codes.

Design Considerations

Heat released by the installed lighting is usually sufficient to offset the design roof heat loss. Therefore, the interior areas of these stores need cooling during business hours throughout the year. The perimeter areas, especially the storefront and entrance areas, may have highly variable heating and cooling requirements. Proper zone control and HVAC design are essential. The location of checkout lanes in this area makes proper environmental control even more important.

System Design. The important factors in selecting discount and outlet store air-conditioning systems are (1) installation costs, (2) floor space required for equipment, (3) maintenance requirements and equipment reliability, and (4) simplicity of control. Roof-mounted units are the most commonly used.

Air Distribution. The air supply for large sales areas should generally be designed to satisfy the primary cooling requirement. In designing air distribution for the perimeter areas, the variable heating and cooling requirements must be considered.

Because of the store requirement to maintain high, clear areas for display and restocking, air is generally distributed from heights of 4.3 m and greater. Air distribution at these heights requires high velocities in the heating season to overcome the buoyancy of the hot air. The velocity of this discharge air creates turbulence in the space, and induces air from the ceiling area complete mixing of the air.

The designer should take advantage of stratification to reduce the equipment load. By introducing air near the customers at low velocity, the air will stratify during the cooling season. With this method of air distribution, the set-point temperature can be maintained in the occupant zone and the temperature in the upper space can be allowed to rise. However, this strategy requires equipment to destratify the air during the heating season. Space-mounted fans, and radiant heating at the perimeter, entrance, and sales areas may be required.

Control. Because the controls are usually operated by personnel who have little knowledge of air-conditioning, it should be simple, dependable, and fully automatic systems—it should be as simple to operate as a residential system. Most unitary equipment has automatic electronic controls for ease of operation.

Maintenance. Most stores do not employ trained maintenance personnel; they rely instead on service contracts with either the installer or a local service company. For suggestions on lowering operating costs, see the previous section on Small Stores.

SUPERMARKETS

Load Determination

Heating and cooling loads should be calculated using the methods outlined in Chapter 28 of the 1997 *ASHRAE Handbook—Fundamentals*. Data for calculating the loads due to people, lights, motors, and heat-producing equipment should be obtained from the store owner or manager or from the equipment manufacturer. In supermarkets, space conditioning is required both for human comfort and for proper operation of refrigerated display cases. The air-conditioning unit should introduce a minimum quantity of outdoor air. This quantity is either the volume required for ventilation based on ASHRAE *Standard* 62 or the volume required to maintain slightly positive pressure in the space, whichever is larger.

Many supermarkets are units of a large chain owned or operated by a single company. The standardized construction, layout, and equipment used in designing many similar stores simplify load calculations.

It is important that the final air-conditioning load be correctly determined. Refer to manufacturers' data for information on the

total heat extraction, sensible heat, latent heat, and percentage of latent to total load for display cases. Engineers report considerable fixture heat removal (case load) variation as the relative humidity and temperature vary in comparatively small increments. Relative humidity above 55% substantially increases the load, while reduced relative humidity substantially decreases the load, as shown in Figure 1. Trends in store design, which include more food refrigeration and more efficient lighting, reduce the sensible component of the load even further.

To calculate the total load and percentage of latent and sensible heat that the air conditioning must handle, the refrigerating effect imposed by the display fixtures must be subtracted from the building's gross air-conditioning requirements.

Modern supermarket designs have a high percentage of closed refrigerated display fixtures. These vertical cases have large glass display doors and greatly reduce the problem of latent and sensible heat removal from the occupied space. The doors do, however, require heaters to prevent condensation and fogging. These heaters should be cycled based on some kind of automatic control.

Design Considerations

Store owners and operators frequently complain about cold aisles, heaters that operate even when the outdoor temperature is above 21ºC, and air-conditioners that operate infrequently. These problems are usually attributed to spillover of cold air from open refrigerated display equipment.

Although refrigerated display equipment may be the cause of cold stores, the problem is not due to excessive spillover or improperly operating equipment. Heating and air-conditioning systems must compensate for the effects of open refrigerated display equipment. Design considerations include the following:

1. Increased heating requirement due to removal of large quantities of heat, even in summer.
2. Net air-conditioning load after deducting the latent and sensible refrigeration effect (Item 1). The load reduction and change in sensible-latent load ratio have a major effect on equipment selection.
3. Need for special air circulation and distribution to offset the heat removed by open refrigerating equipment.
4. Need for independent temperature and humidity control.

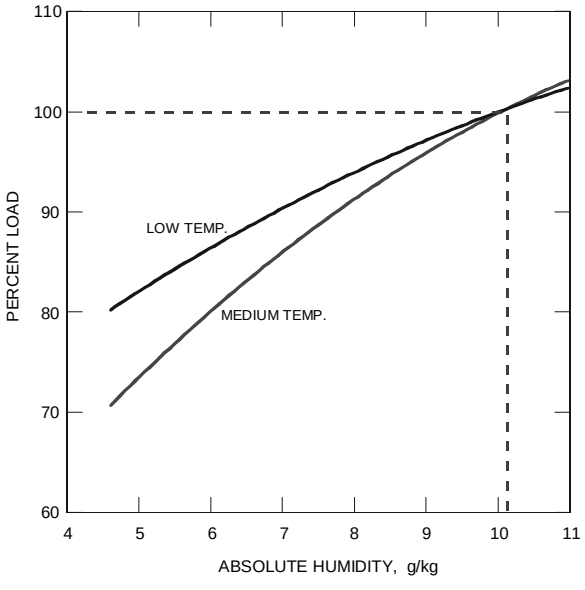

Fig. 1 Refrigerated Case Load Variation with Store Air Humidity

Each of these problems is present to some degree in every supermarket, although situations vary with climate and store layout. Methods of overcoming these problems are discussed in the following sections. Extremely high energy cost may ensue if the year-round air-conditioning system has not been designed to compensate for the effects of refrigerated display equipment.

Heat Removed by Refrigerated Displays. The display refrigerator not only cools a displayed product but envelops it in a blanket of cold air that absorbs heat from the room air in contact with it. Approximately 80 to 90% of the heat removed from the room by vertical refrigerators is absorbed through the display opening. Thus, the open refrigerator acts as a large air cooler, absorbing heat from the room and rejecting it via the condensers outside the building. Occasionally, this conditioning effect can be greater than the design air-conditioning capacity of the store. The heat removed by the refrigeration equipment *must* be considered in the design of the air-conditioning and heating systems because this heat is being removed constantly, day and night, summer and winter, regardless of the store temperature.

The display cases increase the heating requirement of the building such that heat is often required at unexpected times. The following example is an indication of the extent of this cooling effect. The desired store temperature is 24ºC. Store heat loss or gain is assumed to be 8 kW/ºC of temperature difference between outdoor and store temperature. (This value varies with store size, location, and exposure.) The heat removed by refrigeration equipment is 56 kW. (This value varies with the number of refrigerators.) The latent heat removed is assumed to be 19% of the total, leaving 81% or 45.4 kW sensible heat removed, which will cool the store 45.4/8 = 5.7ºC. By constantly removing sensible heat from its environment, the refrigeration equipment in this store will cool the store 5.7ºC below outdoor temperature in winter and in summer. Thus, in mild climates, heat must be added to the store to maintain comfort conditions.

The designer has the choice of discarding or reclaiming the heat removed by refrigeration. If economics and store heat data indicate that the heat should be discarded, heat extraction from the space must be included in the heating load calculation. If this internal heat loss is not included, the heating system may not have sufficient capacity to maintain the design temperature under peak conditions.

The additional sensible heat removed by the cases may change the air-conditioning latent load ratio from 32% to as much as 50% of the net heat load. Removal of a 50% latent load by means of refrigeration alone is very difficult. Normally, it requires specially designed equipment with reheat or chemical adsorption.

Multishelf refrigerated display equipment requires 55% rh or less. In the dry-bulb temperature ranges of average stores, humidity in excess of 55% can cause heavy coil frosting, product zone frosting in low-temperature cases, fixture sweating, and substantially increased refrigeration power consumption.

A humidistat can be used during summer cooling to control humidity by transferring heat from the condenser to a heating coil in the airstream. The store thermostat maintains proper summer temperature conditions. Override controls prevent conflict between the humidistat and the thermostat.

The equivalent result can be accomplished with a conventional air-conditioning system by using three- or four-way valves and reheat condensers in the ducts. This system borrows heat from the standard condenser and is controlled by a humidistat. For higher energy efficiency, specially designed equipment should be considered. Desiccant dehumidifiers and heat pipes have also been used.

Humidity. Cooling from the refrigeration equipment does not preclude the need for air conditioning. On the contrary, it increases the need for humidity control.

With increases in store humidity, heavier loads are imposed on the refrigeration equipment, operating costs rise, more defrost

periods are required, and the display life of products is shortened. The dew point rises with the relative humidity, and sweating can become profuse to the extent that even nonrefrigerated items such as shelving superstructures, canned products, mirrors, and walls may sweat.

There are two commonly used devices for achieving humidity control. One is an electric vapor compression air conditioner, which overcools the air to condense the moisture and then reheats it to a comfortable temperature. Condenser waste heat is often used. Vapor compression holds humidity levels at 50 to 55% rh.

The second dehumidification device is a desiccant dehumidifier. A desiccant absorbs or adsorbs moisture directly from the air to its surface. The desiccant material is reactivated by passing hot air at 80 to 110°C through the desiccant base. Condenser waste heat can provide as much as 40% of the heat required. Desiccant systems in supermarkets can maintain humidity in the lower ranges of the comfort index. Lower humidity results in lower operating costs for the refrigerated cases.

System Design. The same air-handling equipment and distribution system are generally used for both cooling and heating. The entrance area is the most difficult section to heat. Many supermarkets in the northern United States are built with vestibules provided with separate heating equipment to temper the cold air entering from the outdoors. Auxiliary heat may also be provided at the checkout area, which is usually close to the front entrance. Methods of heating entrance areas include the use of (1) air curtains, (2) gas-fired or electric infrared radiant heaters, and (3) waste heat from the refrigeration condensers.

Air-cooled condensing units are the most commonly used in supermarkets. Typically, a central air handler conditions the entire sales area. Specialty areas like bakeries, computer rooms, or warehouses are better served with a separate air handler because the loads in these areas vary and require different control than the sales area.

Most installations are made on the roof of the supermarket. If air-cooled condensers are located on the ground outside the store, they must be protected against vandalism as well as truck and customer traffic. If water-cooled condensers are used on the air-conditioning equipment and a cooling tower is required, provisions should be made to prevent freezing during winter operation.

Air Distribution. Designers overcome the concentrated load at the front of a supermarket by discharging a large portion of the total air supply into the front third of the sales area.

The air supply to the space with the vapor compression system has typically been 5 L/s per square metre of sales area. This value should be calculated based on the sensible and latent internal loads. The desiccant system typically requires less air supply due to its high moisture removal rate. In most cases, only about 40% of the circulation rate passes through the dehumidifier.

Being more dense, the air cooled by the refrigerators settles to the floor and becomes increasingly colder, especially in the first 900 mm above the floor. If this cold air remains still, it causes discomfort and serves no purpose, even when other areas of the store need more cooling. Cold floors or areas in the store cannot be eliminated by the simple addition of heat. Any reduction of air-conditioning capacity without circulation of the localized cold air would be analogous to installing an air conditioner without a fan. To take advantage of the cooling effect of the refrigerators and provide an even temperature in the store, the cold air must be mixed with the general store air.

To accomplish the necessary mixing, air returns should be located at floor level; they should also be strategically placed to remove the cold air near concentrations of refrigerated fixtures. The returns should be designed and located to avoid the creation of drafts. There are two general solutions to this problem:

1. **Return Ducts in Floor.** This is the preferred method and can be accomplished in two ways. The floor area in front of the refrigerated display cases is the coolest area. Refrigerant lines are run to all of these cases, usually in tubes or trenches. If the trenches or tubes are enlarged and made to open under the cases for air return, air can be drawn in from the cold area (see Figure 2). The air is returned to the air-handling unit through a tee connection to the trench before it enters the back room area. The opening through which the refrigerant lines enter the back room should be sealed.

   If refrigerant line conduits are not used, the air can be returned through inexpensive underfloor ducts. If refrigerators have insufficient undercase air passage, the manufacturer should be consulted. Often they can be raised off the floor approximately 40 mm. Floor trenches can also be used as ducts for tubing, electrical supply, and so forth.

   Floor-level return relieves the problem of localized cold areas and cold aisles and uses the cooling effect for store cooling, or increases the heating efficiency by distributing the air to the areas that need it most.
2. **Fans Behind Cases.** If ducts cannot be placed in the floor, circulating fans can draw air from the floor and discharge it above the cases (see Figure 3). While this approach prevents objectionable cold aisles in front of the refrigerated display cases, it does not prevent the area with a concentration of refrigerated fixtures from remaining colder than the rest of the store.

Control. Store personnel should only be required to change the position of a selector switch to start or stop the system or to change

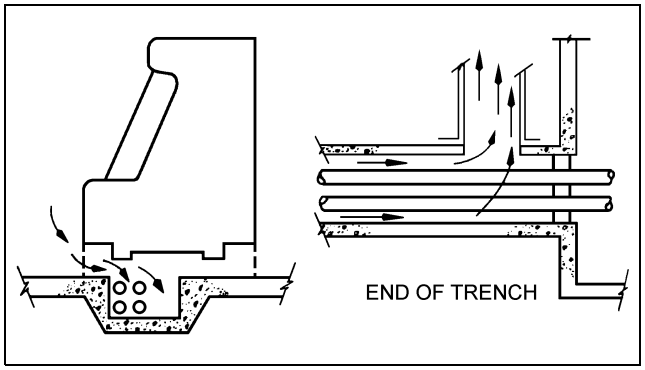

Fig. 2 Floor Return Ducts

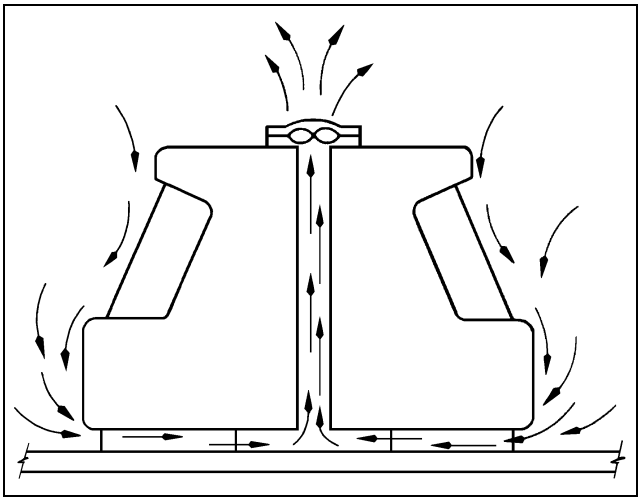

Fig. 3 Air Mixing Using Fans Behind Cases

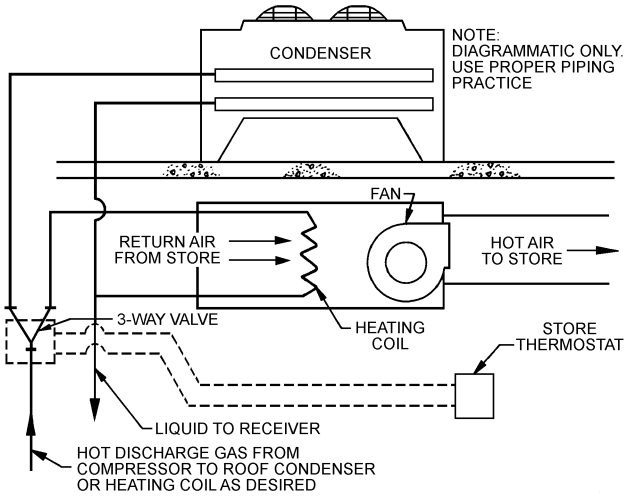

Fig. 4 Heat Reclaiming Systems

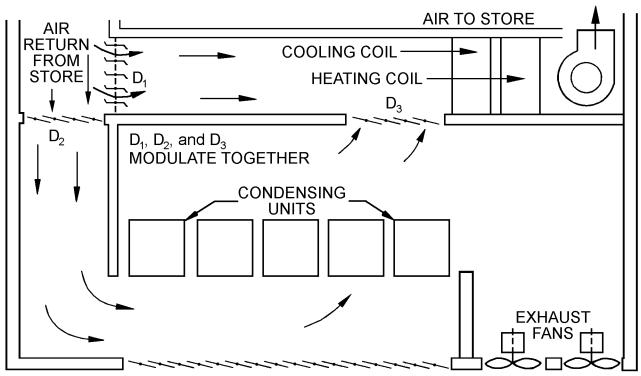

Fig. 5 Machine Room with Automatic Temperature Control Interlocked with Store Temperature Control

from heating to cooling or from cooling to heating. Control systems for heat recovery applications are more complex and should be coordinated with the equipment manufacturer.

Maintenance and Heat Reclamation. Most supermarkets, except large chains, do not employ trained maintenance personnel, but rather rely on service contracts with either the installer or a local service company. This relieves the store management of the responsibility of keeping the air conditioning operating properly.

The heat extracted from the store and the heat of compression may be reclaimed for heating cost saving. One method of reclaiming the rejected heat is to use a separate condenser coil located in the air conditioner's air handler, either alternately or in conjunction with the main refrigeration condensers, to provide heat as required (see Figure 4). Another system uses water-cooled condensers and delivers its rejected heat to a water coil in the air handler.

The heat rejected by conventional machines using air-cooled condensers may be reclaimed by proper duct and damper design (see Figure 5). Automatic controls can either reject this heat to the outdoors or recirculate it through the store.

DEPARTMENT STORES

Department stores vary in size, type, and location, so air-conditioning design should be specific to each store. An ample minimum quantity of outdoor air reduces or eliminates odor problems. Essential features of a quality system include (1) an automatic control system properly designed to compensate for load fluctuations, (2) zoned air distribution to maintain uniform conditions under shifting loads, and (3) use of outdoor air for cooling during intermediate seasons and peak sales periods. It is also desirable to adjust indoor temperature for variations in the outdoor temperature. While the close control of humidity is not necessary, a properly designed system should operate to maintain relative humidity at 50% or below with a corresponding dry-bulb temperature of 26ºC. This humidity limit eliminates musty odors and retards perspiration, particularly in fitting rooms.

Load Determination

Because the occupancy (except store personnel) is transient, indoor conditions are commonly set not to exceed 26ºC db and 50% rh at outdoor summer design conditions, and 21ºC db at outdoor winter design conditions. Winter humidification is seldom used in store air conditioning.

The number of customers and store personnel normally found on each conditioned floor must be ascertained, particularly in specialty departments or other areas having a greater-than-average concentration of occupants. Lights should be checked for wattage and type. Table 1 gives approximate values for lighting in various areas; Table 2 gives approximate occupancies.

Other loads, such as those from motors, beauty parlor and restaurant equipment, and any special display or merchandising equipment, should be determined.

The minimum outdoor air requirement should be as defined in the ASHRAE *Standard* 62, which are generally acceptable and adequate for removing odors and keeping the building atmosphere fresh. However, local ventilation ordinances may require greater quantities of outdoor air.

Paint shops, alteration rooms, rest rooms, eating places, and locker rooms should be provided with positive exhaust ventilation, and their requirements must be checked against local codes.

Design Considerations

Before performing load calculations, the designer should examine the store arrangement to determine what will affect the load and the system design. For existing buildings, a survey can be made of actual construction, floor arrangement, and load sources. For new buildings, an examination of the drawings and a discussion with the architect or owner will be required.

Larger stores may contain beauty parlors, restaurants, lunch counters, or auditoriums. These special areas may operate during all store hours. If one of these areas has a load that is small in proportion to the total load, the load may be met by the portion of the air conditioning serving that floor. If present or future operation could for any reason be compromised by such a strategy, this space should be served by separate air conditioning. Because of the concentrated load in the beauty parlor, separate air distribution should be provided for this area.

Table 1 Approximate Lighting Load for Department Stores

Area	W/m^2
Basement	30 to 50
First floor	40 to 70
Upper floors, women's wear	30 to 50
Upper floors, house furnishings	20 to 30

Table 2 Approximate Occupancy for Department Stores

Area	m^2 per person
Basement, metropolitan area	2 to 9
Basement, other with occasional peak	2 to 9
First floor, metropolitan area	2 to 7
First floor, suburban	2 to 7
Upper floors, women's wear	5 to 9
Upper floors, house furnishings	9 or more

The restaurant, because of its required service facilities, is generally centrally located. It is often used only during the noon hours. For control of odors, a separate air-handling system should be considered. Future plans for the store must be ascertained because they can have a great effect on the type of air conditioning and refrigeration to be used.

System Design. Air conditioning for department stores may be of the unitary or central-station type. Selection should be based on owning and operating costs as well as any other special considerations for the particular store, such as store hours, load variations, and size of load.

Large department stores often use central-station systems consisting of air-handling units having chilled water cooling coils, hot water heating coils, fans, and filters. Air systems must have adequate zoning for varying loads, occupancy, and usage. Wide variations in people loads may justify consideration of variable volume air distribution systems. The water chilling and heating plants distribute water to the various air handlers and zones and may take advantage of some load diversity throughout the building.

Air-conditioning equipment should not be placed in the sales area; instead, it should be located in ceiling, roof, and mechanical equipment room areas whenever practicable. Maintenance and operation after installation should be considered in the location of equipment.

Air Distribution. All buildings must be studied for orientation, wind exposure, construction, and floor arrangement. These factors affect not only load calculations, but also zone arrangements and duct locations. In addition to entrances, wall areas with significant glass, roof areas, and population densities, the expected locations of various departments (e.g., the lamp department) should be considered. Flexibility must be left in the duct design to allow for future movement of departments. The preliminary duct layout should also be checked in regard to winter heating to determine any special situations. It is usually necessary to design separate air systems for entrances, particularly in northern areas. This is also true for storage areas where cooling is not contemplated.

Air curtains may be installed at entrance doorways to limit or prevent infiltration of unconditioned air, at the same time providing greater ease of entry.

Control. The necessary extent of automatic control depends on the type of installation and the extent to which it is zoned. Control must be such that correctly conditioned air is delivered to each zone. Outdoor air intake should be automatically controlled to operate at minimum cost. Partial or full automatic control should be provided for cooling to compensate for load fluctuations. Completely automatic refrigeration plants should be considered.

Maintenance. Most department stores employ personnel for routine operation and maintenance, but rely on service and preventive maintenance contracts for refrigeration cycles, chemical treatment, central plant systems, and major repairs.

Improving Operating Cost. An outdoor air economizer can reduce the operating cost of cooling in most climates. These are generally available as factory options or accessories with the air-handling units or control systems. Heat recovery and thermal storage should also be analyzed.

CONVENIENCE CENTERS

Many small stores, discount stores, supermarkets, drugstores, theaters, and even department stores are located in convenience centers. The space for an individual store is usually leased. Arrangements for installing air conditioning in leased space vary. In a typical arrangement, the developer builds a shell structure and provides the tenant with an allowance for typical heating and cooling and other minimum interior finish work. The tenant must then install an HVAC system. In another arrangement, developers install HVAC units in the small stores with the shell construction, often before the space is leased or the occupancy is known. The larger stores typically provide their own HVAC design and installation.

Design Considerations

The developer or owner may establish standards for typical heating and cooling that may or may not be sufficient for the tenant's specific requirements. The tenant may therefore have to install systems of different sizes and types than originally allowed for by the developer. The tenant must ascertain that power and other services will be available for the total intended requirements.

The use of party walls in convenience centers tends to reduce heating and cooling loads. However, the effect an unoccupied adjacent space has on the partition load must be considered.

REGIONAL SHOPPING CENTERS

Regional shopping centers generally incorporate an enclosed heated and air-conditioned mall. These centers are normally owned by a developer, who may be an independent party, a financial institution, or one of the major tenants in the center.

The major department stores are typically considered to be separate buildings, although they are attached to the mall. The space for individual small stores is usually leased. Arrangements for installing air conditioning in the individually leased spaces vary, but are similar to those for small stores in convenience centers.

Table 3 presents typical data that can be used as check figures and field estimates. However, this table should not be used for final determination of load, since the values are only averages.

Design Considerations

The owner provides the air-conditioning system for the enclosed mall. The mall may use a central plant or unitary equipment. The owner generally requires that the individual tenant stores connect to a central plant and includes charges for heating and cooling in the rent. Where unitary systems are used, the owner generally requires that the individual tenant install a unitary system of similar design.

The owner may establish standards for typical heating and cooling systems that may or may not be sufficient for the tenant's specific requirements. Therefore, the tenant may have to install systems of different sizes than originally allowed for by the developer.

Leasing arrangements may include provisions that have a detrimental effect on conservation (such as allowing excessive lighting and outdoor air or deleting requirements for economizer systems). The designer of HVAC for tenants in a shopping center must be well aware of the lease requirements and work closely with leasing agents to guide these systems toward better energy efficiency.

Many regional shopping centers now contain specialty food court areas that require special considerations for odor control, outdoor air requirements, kitchen exhaust, heat removal, and refrigeration equipment.

System Design. Regional shopping centers vary widely in physical arrangement and architectural design. Single-level and smaller centers usually use unitary systems for mall and tenant air conditioning; multilevel and larger centers usually use a central plant. The owner sets the design of the mall and generally requires that similar systems be installed for tenant stores.

A typical central plant may distribute chilled air to the individual tenant stores and to the mall air-conditioning system and employ variable volume control and electric heating at the local use point. Some plants distribute both hot and chilled water. All-air systems have also been used that distribute chilled or heated air to the individual tenant stores and to the mall air conditioning and use variable volume control at the local use point. The central plant provides improved efficiency and better overall economics of operation. They also provide the basic components required for smoke control.

Table 3 Typical Installed Capacity and Energy Use in Enclosed Mall Centers[a]

Based on 1979 Data—Midwestern United States

Type of Space	Installed Cooling W/m^2	Annual Consumption, MJ/m^2			
		Lighting[b]	Cooling[c]	Heating[d]	Miscellaneous
Candy store	141 to 246	926 to 1147	302 to 911	372 to 221	93 to 2716
Clothing store	118 to 144	546 to 965	310 to 372	345 to 198	47 to 260
Fast food	152 to 246	647 to 1256	380 to 911	372 to 147	1476 to 2713
Game room	107 to 140	264 to 484	279 to 283	535 to 182	8 to 535
Gen. merchandise	104 to 138	512 to 903	244 to 376	244 to 217	54 to 360
Gen. service	124 to 159	608 to 674	302 to 357	465 to 229	295 to 318
Gift store	115 to 161	496 to 887	244 to 388	275 to 190	16 to 85
Grocery	219 to 272	422 to 748	205 to 345	233 to 271	721 to 814
Jewelry	169 to 209	1442 to 1740	411 to 477	217 to 140	295 to 360
Mall	95 to 151	209 to 465	322 to 531	446 to 217	8 to 58
Restaurant	126 to 167	194 to 853	302 to 477	736 to 647	667 to 814
Shoe store	116 to 160	791 to 1244	287 to 442	279 to 178	39 to 89
Center average	95 to 151	698 to 1085	310 to 581	233 to 116	39 to 116

[a]Operation of center assumed to be 12 h/day and 6.5 days/week.
[b]Lighting includes miscellaneous and receptacle loads.
[c]Cooling includes blower motor and is for unitary-type system.
[d]Heating includes blower and is for electric resistance heating.

Air Distribution. Air distribution for individual stores should be designed for a particular space occupancy. Some tenant stores maintain a negative pressure relative to the mall for odor control.

The air distribution should maintain a slight positive pressure relative to atmospheric pressure and a neutral pressure relative to most of the individual tenant stores. Exterior entrances should have vestibules with independent heating systems.

Smoke management is required by many building codes, so the air distribution should be designed to easily accommodate smoke control requirements.

Maintenance. Methods for ensuring the operation and maintenance of HVAC systems in regional shopping centers are similar to those used in department stores. Individual tenant stores may have to provide their own maintenance.

Improving Operating Cost. Methods for lowering operating costs in shopping centers are similar to those used in department stores. Some shopping centers have successfully employed cooling tower heat exchanger economizers.

Central plant systems for regional shopping centers typically have much lower operating costs than unitary systems. However, the initial cost of the central plant system is typically higher.

MULTIPLE-USE COMPLEXES

Multiple-use complexes are being developed in most metropolitan areas. These complexes generally combine retail facilities with other facilities such as offices, hotels, residences, or other commercial space into a single site. This consolidation of facilities into a single site or structure provides benefits such as improved land use; structural savings; more efficient parking; utility savings; and opportunities for more efficient electrical, fire protection, and mechanical systems.

Load Determination

The various occupancies may have peak HVAC demands that occur at different times of the day or even of the year. Therefore, the HVAC loads of the various occupancies should be determined independently. Where a combined central plant is under consideration, a block load should also be determined.

Design Considerations

Retail facilities are generally located on the lower levels of multiple-use complexes, and other commercial facilities are on upper levels. Generally, the perimeter loads of the retail portion differ from those of the other commercial spaces. Greater lighting and population densities also make the HVAC demands for the retail space different from those for the other commercial space.

The differences in HVAC characteristics for the various occupancies within a multiple-use complex indicate that separate air handling and distribution should be used for the separate spaces. However, combining the heating and cooling requirements of the various facilities into a central plant can achieve a substantial saving. A combined central heating and cooling plant for a multiple-use complex also provides good opportunities for heat recovery, thermal storage, and other similar functions that may not be economical in a single-use facility.

Many multiple-use complexes have atriums. The stack effect created by atriums requires special design considerations for tenants and space on the main floor. Areas near entrances require special considerations to prevent drafts and accommodate extra heating requirements.

System Design. Individual air-handling and distribution systems should be designed for the various occupancies. The central heating and cooling plant may be sized for the block load requirements, which may be less than the sum of each occupancy's demand.

Control. Multiple-use complexes typically require centralized control. It may be dictated by requirements for fire and smoke control, security, remote monitoring, billing for central facilities use, maintenance control, building operations control, and energy management.

CHAPTER 3

COMMERCIAL AND PUBLIC BUILDINGS

General Criteria 3.1
Dining and Entertainment Centers 3.4
Office Buildings 3.6
Bowling Centers 3.8
Communication Centers 3.9
Transportation Centers 3.9
Warehouses 3.11

THIS chapter summarizes the load characteristics and both the general and specific design criteria that apply to commercial buildings. Design criteria include such factors as comfort level; cost; and fire, smoke, and odor control. Specific information is included on dining and entertainment centers, office buildings, bowling centers, communication centers, transportation centers, and warehouses are covered. Museums, libraries, and archives are covered in Chapter 20.

GENERAL CRITERIA

In theory, most systems, if properly applied, can be successful in any building. However, in practice, such factors as initial and operating costs, space allocation, architectural design, location, and the engineer's evaluation and experience limit the proper choices for a given building type.

Heating and air-conditioning systems that are simple in design and of the proper size for a given building generally have fairly low maintenance and operating costs. For optimum results, as much inherent thermal control as is economically possible should be built into the basic structure. The relationship between the shape, orientation, and air-conditioning capacity of a building should also be considered. Because the exterior load may vary from 30 to 60% of the total air-conditioning load when the fenestration area ranges from 25 to 75% of the exterior envelope surface area, it may be desirable to minimize the perimeter area. For example, a rectangular building with a four-to-one aspect ratio requires substantially more refrigeration than a square building with the same floor area.

Building size, shape, and component selection is normally determined by the building architect and/or owner. Bringing about changes in any of these areas in an attempt to reach optimum results requires the cooperation of these individuals or groups.

Proper design also considers controlling noise and minimizing pollution of the atmosphere and water systems around the building.

Retrofitting existing buildings is also an important part of the construction industry because of increased costs of construction and the necessity of reducing energy consumption. Table 1 lists factors to consider before selecting a system for any building. The selection is often made by the owner and may not be based on an engineering study. To a great degree, system selection is based on the engineer's ability to relate those factors involving higher first cost or lower life-cycle cost and benefits that have no calculable monetary value.

Some buildings are constructed with only heating and ventilating systems. For these buildings, greater design emphasis should be placed on natural or forced ventilation systems to minimize occupant discomfort during hot weather. If such buildings are to provide for future cooling, humidification, or both, the design principles are the same as those for a fully air-conditioned building.

The preparation of this chapter is assigned to TC 9.8, Large Building Air-Conditioning Applications.

Load Characteristics

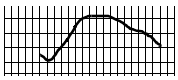
Load characteristics for the building must be understood to ensure that systems respond adequately at part load as well as at full load. Systems must be capable of responding to load fluctuations based on the combination of occupancy variations, process load shifts, solar load variations, and atmospheric weather conditions (e.g., temperature and humidity changes). Some building loads may be brief and infrequent such as an annual meeting of a large group in a conference room, while others may be more constant and long lasting such as the operation of data processing equipment.

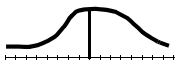
Analysis of any building for heat recovery or total energy systems requires sufficient load profile and load duration information on all forms of building input to (1) properly evaluate the instantaneous effect of one on the other when no energy storage is contemplated and (2) evaluate short-term effects (up to 48 h) when energy storage is used.

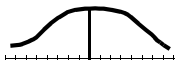
Load profile curves consist of appropriate energy loads plotted against the time of day. Load duration curves indicate the accumulated number of hours at each load condition, from the highest to the lowest load for a day, a month, or a year. The area under load profile and load duration curves for corresponding periods is equivalent to the load multiplied by the time. These calculations must consider the type of air and water distribution systems in the building.

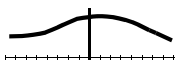
Load profiles for two or more energy forms during the same operating period may be compared to determine load-matching characteristics under diverse operating conditions. For example, when thermal energy is recovered from a diesel-electric generator at a rate equal to or less than the thermal energy demand, the energy can be used instantaneously, avoiding waste. But it may be worthwhile to store thermal energy when it is generated at a greater rate than demanded. A load profile study helps determine the economics of thermal storage.

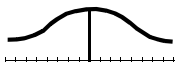
Similarly, with internal source heat recovery, load matching must be integrated over the operating season with the aid of load duration curves for overall feasibility studies. These curves are useful in energy consumption analysis calculations as a basis for hourly input values in computer programs (see Chapter 30 of the 1997 *ASHRAE Handbook—Fundamentals*).











Aside from environmental considerations, the economic feasibility of district heating and cooling is influenced by load density and diversity factors for branch feeds to buildings along distribution mains. For example, the load density or energy per unit length of distribution main can be small enough in a complex of low-rise, lightly loaded buildings located at a considerable distance from one another, to make a central heating, cooling, or heating and cooling plant uneconomical.

Concentrations of internal loads peculiar to each application are covered later in this chapter and in Chapters 27, 28, and 29 of the 1997 *ASHRAE Handbook—Fundamentals*.

Table 1 General Design Criteria[a, b]

General Category	Specific Category	Inside Design Conditions		Air Movement	Circulation, air changes per hour
		Winter	Summer		
Dining and Entertainment Centers	Cafeterias and Luncheonettes	21 to 23°C 20 to 30% rh	26°C[e] 50% rh	0.25 m/s at 1.8 m above floor	12 to 15
	Restaurants	21 to 23°C 20 to 30% rh	23 to 26°C 55 to 60% rh	0.13 to 0.15 m/s	8 to 12
	Bars	21 to 23°C 20 to 30% rh	23 to 26°C 50 to 60% rh	0.15 m/s at 1.8 m above floor	15 to 20
	Nightclubs and Casinos	21 to 23°C 20 to 30% rh	23 to 26°C 50 to 60% rh	below 0.13 m/s at 1.5 m above floor	20 to 30
	Kitchens	21 to 23°C	29 to 31°C	0.15 to 0.25 m/s	12 to 15[h]
Office Buildings		21 to 23°C 20 to 30% rh	23 to 26°C 50 to 60% rh	0.13 to 0.23 m/s 4 to 10 L/(s·m^2)	4 to 10
Museums, Libraries, and Archives (Also see Chapter 20.)	Average	20 to 22°C 40 to 55% rh		below 0.13 m/s	8 to 12
	Archival	See Chapter 20, Museums, Libraries, and Archives		below 0.13 m/s	8 to 12
Bowling Centers		21 to 23°C 20 to 30% rh	24 to 26°C 50 to 55% rh	0.25 m/s at 1.8 m above floor	10 to 15
Communication Centers	Telephone Terminal Rooms	22 to 26°C 40 to 50% rh	22 to 26°C 40 to 50% rh	0.13 to 0.15 m/s	8 to 20
	Radio and Television Studios	21 to 23°C 40 to 50% rh	23 to 26°C 45 to 55% rh	0.13 to 0.15 m/s	15 to 40
Transportation Centers	Airport Terminals	23 to 26°C 30 to 40% rh	23 to 26°C 40 to 55% rh	below 0.13 m/s at 3.7 m above floor	8 to 12
	Ship Docks	21 to 23°C 20 to 30% rh	23 to 26°C 50 to 60% rh	0.13 to 0.15 m/s at 1.8 m above floor	8 to 12
	Bus Terminals	21 to 23°C 20 to 30% rh	23 to 26°C 50 to 60% rh	0.13 to 0.15 m/s at 1.8 m above floor	8 to 12
	Garages[l]	4 to 13°C	27 to 38°C	0.15 to 0.38 m/s	4 to 6
Warehouses		Inside design temperatures for warehouses often depend on the materials stored.			1 to 4

Table 1 General Design Criteria[a, b] (*Concluded*)

Noise[c]	Filtering Efficiencies (ASHRAE *Standard* 52.1)	Load Profile	Comments
NC 40 to 50[e]	35% or better	Peak at 1 to 2 P.M. 	Prevent draft discomfort for patrons waiting in serving lines
NC 35 to 40	35% or better	Peak at 1 to 2 P.M. 	
NC 35 to 50	Use charcoal for odor control with manual purge control for 100% outside air to exhaust ±35% prefilters	Peak at 5 to 7 P.M. 	
NC 35 to 45[f]	Use charcoal for odor control with manual purge control for 100% outside air to exhaust ±35% prefilters	Nightclubs peak at 8 P.M. to 2 A.M. Casinos peak at 4 P.M. to 2 A.M. Equipment, 24 h/day	Provide good air movement but prevent cold draft discomfort for patrons
NC 40 to 50	10 to 15% or better		Negative air pressure required for odor control. (See also Chapter 30, Kitchen Ventilation.)
NC 30 to 45	35 to 60% or better	Peak at 4 P.M. 	
NC 35 to 40	35 to 60% or better	Peak at 3 P.M. 	
NC 35	35% prefilters plus charcoal filters 85 to 95% final[i]	Peak at 3 P.M. 	
NC 40 to 50	10 to 15%	Peak at 6 to 8 P.M. 	
to NC 60	85% or better	Varies with location and use	Constant temperature and humidity required
NC 15 to 25	35% or better	Varies widely due to changes in lighting and people	Constant temperature and humidity required
NC 35 to 50	35% or better and charcoal filters	Peak at 10 A.M. to 9 P.M. 	Positive air pressure required in terminal
NC 35 to 50	10 to 15%	Peak at 10 A.M. to 5 P.M. 	Positive air pressure required in waiting area
NC 35 to 50	35% with exfiltration	Peak at 10 A.M. to 5 P.M. 	Positive air pressure required in terminal
NC 35 to 50	10 to 15%	Peak at 10 A.M. to 5 P.M. 	Negative air pressure required to remove fumes; positive air in pressure adjacent occupied spaces
to NC 75	10 to 35%	Peak at 10 A.M. to 3 P.M. 	

Notes to Table 1, General Design Criteria

[a]This table shows design criteria differences between various commercial and public buildings. It should not be used as the sole source for design criteria. Each type of data contained here can be determined from the *ASHRAE Handbooks* and *Standards*.

[b]Consult governing codes to determine minimum allowable requirements. Outdoor air requirements may be reduced if high-efficiency adsorption equipment or other odor- or gas-removal equipment is used. See ASHRAE *Standard* 62 for calculation procedures. Also see Chapter 44 in this volume and Chapter 13 of the 1997 *ASHRAE Handbook—Fundamentals.*

[c]Refer to Chapter 46.

[d]Food in these areas is often eaten more quickly than in a restaurant, therefore, the turnover of diners is much faster. Because diners seldom remain for long periods, they do not require the degree of comfort necessary in restaurants. Thus, it may be possible to lower design criteria standards and still provide reasonably comfortable conditions. Although space conditions of 27°C and 50% rh may be satisfactory for patrons when it is 35°C and 50% rh outside, indoor conditions of 26°C and 40% rh are better.

[e]Cafeterias and luncheonettes usually have some or all of the food preparation equipment and trays in the same room with the diners. These eating establishments are generally noisier than restaurants, so that noise transmission from the air-conditioning equipment is not as critical.

[f]In some nightclubs, the noise from the air-conditioning system must be kept low so that all patrons can hear the entertainment.

[g]Usually determined by kitchen hood requirements.

[h]Peak kitchen heat load does not generally occur at peak dining load, although in luncheonettes and some cafeterias where cooking is done in the dining areas, peaks may be simultaneous.

[i]Methods for removal of chemical pollutants must also be considered.

[j]Also includes service stations.

Design Concepts

If a structure is characterized by several exposures and multipurpose use, especially with wide load swings and noncoincident energy use in certain areas, multiunit or unitary systems may be considered for such areas, but not necessarily for the entire building. The benefits of transferring heat absorbed by cooling from one area to other areas, processes, or services that require heat may enhance the selection of such systems. Systems such as incremental closed-loop heat pumps may be cost-effective.

When the cost of energy is included in the rent with no means for permanent or checkmetering, tenants tend to consume excess energy. This energy waste raises operating costs for the owner, decreases profitability, and has a detrimental effect on the environment. While design features can minimize excess energy penalties, they seldom eliminate waste. For example, U.S. Department of Housing and Urban Development nationwide field records for total-electric housing show that rent-included dwellings use approximately 20% more energy than those directly metered by a public utility company.

Diversity factor benefits for central heating and cooling in rent-included buildings may result in lower building demand and connected loads. However, energy waste may easily result in load factors and annual energy consumption exceeding that of buildings where the individual has a direct economic incentive to reduce energy consumption. Heat flow meters should be considered for charging for energy consumption.

Design Criteria

In many applications, design criteria are fairly evident, but in all cases, the engineer should understand the owner's and user's intent because any single factor may influence system selection. The engineer's personal experience and judgment in the projection of future needs may be a better criterion for system design than any other single factor.

Comfort Level. Comfort, as measured by temperature, humidity, air motion, air quality, noise, and vibration, is not identical for all buildings, occupant activities, or uses of space. The control of static electricity may be a consideration in humidity control.

Costs. Owning and operating costs can affect system selection and seriously conflict with other criteria. Therefore, the engineer must help the owner resolve these conflicts by considering factors such as the cost and availability of different fuels, the ease of equipment access, and the maintenance requirements.

Local Conditions. Local, state, and national codes, regulations, and environmental concerns must be considered in the design. Chapters 25 and 26 of the 1997 *ASHRAE Handbook—Fundamentals* give information on calculating the effects of weather in specific areas.

Automatic Temperature Control. Proper automatic temperature control maintains occupant comfort during varying internal and external loads. Improper temperature control may mean a loss of customers in restaurants and other public buildings. An energy management control system can be combined with a building automation system to allow the owner to manage energy, lighting, security, fire protection, and other similar systems from one central control point. Chapters 34 and 45 include more details.

Fire, Smoke, and Odor Control. Fire and smoke can easily spread through elevator shafts, stairwells, ducts, and other routes. Although an air-conditioning system can spread fire and smoke by (1) fan operation, (2) penetrations required in walls or floors, or (3) the stack effect without fan circulation, a properly designed and installed system can be a positive means of fire and smoke control.

Chapter 51 has information on techniques for positive control after a fire starts. Effective attention to fire and smoke control also helps prevent odor migration into unventilated areas (see Chapter 44). The design of the ventilation system should consider applicable National Fire Protection Association standards, especially NFPA *Standards* 90A and 96.

DINING AND ENTERTAINMENT CENTERS

Load Characteristics

Air conditioning of restaurants, cafeterias, bars, and nightclubs presents common load problems encountered in comfort conditioning, with additional factors pertinent to dining and entertainment applications. Such factors include

- Extremely variable loads with high peaks, in many cases, occurring twice daily
- High sensible and latent heat gains because of gas, steam, electric appliances, people, and food
- Sensible and latent loads that are not always coincident
- Large quantities of makeup air normally required
- Localized high sensible and latent heat gains in dancing areas
- Unbalanced conditions in restaurant areas adjacent to kitchens which, although not part of the conditioned space, still require special attention
- Heavy infiltration of outdoor air through doors during rush hours
- Smoking versus nonsmoking areas

Internal heat and moisture loads come from occupants, motors, lights, appliances, and infiltration. Separate calculations should be made for patrons and employees. The sensible and latent heat load must be proportioned in accordance with the design temperature selected for both sitting and working people, because the latent to sensible heat ratio for each category decreases as the room temperature decreases.

Hoods required to remove heat from appliances may also substantially reduce the space latent loads.

Infiltration is a considerable factor in many restaurant applications because of short occupancy and frequent door use. It is

increased by the need for large quantities of makeup air, which should be provided by mechanical means to replace air exhausted through hoods and for smoke removal. Systems for hood exhaust makeup should concentrate on exhausting nonconditioned and minimally heated makeup air. Wherever possible, vestibules or revolving doors should be installed to reduce infiltration.

Design Concepts

The following factors influence system design and equipment selection:

- High concentrations of food, body, and tobacco-smoke odors require adequate ventilation with proper exhaust facilities.
- Step control of refrigeration plants gives satisfactory and economical operation under reduced loads.
- Exhausting air at the ceiling removes smoke and odor.
- Building design and space limitations often favor one equipment type over another. For example, in a restaurant having a vestibule with available space above it, air conditioning with condensers and evaporators remotely located above the vestibule may be satisfactory. Such an arrangement saves valuable space, even though self-contained units located within the conditioned space may be somewhat lower in initial cost and maintenance cost. In general, small cafeterias, bars, and the like, with loads up to 35 kW, can be most economically conditioned with packaged units; larger and more elaborate establishments require central plants.
- Smaller restaurants with isolated plants usually use direct-expansion systems.
- Mechanical humidification is typically not provided due to high internal latent loads.
- Some air-to-air heat recovery equipment can reduce the energy required for heating and cooling ventilation air. Chapter 44 of the 2000 *ASHRAE Handbook—Systems and Equipment* includes details. The potential for grease condensation on heat recovery surfaces must also be considered.
- A vapor compression or desiccant-based dehumidifier should be considered for makeup air handling and enhanced humidity control.

Because eating and entertainment centers generally have low sensible heat factors and require high ventilation rates, fan-coil and induction systems are usually not applicable. All-air systems are more suitable. Space must be established for ducts, except for small systems with no ductwork. Large establishments are often served by central chilled water systems.

In cafeterias and luncheonettes, the air distribution system must keep food odors at the serving counters away from areas where patrons are eating. This usually means heavy exhaust air requirements at the serving counters, with air supplied into, and induced from, eating areas. Exhaust air must also remove the heat from hot trays, coffee urns, and ovens to minimize patron and employee discomfort and to reduce air-conditioning loads. These factors often create greater air-conditioning loads for cafeterias and luncheonettes than for restaurants.

Odor Removal. Transferring air from dining areas into the kitchen keeps odors and heat out of dining areas and cools the kitchen. Outdoor air intake and kitchen exhaust louvers should be located so that exhaust air is neither drawn back into the system nor allowed to cause discomfort to passersby.

Where odors can be drawn back into dining areas, activated charcoal filters, air washers, or ozonators are used to remove odors. Kitchen, locker room, toilet, or other malodorous air should not be recirculated unless air purifiers are used.

Kitchen Air Conditioning. If planned in the initial design phases, kitchens can often be air conditioned effectively without excessive cost. It is not necessary to meet the same design criteria as for dining areas, but kitchen temperatures can be reduced significantly. The relatively large number of people and food loads in dining and kitchen areas produce a high latent load. Additional cooling required to eliminate excess moisture increases refrigeration plant, cooling coil, and air-handling equipment size.

Advantageously located self-contained units with air distribution designed so as not to produce drafts off hoods and other equipment, can be used to spot cool intermittently. High-velocity air distribution may be effective. The costs are not excessive, and kitchen personnel efficiency can be improved greatly.

Even in climates with high wet-bulb temperatures, direct or indirect evaporative cooling may be a good compromise between the expense of air conditioning and the lack of comfort in ventilated kitchens. For more information, see Chapter 30, Kitchen Ventilation.

Special Considerations

In establishing design conditions, the duration of individual patron occupancy should be considered. Patrons entering from outdoors are more comfortable in a room with a high temperature than those who remain long enough to become acclimated. Nightclubs and deluxe restaurants are usually operated at a lower effective temperature than cafeterias and luncheonettes.

Often, the ideal design condition must be rejected for an acceptable condition because of equipment cost or performance limitations. Restaurants are frequently affected in this way because ratios of latent to sensible heat may result in uneconomical or oversized equipment selection, unless an enhanced dehumidification system or a combination of lower design dry-bulb temperature and higher relative humidity (which gives an equal effective temperature) is selected.

In severe climates, entrances and exits in any dining establishment should be completely shielded from diners to prevent drafts. Vestibules provide a measure of protection. However, both vestibule doors are often open simultaneously. Revolving doors or local means for heating or cooling infiltration air may be provided to offset drafts.

Uniform employee comfort is difficult to maintain because of (1) temperature differences between the kitchen and dining room and (2) the constant motion of employees. Since customer satisfaction is essential to a dining establishment's success, patron comfort is the primary consideration. However, maintenance of satisfactory temperature and atmospheric conditions for customers also helps alleviate employee discomfort.

One problem in dining establishments is the use of partitions to separate areas into modular units. Partitions create such varied load conditions that individual modular unit control is generally necessary.

Baseboard radiation or convectors, if required, should be located so as not to overheat patrons. This is difficult to achieve in some layouts because of movable chairs and tables. For these reasons, it is desirable to enclose all dining room and bar heating elements in insulated cabinets with top outlet grilles and baseboard inlets. With heating elements located under windows, this practice has the additional advantage of directing the heat stream to combat window downdraft and air infiltration. Separate smoking and nonsmoking areas may be required. The smoking area should be exhausted or served by separate air-handling equipment. Air diffusion device selection and placement should minimize smoke migration toward nonsmoking areas. Smoking areas must have a negative air pressure relationship with adjacent occupied areas.

Restaurants. In restaurants, people are seated and served at tables, while food is generally prepared in remote areas. This type of dining is usually enjoyed in a leisurely and quiet manner, so the ambient atmosphere should be such that the air conditioning is not noticed. Where specialized or open cooking is a feature, provisions should be made for the control and handling of cooking odors and smoke.

Bars. Bars are often a part of a restaurant or nightclub. If they are establishments on their own, they often serve food as well as drinks, and they should be classified as restaurants with food preparation in remote areas. Alcoholic beverages produce pungent vapors, which must be drawn off. In addition, smoking at bars is generally considerably heavier than in restaurants. Therefore, outdoor air requirements are relatively high by comparison.

Nightclubs and Casinos. Both nightclubs and casinos may include a restaurant, bar, stage, and dancing area. The bar should be treated as a separately zoned area, with its own supply and exhaust system. People in the restaurant area who dine and dance may require twice the air changes and cooling required by patrons who dine and then watch a show. The length of stay generally exceeds that encountered in most eating places. In addition, eating in nightclubs and casinos is usually secondary to drinking and smoking. Patron density usually exceeds that of conventional eating establishments.

Kitchens. The kitchen has the greatest concentration of noise, heat load, smoke, and odors; ventilation is the chief means of removing these objectionable elements and preventing them from entering dining areas. To ensure odor control, kitchen air pressure should be kept negative relative to other areas. Maintenance of reasonably comfortable working conditions is important. For more information, see Chapter 30, Kitchen Ventilation.

OFFICE BUILDINGS

Load Characteristics

Office buildings usually include both peripheral and interior zone spaces. The peripheral zone extends from 3 to 3.6 m inward from the outer wall toward the interior of the building and frequently has a large window area. These zones may be extensively subdivided. Peripheral zones have variable loads because of changing sun position and weather. These zone areas typically require heating in winter. During intermediate seasons, one side of the building may require cooling, while another side requires heating. However, the interior zone spaces usually require a fairly uniform cooling rate throughout the year because their thermal loads are derived almost entirely from lights, office equipment, and people. Interior space conditioning is often by systems that have variable air volume control for low- or no-load conditions.

Most office buildings are occupied from approximately 8:00 A.M. to 6:00 P.M.; many are occupied by some personnel from as early as 5:30 A.M. to as late as 7:00 P.M. Some tenants' operations may require night work schedules, usually not to extend beyond 10:00 P.M. Office buildings may contain printing plants, communications operations, broadcasting studios, and computing centers, which could operate 24 h per day. Therefore, for economical air-conditioning design, the intended uses of an office building must be well established before design development.

Occupancy varies considerably. In accounting or other sections where clerical work is done, the maximum density is approximately one person per 7 m^2 of floor area. Where there are private offices, the density may be as little as one person per 19 m^2. The most serious cases, however, are the occasional waiting rooms, conference rooms, or directors' rooms where occupancy may be as high as one person per 2 m^2.

The lighting load in an office building constitutes a significant part of the total heat load. Lighting and normal equipment electrical loads average from 10 to 50 W/m^2 but may be considerably higher, depending on the type of lighting and the amount of equipment. Buildings with computer systems and other electronic equipment can have electrical loads as high as 50 to 110 W/m^2. An accurate appraisal should be made of the amount, size, and type of computer equipment anticipated for the life of the building to size the air-handling equipment properly and provide for future installation of air-conditioning apparatus.

About 30% of the total lighting heat output from recessed fixtures can be withdrawn by exhaust or return air and, therefore, will not enter into space-conditioning supply air requirements. By connecting a duct to each fixture, the most balanced air system can be provided. However, this method is expensive, so the suspended ceiling is often used as a return air plenum with the air drawn from the space to above the suspended ceiling.

Miscellaneous allowances (for fan heat, duct heat pickup, duct leakage, and safety factors) should not exceed 12% of the total load.

Building shape and orientation are often determined by the building site, but certain variations in these factors can produce increases of 10 to 15% in the refrigeration load. Shape and orientation should therefore be carefully analyzed in the early design stages.

Design Concepts

The variety of functions and range of design criteria applicable to office buildings have allowed the use of almost every available air-conditioning system. While multistory structures are discussed here, the principles and criteria are similar for all sizes and shapes of office buildings.

Attention to detail is extremely important, especially in modular buildings. Each piece of equipment, duct and pipe connections, and the like may be duplicated hundreds of times. Thus, seemingly minor design variations may substantially affect construction and operating costs. In initial design, each component must be analyzed not only as an entity, but also as part of an integrated system. This systems design approach is essential for achieving optimum results.

There are several classes of office buildings, determined by the type of financing required and the tenants who will occupy the building. Design evaluation may vary considerably based on specific tenant requirements; it is not enough to consider typical floor patterns only. Included in many larger office buildings are stores, restaurants, recreational facilities, data centers, telecommunication centers, radio and television studios, and observation decks.

Built-in system flexibility is essential for office building design. Business office procedures are constantly being revised, and basic building services should be able to meet changing tenant needs.

The type of occupancy may have an important bearing on the selection of the air distribution system. For buildings with one owner or lessee, operations may be defined clearly enough that a system can be designed without the degree of flexibility needed for a less well-defined operation. However, owner-occupied buildings may require considerable design flexibility because the owner will pay for all alterations. The speculative builder can generally charge alterations to tenants. When different tenants occupy different floors, or even parts of the same floor, the degree of design and operation complexity increases to ensure proper environmental comfort conditions to any tenant, group of tenants, or all tenants at once. This problem is more acute if tenants have seasonal and variable overtime schedules.

Stores, banks, restaurants, and entertainment facilities may have hours of occupancy or design criteria that differ substantially from those of office buildings; therefore, they should have their own air distribution systems and, in some cases, their own heating and/or refrigeration equipment.

Main entrances and lobbies are sometimes served by a separate system because they buffer the outside atmosphere and the building interior. Some engineers prefer to have a lobby summer temperature 2 to 3.5 K above office temperature to reduce operating cost and the temperature shock to people entering or leaving the building.

The unique temperature and humidity requirements of data processing installations and the fact that they often run 24 h per day for extended periods generally warrant separate refrigeration and air distribution systems. Separate backup systems may be required for data processing areas in case the main building HVAC system fails. Chapter 16 has further information.

The degree of air filtration required should be determined. The service cost and the effect of air resistance on energy costs should be analyzed for various types of filters. Initial filter cost and air pollution characteristics also need to be considered. Activated charcoal filters for odor control and reduction of outdoor air requirements are another option to consider.

Providing office buildings with continuous 100% outdoor air is seldom justified; therefore, most office buildings are designed to minimize outdoor air use, except during economizer operation. However, attention to indoor air quality may dictate higher levels of ventilation air. In addition, the minimum volume of outdoor air should be maintained in variable volume air-handling systems. Dry-bulb or enthalpy controlled economizer cycles should be considered for reducing energy costs.

When an economizer cycle is used, systems should be zoned so that energy waste will not occur due to heating of outside air. This is often accomplished by a separate air distribution system for the interior and each major exterior zone.

High-rise office buildings have traditionally used perimeter dual-duct, induction, or fan-coil systems. Where fan-coil or induction systems have been installed at the perimeter, separate all-air systems have generally been used for the interior. More recently, variable air volume systems, including modulated air diffusers and self-contained perimeter unit systems, have also been used. If variable air volume systems serve the interior, perimeters are usually served by variable volume or dual-duct systems supplemented with fan-powered terminals, terminals with reheat coils, or radiation (ceiling panels or baseboard). The perimeter systems can be hydronic or electric.

Many office buildings without an economizer cycle have a bypass multizone unit installed on each floor or several floors with a heating coil in each exterior zone duct. Variable air volume variations of the bypass multizone and other floor-by-floor, all-air systems are also being used. These systems are popular due to low fan power, low initial cost, and energy savings resulting from independent operating schedules, which are possible between floors occupied by tenants with different operating hours.

Perimeter radiation or infrared systems with conventional, single-duct, low-velocity air conditioning that furnishes air from packaged air-conditioning units or multizone units may be more economical for small office buildings. The need for a perimeter system, which is a function of exterior glass percentage, external wall thermal value, and climate severity, should be carefully analyzed.

A perimeter heating system separate from the cooling system is preferable, since air distribution devices can then be selected for a specific duty rather than as a compromise between heating and cooling performance. The higher cost of additional air-handling or fan-coil units and ductwork may lead the designer to a less expensive option, such as fan-powered terminal units with heating coils serving perimeter zones in lieu of a separate heating system. Radiant ceiling panels for the perimeter zones are another option.

Interior space usage usually requires that interior air-conditioning systems permit modification to handle all load situations. Variable air volume systems are often used. When using these systems, a careful evaluation of low-load conditions should be made to determine whether adequate air movement and outdoor air can be provided at the proposed supply air temperature without overcooling. Increases in supply air temperature tend to nullify energy savings in fan power, which are characteristic of variable air volume systems. Low-temperature air distribution for additional savings in transport energy is seeing increased use, especially when coupled with an ice storage system.

In small to medium-sized office buildings, air-source heat pumps may be chosen. In larger buildings, internal source heat pump systems (water-to-water) are feasible with most types of air-conditioning systems. Heat removed from core areas is rejected to either a cooling tower or perimeter circuits. The internal source heat pump can be supplemented by a central heating system or electrical coils on extremely cold days or over extended periods of limited occupancy. Removed excess heat may also be stored in hot water tanks.

Many heat recovery or internal source heat pump systems exhaust air from conditioned spaces through lighting fixtures. Approximately 30% of lighting heat can be removed in this manner. One design advantage is a reduction in required air quantities. In addition, lamp life is extended by operation in a much cooler ambient environment.

Suspended ceiling return air plenums eliminate sheet metal return air ductwork to reduce floor-to-floor height requirements. However, suspended ceiling plenums may increase the difficulty of proper air balancing throughout the building. Problems often connected with suspended ceiling return plenums are as follows:

- Air leakage through cracks, with resulting smudges
- Tendency of return air openings nearest to a shaft opening or collector duct to pull too much air, thus creating uneven air motion and possible noise
- Noise transmission between office spaces

Air leakage can be minimized by proper workmanship. To overcome drawing too much air, return air ducts can be run in the suspended ceiling pathway from the shaft, often in a simple radial pattern. The ends of the ducts can be left open or dampered. Generous sizing of return air grilles and passages lowers the percentage of circuit resistance attributable to the return air path. This bolsters effectiveness of supply air balancing devices and reduces the significance of air leakage and drawing too much air. Structural blockage can be solved by locating openings in beams or partitions with fire dampers, where required.

Spatial Requirements

Total office building electromechanical space requirements vary tremendously based on types of systems planned; however, the average is approximately 8 to 10% of the gross area. Clear height required for fan rooms varies from approximately 3 to 5.5 m, depending on the distribution system and equipment complexity. On office floors, perimeter fan-coil or induction units require approximately 1 to 3% of the floor area. Interior air shafts and pipe chases require approximately 3 to 5% of the floor area. Therefore, ducts, pipes, and equipment require approximately 4 to 8% of each floor's gross area.

Where large central units supply multiple floors, shaft space requirements depend on the number of fan rooms. In such cases, one mechanical equipment room usually furnishes air requirements for 8 to 20 floors (above and below for intermediate levels), with an average of 12 floors. The more floors served, the larger the duct shafts and equipment required. This results in higher fan room heights and greater equipment size and mass.

The fewer floors served by an equipment room, the more equipment rooms will be required to serve the building. This axiom allows greater flexibility in serving changing floor or tenant requirements. Often, one mechanical equipment room per floor and complete elimination of vertical shafts requires no more total floor area than a few larger mechanical equipment rooms, especially when there are many small rooms and they are the same height as typical floors. Equipment can also be smaller, although maintenance costs will be higher. Energy costs may be reduced, with more equipment rooms serving fewer areas, because the equipment can be shut off in unoccupied areas, and high-pressure ductwork will not be required. Equipment rooms on upper levels generally cost more to install because of rigging and transportation logistics.

In all cases, mechanical equipment rooms must be thermally and acoustically isolated from office areas.

Cooling Towers. Cooling towers are the largest single piece of equipment required for air-conditioning systems. Cooling towers require approximately 1 m^2 of floor area per 400 m^2 of total building

area and are from 4 to 12 m high. When towers are located on the roof, the building structure must be capable of supporting the cooling tower and dunnage, full water load (approximately 590 to 730 kg/m^2), and seismic and wind load stresses.

Where cooling tower noise may affect neighboring buildings, towers should be designed to include sound traps or other suitable noise baffles. This may affect tower space, mass of the units, and motor power. Slightly oversizing cooling towers can reduce noise and power consumption due to lower speeds, but this may increase the initial cost.

Cooling towers are sometimes enclosed in a decorative screen for aesthetic reasons; therefore, calculations should ascertain that the screen has sufficient free area for the tower to obtain its required air quantity and to prevent recirculation.

If the tower is placed in a rooftop well or near a wall, or split into several towers at various locations, design becomes more complicated, and initial and operating costs increase substantially. Also, towers should not be split and placed on different levels because hydraulic problems increase. Finally, the cooling tower should be built high enough above the roof so that the bottom of the tower and the roof can be maintained properly.

Special Considerations

Office building areas with special ventilation and cooling requirements include elevator machine rooms, electrical and telephone closets, electrical switchgear, plumbing rooms, refrigeration rooms, and mechanical equipment rooms. The high heat loads in some of these rooms may require air-conditioning units for spot cooling.

In larger buildings having intermediate elevator, mechanical, and electrical machine rooms, it is desirable to have these rooms on the same level or possibly on two levels. This may simplify the horizontal ductwork, piping, and conduit distribution systems and permit more effective ventilation and maintenance of these equipment rooms.

An air-conditioning system cannot prevent occupants at the perimeter from feeling direct sunlight. Venetian blinds and drapes are often provided but seldom used. External shading devices (screens, overhangs, etc.) or reflective glass are preferable.

Tall buildings in cold climates experience severe stack effect. The extra amount of heat provided by the air-conditioning system in attempts to overcome this problem can be substantial. The following features help combat infiltration due to the stack effect:

- Revolving doors or vestibules at exterior entrances
- Pressurized lobbies or lower floors
- Tight gaskets on stairwell doors leading to the roof
- Automatic dampers on elevator shaft vents
- Tight construction of the exterior skin
- Tight closure and seals on all dampers opening to the exterior

BOWLING CENTERS

Bowling centers may also contain a bar, a restaurant, a children's play area, offices, locker rooms, and other types of facilities. Such auxiliary areas are not discussed in this section, except as they may affect design for the bowling area, which consists of alleys and a spectator area.

Load Characteristics

Bowling alleys usually have their greatest period of use in the evenings, but weekend daytime use may also be heavy. Thus, when designing for the peak air-conditioning load on the building, it is necessary to compare the day load and its high outside solar load and off-peak people load with the evening peak people load and zero solar load. Because bowling areas generally have little fenestration, the solar load may not be important.

If the building contains auxiliary areas, these areas may be included in the refrigeration, heating, and air distribution systems for the bowling alleys, with suitable provisions for zoning the different areas as dictated by load analysis. Alternatively, separate systems may be established for each area having different load operation characteristics.

Heat buildup due to lights, external transmission load, and pin-setting machinery in front of the foul line can be reduced by exhausting some air above the alleys or from the area containing the pin-setting machines; however, this gain should be compared against the cost of conditioning additional makeup air. In the calculation of the air-conditioning load, a portion of the unoccupied alley space load is included. Because this consists mainly of lights and some transmission load, about 15 to 30% of this heat load may have to be taken into account. The higher figure may apply when the roof is poorly insulated, no exhaust air is taken from this area, or no vertical baffle is used at the foul line. One estimate is 16 to 32 W per square metre of vertical surface at the foul line, depending mostly on the type and intensity of the lighting.

The heat load from bowlers and spectators may be found in Table 3 in Chapter 28 of the 1997 *ASHRAE Handbook—Fundamentals*. The proper heat gain should be applied for each person to avoid too large a design heat load.

Design Concepts

As with other building types having high occupancy loads, heavy smoke and odor concentration, and low sensible heat factors, all-air systems are generally the most suitable for bowling alley areas. Since most bowling alleys are almost windowless structures except for such areas as entrances, exterior restaurants, and bars, it is uneconomical to use terminal unit systems because of the small number required. Where required, radiation in the form of baseboard or radiant ceiling panels is generally placed at perimeter walls and entrances.

It is not necessary to maintain normal indoor temperatures down the length of the alleys; temperatures may be graded down to the pin area. Unit heaters are often used at this location.

Air Pressurization. Spectator and bowling areas must be well shielded from entrances so that no cold drafts are created in these areas. To minimize infiltration of outdoor air into the alleys, the exhaust and return air system should handle only 85 to 90% of the total supply air, thus maintaining a positive pressure within the space when outside air pressurization is taken into consideration.

Air Distribution. Packaged units without ductwork produce uneven space temperatures, and unless they are carefully located and installed, the units may cause objectionable drafts. Central ductwork is recommended for all but the smallest buildings, even where packaged refrigeration units are used. Because only the areas behind the foul line are air conditioned, the ductwork should provide comfortable conditions within this area.

The return and exhaust air systems should have a large number of small registers uniformly located at high points, or pockets, to draw off the hot, smoky, and odorous air. In some parts of the country and for larger bowling alleys, it may be desirable to use all outdoor air to cool during intermediate seasons.

Special Considerations

People in sports and amusement centers engage in a high degree of physical activity, which makes them feel warmer and increases their rate of evaporation. In these places, odor and smoke control are important environmental considerations.

Bowling centers are characterized by the following:

- A large number of people concentrated in a relatively small area of a very large room. A major portion of the floor area is unoccupied.
- Heavy smoking, high physical activity, and high latent heat load.
- Greatest use from about 6:00 P.M. to midnight.

The first two items make furnishing large amounts of outdoor air mandatory to minimize odors and smoke in the atmosphere.

The area between the foul line and the bowling pins need not be air conditioned or ventilated. Transparent or opaque vertical partitions are sometimes installed to separate the upper portions of the occupied and unoccupied areas so that air distribution is better contained within the occupied area.

COMMUNICATION CENTERS

Communication centers include telephone terminal buildings, radio stations, television studios, and transmitter and receiver stations. Most telephone terminal rooms are air conditioned because constant temperature and relative humidity help prevent breakdowns and increase equipment life. In addition, air conditioning permits the use of a lower number of air changes, which, for a given filter efficiency, decreases the chances of damage to relay contacts and other delicate equipment.

Radio and television studios require critical analysis for the elimination of heat buildup and the control of noise. Television studios have the added problem of air movement, lighting, and occupancy load variations. This section deals with television studios because they present most of the problems also found in radio studios.

Load Characteristics

Human occupancy is limited, so the air-conditioning load for telephone terminal rooms is primarily equipment heat load.

Television studios have very high lighting capacities, and the lighting load may fluctuate considerably in intensity over short periods. The operating hours may vary every day. In addition, there may be from one to several dozen people onstage for short times. The air-conditioning system must be extremely flexible and capable of handling wide load variations quickly, accurately, and efficiently, similar to the conditions of a theater stage. The studio may also have an assembly area with a large number of spectator seats. Generally, studios are located so that they are completely shielded from external noise and thermal environments.

Design Concepts

The critical areas of a television studio are the performance studio and control rooms. The audience area may be treated much like a place of assembly. Each area should have its own air distribution system or at least its own zone control separate from the studio system. The heat generated in the studio area should not be allowed to permeate the audience atmosphere.

The air distribution system selected must have the capabilities of a dual-duct, single-duct system with cooling and heating booster coils, a variable air volume systems, or a multizone system to satisfy design criteria. The air distribution system should be designed so that simultaneous heating and cooling cannot occur unless heating is achieved solely by heat recovery.

Studio loads seldom exceed 350 kW of refrigeration. Even if the studio is part of a large communications center or building, the studio should have its own refrigeration system in case of emergencies. The refrigeration equipment in this size range may be reciprocating units, which require a remote location so that machine noise is isolated from the studio.

Special Considerations

On-Camera Studios. This is the stage of the television studio and requires the same general considerations as a concert hall stage. Air movement must be uniform, and, because scenery, cameras, and equipment may be moved during the performance, ductwork must be planned carefully to avoid interference with proper studio operation.

Control Rooms. Each studio may have one or more control rooms serving different functions. The video control room, which is occupied by the program and technical directors, contains monitors and picture-effect controls. The room may require up to 30 air changes per hour to maintain proper conditions. The large number of necessary air changes and the low sound level that must be maintained require special analysis of the air distribution system.

If a separate control room is furnished for the announcer, the heat load and air distribution problems will not be as critical as those for control rooms for the program, technical, and audio directors.

Thermostatic control should be furnished in each control room, and provisions should be made to enable occupants to turn the air conditioning on and off.

Noise Control. Studio microphones are moved throughout the studio during a performance, and they may be moved past or set near air outlets or returns. These microphones are considerably more sensitive than the human ear; therefore, air outlets or returns should be located away from areas where microphones are likely to be used. Even a leaky pneumatic thermostat can be a problem.

Air Movement. It is essential that air movement within the stage area, which often contains scenery and people, be kept below 0.13 m/s within 3.7 m of the floor. The scenery is often fragile and will move in air velocities above 0.13 m/s; also, actors' hair and clothing may be disturbed.

Air Distribution. Ductwork must be fabricated and installed so that there are no rough edges, poor turns, or improperly installed dampers to cause turbulence and eddy currents within the ducts. Ductwork should contain no holes or openings that might create whistles. Air outlet locations and the distribution pattern must be carefully analyzed to eliminate turbulence and eddy currents within the studio that might cause noise that could be picked up by studio microphones.

At least some portions of supply, return, and exhaust ductwork will require acoustical material to maintain noise criterion (NC) levels from 20 to 25. Any duct serving more than one room should acoustically separate each room by means of a sound trap. All ductwork should be suspended by means of neoprene or rubber in shear-type vibration mountings. Where ductwork goes through wall or floor slabs, the openings should be sealed with acoustically deadening material. The supply fan discharge and the return and exhaust fan inlets should have sound traps; all ductwork connections to fans should be made with nonmetallic, flexible material. Air outlet locations should be coordinated with ceiling-mounted tracks and equipment. Air distribution for control rooms may require a perforated ceiling outlet or return air plenum system.

Piping Distribution. All piping within the studio, as well as in adjacent areas that might transmit noise to the studio, should be supported by suitable vibration isolation hangers. To prevent transmission of vibration, piping should be supported from rigid structural elements to maximize absorption.

Mechanical Equipment Rooms. These rooms should be located as remotely from the studio as possible. All equipment should be selected for very quiet operation and should be mounted on suitable vibration-eliminating supports. Structural separation of these rooms from the studio is generally required.

Offices and Dressing Rooms. The functions of these rooms are quite different from each other and from the studio areas. It is recommended that such rooms be treated as separate zones, with their own controls.

Air Return. Whenever practicable, the largest portion of studio air should be returned over the banks of lights. This is similar to theater stage practice. Sufficient air should also be removed from studio high points to prevent heat buildup.

TRANSPORTATION CENTERS

The major transportation facilities are airports, ship docks, bus terminals, and passenger car garages. Airplane hangars and freight and mail buildings are also among the types of buildings

to be considered. Freight and mail buildings are usually handled as standard warehouses.

Load Characteristics

Airports, ship docks, and bus terminals operate on a 24 h basis, with a reduced schedule during late night and early morning hours.

Airports. Terminal buildings consist of large, open circulating areas, one or more floors high, often with high ceilings, ticketing counters, and various types of stores, concessions, and convenience facilities. Lighting and equipment loads are generally average, but occupancy varies substantially. Exterior loads are, of course, a function of architectural design. The largest single problem often results from thermal drafts created by large entranceways, high ceilings, and long passageways, which have many openings to the outdoors.

Ship Docks. Freight and passenger docks consist of large, high-ceilinged structures with separate areas for administration, visitors, passengers, cargo storage, and work. The floor of the dock is usually exposed to the outdoors just above the water level. Portions of the side walls are often open while ships are in port. In addition, the large ceiling (roof) area presents a large heating and cooling load. Load characteristics of passenger dock terminals generally require the roof and floors to be well insulated. Occasional heavy occupancy loads in visitor and passenger areas must be considered.

Bus Terminals. This building type consists of two general areas: the terminal building, which contains passenger circulation, ticket booths, and stores or concessions, and the bus loading area. Waiting rooms and passenger concourse areas are subject to a highly variable people load. Occupancy density may reach 1 m^2 per person and, at extreme periods, 0.3 to 0.5 m^2 per person. Chapter 12, Enclosed Vehicular Facilities, has further information on bus terminals.

Design Concepts

Heating and cooling is generally centralized or provided for each building or group in a complex. In large, open circulation areas of transportation centers, any all-air system with zone control can be used. Where ceilings are high, air distribution is often along the side wall to concentrate the air conditioning where desired and avoid disturbing stratified air. Perimeter areas may require heating by radiation, a fan-coil system, or hot air blown up from the sill or floor grilles, particularly in colder climates. Hydronic perimeter radiant ceiling panels may be especially suited to these high-load areas.

Airports. Airports generally consist of one or more central terminal buildings connected by long passageways or trains to rotundas containing departure lounges for airplane loading. Most terminals have portable telescoping-type loading bridges connecting departure lounges to the airplanes. These passageways eliminate the heating and cooling problems associated with traditional permanent structure passenger loading.

Because of difficulties in controlling the air balance due to the many outside openings, high ceilings, and long, low passageways (which often are not air conditioned), the terminal building (usually air conditioned) should be designed to maintain a substantial positive pressure. Zoning is generally required in passenger waiting areas, in departure lounges, and at ticket counters to take care of the widely variable occupancy loads.

Main entrances may be designed with vestibules and windbreaker partitions to minimize undesirable air currents within the building.

Hangars must be heated in cold weather, and ventilation may be required to eliminate possible fumes (although fueling is seldom permitted in hangars). Gas-fired, electric, and low- and high-intensity radiant heaters are used extensively in hangars because they provide comfort for employees at relatively low operating costs.

Hangars may also be heated by large air blast heaters or floor-buried heated liquid coils. Local exhaust air systems may be used to evacuate fumes and odors that result in smaller ducted systems. Under some conditions, exhaust systems may be portable and may possibly include odor-absorbing devices.

Ship Docks. In severe climates, occupied floor areas may contain heated floor panels. The roof should be well insulated, and, in appropriate climates, evaporative spray cooling substantially reduces the summer load. Freight docks are usually heated and well ventilated but seldom cooled.

High ceilings and openings to the outdoors may present serious draft problems unless the systems are designed properly. Vestibule entrances or air curtains help minimize cross drafts. Air door blast heaters at cargo opening areas may be quite effective.

Ventilation of the dock terminal should prevent noxious fumes and odors from reaching occupied areas. Therefore, occupied areas should be under positive pressure, and the cargo and storage areas exhausted to maintain negative air pressure. Occupied areas should be enclosed to simplify any local air conditioning.

In many respects, these are among the most difficult buildings to heat and cool because of their large open areas. If each function is properly enclosed, any commonly used all-air or large fan-coil system is suitable. If areas are left largely open, the best approach is to concentrate on proper building design and heating and cooling of the openings. High-intensity infrared spot heating is often advantageous (see Chapter 15 of the 2000 *ASHRAE Handbook—Systems and Equipment*). Exhaust ventilation from tow truck and cargo areas should be exhausted through the roof of the dock terminal.

Bus Terminals. Conditions are similar to those for airport terminals, except that all-air systems are more practical because ceiling heights are often lower, and perimeters are usually flanked by stores or office areas. The same systems are applicable as for airport terminals, but ceiling air distribution is generally feasible.

Properly designed radiant hydronic or electric ceiling systems may be used if high-occupancy latent loads are fully considered. This may result in smaller duct sizes than are required for all-air systems and may be advantageous where bus loading areas are above the terminal and require structural beams. This heating and cooling system reduces the volume of the building that must be conditioned. In areas where latent load is a concern, heating-only panels may be used at the perimeter, with a cooling-only interior system.

The terminal area air supply system should be under high positive pressure to ensure that no fumes and odors infiltrate from bus areas. Positive exhaust from bus loading areas is essential for a properly operating total system (see Chapter 12).

Special Considerations

Airports. Filtering outdoor air with activated charcoal filters should be considered for areas subject to excessive noxious fumes from jet engine exhausts. However, locating outside air intakes as remotely as possible from airplanes is a less expensive and more positive approach.

Where ionization filtration enhancers are used, outdoor air quantities are sometimes reduced due to cleaner air. However, care must be taken to maintain sufficient amounts of outside air for space pressurization.

Ship Docks. Ventilation design must ensure that fumes and odors from forklifts and cargo in work areas do not penetrate occupied and administrative areas.

Bus Terminals. The primary concerns with enclosed bus loading areas are health and safety problems, which must be handled by proper ventilation (see Chapter 12). Although diesel engine fumes are generally not as noxious as gasoline fumes, bus terminals often have many buses loading and unloading at the same time, and the total amount of fumes and odors may be quite disturbing.

Enclosed Garages. In terms of health and safety, enclosed bus loading areas and automobile parking garages present the most serious problems in these buildings. Three major problems are encountered. The first and most serious is emission of carbon monoxide (CO) by cars and oxides of nitrogen by buses, which can

cause serious illness and possibly death. The second problem is oil and gasoline fumes, which may cause nausea and headaches and can also create a fire hazard. The third is lack of air movement and the resulting stale atmosphere that develops because of the increased carbon dioxide content in the air. This condition may cause headaches or grogginess. Most codes require a minimum ventilation rate to ensure that the CO concentration does not exceed safe limits. Chapter 12 covers the ventilation requirements and calculation procedures for enclosed vehicular facilities in detail.

All underground garages should have facilities for testing the CO concentration or should have the garage checked periodically. Clogged duct systems; improperly operating fans, motors, or dampers; clogged air intake or exhaust louvers, etc., may not allow proper air circulation. Proper maintenance is required to minimize any operational defects.

WAREHOUSES

Warehouses are used to store merchandise and may be open to the public at times. They are also used to store equipment and material inventory at industrial facilities. The buildings are generally not air conditioned, but often have sufficient heat and ventilation to provide a tolerable working environment. Facilities such as shipping, receiving, and inventory control offices associated with warehouses and occupied by office workers are generally air conditioned.

Load Characteristics

Internal loads from lighting, people, and miscellaneous sources are generally low. Most of the load is thermal transmission and infiltration. An air-conditioning load profile tends to flatten where materials stored are massive enough to cause the peak load to lag.

Design Concepts

Most warehouses are only heated and ventilated. Forced flow unit heaters may be located near heat entrances and work areas. Large central heating and ventilating units are widely used. Even though comfort for warehouse workers may not be considered, it may be necessary to keep the temperature above 4°C to protect sprinkler piping or stored materials from freezing.

A building designed for the addition of air conditioning at a later date will require less heating and be more comfortable. For maximum summer comfort without air conditioning, excellent ventilation with noticeable air movement in work areas is necessary. Even greater comfort can be achieved in appropriate climates by adding roof spray cooling. This can reduce the roof's surface temperature by 20 to 30 K, thereby reducing ceiling radiation inside. Low- and high-intensity radiant heaters can be used to maintain the minimum ambient temperature throughout a facility above freezing. Radiant heat may also be used for occupant comfort in areas permanently or frequently open to the outside.

If the stored product requires defined indoor conditions, an air-conditioning system must be added. Using only ventilation may help in maintaining lower space temperature, but caution should be exercised not to damage the stored product with uncontrolled humidity. Direct or indirect evaporative cooling may also be an option.

Special Considerations

Forklifts and trucks powered by gasoline, propane, and other fuels are often used inside warehouses. Proper ventilation is necessary to alleviate the buildup of CO and other noxious fumes. Proper ventilation of battery-charging rooms for electrically powered forklifts and trucks is also required.

CHAPTER 4

PLACES OF ASSEMBLY

General Criteria 4.1
Houses of Worship 4.3
Auditoriums 4.3
Arenas and Stadiums 4.4
Convention and Exhibition Centers 4.5
Natatoriums 4.5
Fairs and Other Temporary Exhibits 4.7
Atriums 4.8

ASSEMBLY rooms are generally large, have relatively high ceilings, and are few in number for any given facility. They usually have a periodically high density of occupancy per unit floor area, as compared to other buildings, and thus have a relatively low design sensible heat ratio.

This chapter summarizes some of the design concerns for enclosed assembly buildings. (Chapter 3, which covers general criteria for commercial and public buildings, also includes information that applies to public assembly buildings.)

GENERAL CRITERIA

Energy conservation codes and standards must be considered because they have a major impact on design and performance.

Assembly buildings may have relatively few hours of use per week and may not be in full use when maximum outdoor temperatures or solar loading occur. Often they are fully occupied for as little as 1 to 2 h, and the load may be materially reduced by precooling. The designer needs to obtain as much information as possible regarding the anticipated hours of use, particularly the times of full seating, so that simultaneous loads may be considered to obtain optimum performance and operating economy. Dehumidification requirements should be considered before reducing equipment size. The intermittent or infrequent nature of the cooling loads may allow these buildings to benefit from thermal storage systems.

The occupants usually generate the major room cooling and ventilation load. The number of occupants is best determined from the seat count, but when this is not available, it can be estimated at 0.7 to 0.9 m^2 per person for the entire seating area, including exit aisles but not the stage, performance areas, or entrance lobbies.

Outdoor Air

Outdoor air ventilation rates as prescribed by ASHRAE *Standard* 62 can be a major portion of the total load. The latent load (dehumidification and humidification) and energy used to maintain the relative humidity within prescribed limits is also a concern. Humidity must be maintained at proper levels to prevent mold and mildew growth and to maintain acceptable indoor air quality and comfort.

Lighting Loads

Lighting loads are one of the few major loads that vary from one type of assembly building to another. Lighting may be at the level of 1600 lux in convention halls where color television cameras are expected to be used, or lighting may be virtually absent, as in a movie theater. In many assembly buildings, lights are controlled by dimmers or other means to present a suitably low level of light during performances, with much higher lighting levels during cleanup, when the house is nearly empty. The designer should ascertain what light levels will be associated with maximum occupancies, not only in the interest of economy but also to determine the proper room sensible heat ratio.

The preparation of this chapter is assigned to TC 9.8, Large Building Air-Conditioning Applications.

Indoor Air Conditions

Indoor air temperature and humidity should follow the ASHRAE comfort recommendations (see Chapter 8 of the 1997 *ASHRAE Handbook—Fundamentals* and ASHRAE *Standard* 55). In addition, the following should be considered:

1. In arenas, stadiums, gymnasiums, and movie theaters, people generally dress informally. Summer indoor conditions may favor the warmer end of the thermal comfort scale while the winter indoor temperature may favor the cooler end of the scale.
2. In churches, concert halls, and theaters, most men wear jackets and ties and women often wear suits. The temperature should favor the middle range of design, and there should be little summer-to-winter variation.
3. In convention and exhibition centers, the public is continually walking. Here the indoor temperature should favor the lower range of comfort conditions both in summer and in winter.
4. In spaces with a high population density or with a sensible heat factor of 0.75 or less, a lower dry-bulb temperature reduces the latent heat load from people, thus saving energy by reducing the need for reheat.

1. Energy conservation codes must be considered in both the design and during operation.

Assembly areas generally require some reheat to maintain the relative humidity at a suitably low level during periods of maximum occupancy. Refrigerant hot gas or condenser water is well suited for this purpose. Face and bypass control of low-temperature cooling coils is also effective. In colder climates, it may also be desirable to provide humidification. High rates of internal gain may make evaporative humidification attractive during economizer cooling.

Filtration

Most places of assembly are minimally filtered with filters rated at 30 to 35% efficiency, as tested in accordance with ASHRAE *Standard* 52.1. Where smoking is permitted, however, filters with a minimum rating of 80% are required to remove tobacco smoke effectively. Filters with 80% or higher efficiency are also recommended for those facilities having particularly expensive interior decor. Because of the few operating hours of these facilities, the added expense of higher efficiency filters can be justified by their longer life. Low-efficiency prefilters are generally used with high-efficiency filters to extend their useful life. Ionization and chemically reactive filters should be considered where high concentrations of smoke or odors are present.

Noise and Vibration Control

The desired noise criteria (NC) vary with the type and quality of the facility. The need for noise control may be minimal in a gymnasium or natatorium, but it is important in a concert hall. Facilities that are used for varied functions require noise control evaluation over the entire spectrum of use.

In most cases, sound and vibration control is required for both equipment and duct systems, as well as in the selection of diffusers and grilles. When designing for a theater or concert hall, an

experienced acoustics engineer should be consulted. In these projects, the quantity and quality or characteristic of the noise is very important.

Transmission of vibration and noise can be decreased by mounting pipes, ducts, and equipment on a separate structure independent of the music hall. If the mechanical equipment space is close to the music hall, the entire mechanical equipment room may need to be floated on isolators, including the floor slab, structural floor members, and other structural elements such as supporting pipes or similar materials that can carry vibrations. Properly designed inertia pads are often used under each piece of equipment. The equipment is then mounted on vibration isolators.

Manufacturers of vibration isolating equipment have devised methods to float large rooms and entire buildings on isolators. Where subway and street noise may be carried into the structure of a music hall, it is necessary to float the entire music hall on isolators. If the music hall is isolated from outside noise and vibration, it also must be isolated from mechanical equipment and other internal noise and vibrations.

External noise from mechanical equipment such as cooling towers should not enter the building. Care should be taken to avoid designs that permit noises to enter the space through air intakes or reliefs and carelessly designed duct systems.

Ancillary Facilities

Ancillary facilities are generally a part of any assembly building; almost all have some office space. Convention centers and many auditoriums, arenas, and stadiums have restaurants and cocktail lounges. Churches may have apartments for the clergy or a school. Many facilities have parking structures. These varied ancillary facilities are discussed in other chapters of this volume. However, for reasonable operating economy, these facilities should be served by separate systems when their hours of use differ from those of the main assembly areas.

Air Conditioning

Because of their characteristic large size and need for considerable ventilation air, assembly buildings are frequently served by single-zone or variable-volume systems providing 100% outdoor air. Separate air-handling units usually serve each zone, although multizone, dual-duct, or reheat types can also be applied with lower operating efficiency. In larger facilities, separate zones are generally provided for the entrance lobbies and arterial corridors that surround the seating space. Low intensity radiant heating is often an efficient alternative. In some assembly rooms, folding or rolling partitions divide the space for different functions, so that a separate zone of control for each resultant space is best. In extremely large facilities, several air-handling systems may serve a single space, due to the limits of equipment size and also for energy and demand considerations.

Precooling

Cooling the building mass several degrees below the desired indoor temperature several hours before it is occupied allows it to absorb a portion of the peak heat load. This cooling reduces the equipment size needed to meet short-term loads. The effect can be used if cooling time of at least one hour is available prior to occupancy, and then only when the period of peak load is relatively short (2 h or less).

The designer must advise the owner that the space temperature will be cold to most people as occupancy begins, but that it will warm up as the performance progresses. This may be satisfactory, but it should be understood by all concerned before proceeding with a precooling concept. Precooling is best applied when the space is used only occasionally during the hotter part of the day and when provision of full capacity for an occasional purpose is not economically justifiable.

Stratification

Because most assembly buildings relatively high ceilings, some heat may stratify above the occupied zone, thereby reducing the load on the equipment. Heat from lights can be stratified, except for the radiant portion (about 50% for fluorescent and 65% for incandescent or mercury-vapor fixtures). Similarly, only the radiant effect of the upper wall and roof load (about 33%) reaches the occupied space. Stratification only occurs when air is admitted and returned at a sufficiently low elevation so that it does not mix with the upper air. Conversely, stratification may increase heating loads during periods of minimal occupancy in winter months. In these cases, ceiling fans, air-handling systems, or high/low air distribution may be desirable to reduce stratification. Balconies may also be affected by stratification and should be well ventilated.

Air Distribution

In assembly buildings, people generally remain in one place throughout a performance, so they cannot avoid drafts. Therefore, good air distribution is essential.

Heating is seldom a major problem, except at entrances or during warm-up prior to occupancy. Generally, the seating area is isolated from the exterior by lobbies, corridors, and other ancillary spaces. For cooling, air can be supplied from the overhead space, where it mixes with heat from the lights and occupants. Return air openings can also aid air distribution. Air returns located below seating or at a low level around the seating can effectively distribute air with minimum drafts. For returns located below the seats, register velocities in excess of 1.4 m/s may cause objectionable drafts and noise.

Because of the configuration of these spaces, supply jet nozzles with long throws of 15 to 45 m may need to be installed on sidewalls. For ceiling distribution, downward throw is not critical provided returns are low. This approach has been successful in applications that are not particularly noise-sensitive, but the designer needs to select air distribution nozzles carefully.

The air-conditioning systems must be quiet. This is difficult to achieve if the supply air is expected to travel 9 m or more from sidewall outlets to condition the center of the seating area. Due to the large size of most houses of worship, theaters, and halls, high air discharge velocities from the wall outlets are required. These high velocities can produce objectionable noise levels for people sitting near the outlets. This can be avoided if the return air system does some of the work. The supply air must be discharged from the air outlet (preferably at the ceiling) at the highest velocity consistent with an acceptable noise level. Although this velocity does not allow the conditioned air to reach all seats, the return air registers, which are located near seats not reached by the conditioned air, pull the air to cool or heat the audience, as required. In this way, the supply air blankets the seating area and is pulled down uniformly by the return air registers under or beside the seats.

A certain amount of exhaust air should be taken from the ceiling of the seating area, preferably over the balcony (if there is one) to prevent pockets of hot air, which can produce a radiant effect and cause discomfort, as well as increase the cost of air conditioning. Where the ceiling is close to the audience (e.g., below balconies and mezzanines), specially designed plaques or air-distributing ceilings should be provided to absorb noise.

Regular ceiling diffusers placed more than 9 m apart normally give acceptable results if careful engineering is applied in the selection of the diffusers. Because large air quantities are generally involved and because the building is large, fairly large capacity diffusers, which tend to be noisy, are frequently selected. Linear diffusers are more acceptable architecturally and perform well if selected properly. Integral dampers in diffusers should not be used as the only means of balancing because they generate intolerable amounts of noise, particularly in larger diffusers.

Mechanical Equipment Rooms

The location of mechanical and electrical equipment rooms affects the degree of sound attenuation treatment required. Mechanical equipment rooms located near the seating area are more critical because of the normal attenuation of sound through space. Mechanical equipment rooms located near the stage area are critical because the stage is designed to project sound to the audience. If possible, mechanical equipment rooms should be located in an area separated from the main seating or stage area by buffers such as lobbies or service areas. The economies of the structure, attenuation, equipment logistics, and site must be considered in the selection of locations for mechanical equipment rooms.

At least one mechanical equipment room is placed near the roof to house the toilet exhaust, general exhaust, cooling tower, kitchen, and emergency stage exhaust fans, if any. Individual roof-mounted exhaust fans may be used, thus eliminating the need for a mechanical equipment room. However, to reduce sound problems, mechanical equipment should not be located on the roof over the music hall or stage but rather over offices, storerooms, or auxiliary areas.

HOUSES OF WORSHIP

Houses of worship seldom have full or near-full occupancy more than once a week, but they have considerable use for smaller functions (meetings, weddings, funerals, christenings, or daycare) throughout the balance of the week. It is important to determine how and when the building will be used. When thermal storage is used, longer operation of equipment prior to occupancy may be required due to the high thermal mass of the structure. The seating capacity of houses of worship is usually well defined. Some houses of worship have a movable partition to form a single large auditorium for special holiday services. It is important to know how often this maximum use is expected.

Houses of worship test a designer's ingenuity in locating equipment and air diffusion devices in architecturally acceptable places. Because occupants are often seated, drafts and cold floors should be avoided. Many houses of worship have a high vaulted ceiling, which creates thermal stratification. Where stained glass is used, a shade coefficient equal to solar glass (SC = 0.70) is assumed.

Houses of worship may also have auxiliary rooms that should be air conditioned. To ensure privacy, sound transmission between adjacent areas should be considered in the air distribution scheme. Diversity in the total air-conditioning load requirements should be evaluated to take full advantage of the characteristics of each area.

In houses of worship, it is desirable to provide some degree of individual control for the platform, sacristy, and bema or choir area.

AUDITORIUMS

The types of auditoriums considered are movie theaters, playhouses, and concert halls. Auditoriums in schools and the large auditoriums in some convention centers may follow the same principles, with varying degrees of complexity.

Movie Theaters

Motion picture theaters are the simplest of the auditorium structures mentioned here. They run continuously for periods of 4 to 8 h or more and, thus, are not a good choice for precooling techniques, except for the first matinee peak. They operate frequently at low occupancy levels, and low-load performance must be considered.

Motion picture sound systems make noise control less important than it is in other kinds of theaters. The lobby and exit passageways in a motion picture theater are seldom densely occupied, although some light to moderate congestion can be expected for short times in the lobby area. A reasonable design for the lobby space is one person per 1.8 to 2.8 m^2.

The lights are usually dimmed when the house is occupied; full lighting intensity is used only during cleaning. A reasonable value for lamps above the seating area during a performance is 5 to 10% of the installed wattage. Designated smoking areas should be handled with separate exhaust or air-handling systems to avoid contamination of the entire facility.

Projection Booths. The projection booth represents the major problem in motion picture theater design. For large theaters using high-intensity lamps, projection room design must follow applicable building codes. If no building code applies, the projection equipment manufacturer usually has specific requirements. The projection room may be air conditioned, but it is normally exhausted or operated at negative pressure. Exhaust is normally taken through the housing of the projectors. Additional exhaust is required for the projectionist's sanitary facilities. Other heat sources include the sound and dimming equipment, which require a continuously controlled environment and necessitate a separate system.

Smaller theaters have fewer requirements for projection booths. It is a good idea to condition the projection room with filtered supply air to avoid soiling lenses. In addition to the projector light, heat sources in the projection room include the sound equipment, as well as the dimming equipment.

Legitimate Theaters

The legitimate theater differs from the motion picture theater in the following ways:

- Performances are seldom continuous. Where more than one performance occurs in a day, the performances are usually separated by a period of 2 to 4 h. Accordingly, precooling techniques are applicable, particularly for afternoon performances.
- Legitimate theaters seldom play to houses that are not full or near full.
- Legitimate theaters usually have intermissions, and the lobby areas are used for drinking and socializing. The intermissions are usually relatively short, seldom exceeding 15 to 20 min; however, the load may be as dense as one person per 0.5 m^2.
- Because sound amplification is less used than that in a motion picture theater, background noise control is more important.
- Stage lighting contributes considerably to the total cooling load in the legitimate theater. Lighting loads can vary from performance to performance.

Stages. The stage presents the most complex problem. It consists of the following loads:

- A heavy, mobile lighting load
- Intricate or delicate stage scenery, which varies from scene to scene and presents difficult air distribution requirements
- Actors, who may perform tasks that require exertion

Approximately 40 to 60% of the lighting load can be eliminated by exhausting air around the lights. This procedure works for lights around the proscenium. However, it is more difficult to place exhaust air ducts directly above lights over the stage because of the scenery and light drops. Careful coordination is required to achieve an effective and flexible layout.

Conditioned air should be introduced from the low side and back stages and returned or exhausted around the lights. Some exhaust air must be taken from the top of the tower directly over the stage containing lights and equipment (i.e., the fly). The air distribution design is further complicated because pieces of scenery may consist of light materials that flutter in the slightest air current. Even the vertical stack effect created by the heat from lights may cause this motion. Therefore, low air velocities are essential and air must be distributed over a wide area with numerous supply and return registers.

With multiple scenery changes, low supply or return registers from the floor of the stage are almost impossible to provide. However, some return air at the footlights and for the prompter should be considered. Air conditioning should also be provided for the stage manager and the control board areas.

One phenomenon encountered in many theaters with overhead flies is the billowing of the stage curtain when it is down. This situation is primarily due to the stack effect created by the height of the main stage tower, the heat from the lights, and the temperature difference between the stage and seating areas. Proper air distribution and balancing can minimize this phenomenon. Bypass damper arrangements with suitable fire protection devices may be feasible.

Loading docks adjacent to stages located in cold climates should be heated. The doors to these areas may be open for long periods, for example, while scenery is being loaded or unloaded for a performance.

On the stage, local code requirements must be followed for emergency exhaust ductwork or skylight (or blow-out hatch) requirements. These openings are often sizable and should be incorporated in the early design concepts.

Concert Halls

Concert halls and music halls are similar to legitimate theaters. They normally have a full stage, complete with fly gallery, and dressing areas for performers. Generally, the only differences between the two are in size and decor, with the concert hall usually being larger and more elaborately decorated.

Air-conditioning design must consider that the concert hall is used frequently for special charity and civic events, which may be preceded by or followed by parties (and may include dancing) in the lobby area. Concert halls often have cocktail lounge areas that become very crowded, with heavy smoking during intermissions. These areas should be equipped with flexible exhaust-recirculation systems. Concert halls may also have full restaurant facilities.

As in theatres, noise control is important. The design must avoid characterized or narrow-band noises in the level of audibility. Much of this noise is structure-borne, resulting from inadequate equipment and piping vibration isolation. An experienced acoustical engineer is essential for help in the design of these applications.

ARENAS AND STADIUMS

Functions at arenas and stadiums may be quite varied, so the air-conditioning loads will vary. Arenas and stadiums are not only used for sporting events such as basketball, ice hockey, boxing, and track meets but may also house circuses; rodeos; convocations; social affairs; meetings; rock concerts; car, cycle, and truck events; and special exhibitions such as home, industrial, animal, or sports shows. For multipurpose operations, the designer must provide systems having a high degree of flexibility. High-volume ventilation may be satisfactory in many instances, depending on load characteristics and outside air conditions.

Load Characteristics

Depending on the range of use, the load may vary from a very low sensible heat ratio for events such as boxing to a relatively high sensible heat ratio for industrial exhibitions. Multispeed fans often improve the performance at these two extremes and can aid in sound control for special events such as concerts or convocations. When using multispeed fans, the designer should consider the performance of the air distribution devices and cooling coils when the fan is operating at lower speeds.

Because total comfort cannot be ensured in an all-purpose facility, the designer must determine the level of discomfort that can be tolerated, or at least the type of performances for which the facility is primarily intended.

As with other assembly buildings, seating and lighting combinations are the most important load considerations. Boxing events, for example, may have the most seating, because the arena area is very small. For the same reason, however, the area that needs to be intensely illuminated is also small. Thus, boxing matches may represent the largest latent load situation. Other events that present large latent loads are rock concerts and large-scale dinner dances, although the audience at a rock concert is generally less concerned with thermal comfort. Ventilation is also essential in removing smoke or fumes at car, cycle, and truck events. Circuses, basketball, and hockey have a much larger arena area and less seating. The sensible load from lighting the arena area does improve the sensible heat ratio. The large expanse of ice in hockey games represents a considerable reduction in both latent and sensible loads. High latent loads caused by occupancy or ventilation can create severe problems in ice arenas such as condensation on interior surfaces and fog. Special attention should be paid to the ventilation system, air distribution, humidity control, and construction materials.

Enclosed Stadiums

An enclosed stadium may have either a retractable or a fixed roof. When the roof is closed, ventilation is needed, so ductwork must be run in the permanent sections of the stadium. The large air volumes required and the long air throws make proper air distribution difficult to achieve; thus, the distribution system must be very flexible and adjustable.

Some open stadiums have radiant heating coils in the floor slabs of the seating areas. Gas-fired or electric high- or low-intensity radiant heating located above the occupants is also used.

Open racetrack stadiums may present a ventilation problem if the grandstand is enclosed. The grandstand area may have multiple levels and be in the range of 400 m long and 60 m deep. The interior (ancillary) areas must be ventilated to control odors from toilet facilities, concessions, and the high population density. General practice provides about four air changes per hour for the stand seating area and exhausts the air through the rear of the service areas. More efficient ventilation systems may be selected if architectural considerations permit. Fogging of windows is a winter concern with glass-enclosed grandstands. This can be minimized by double glazing, humidity control, moving dry air across the glass, or a radiant heating system for perimeter glass areas.

Air-supported structures require the continuous operation of a fan to maintain a properly inflated condition. The possibility of condensation on the underside of the air bubble should be considered. The U-factor of the roof should be sufficient to prevent condensation at the lowest expected ambient temperature. Heating and air-conditioning functions can be either incorporated into the inflating system or furnished separately. Solar and radiation control is also possible through the structure's skin. Applications, though increasing rapidly, still require working closely with the enclosure manufacturer to achieve proper and integrated results.

Ancillary Spaces

The concourse areas of arenas and stadiums are heavily populated during entrance, exit, and intermission periods. Considerable odor is generated in these areas by food, drink, and smoke, requiring considerable ventilation. If energy conservation is an important factor, carbon filters and controllable recirculation rates should be considered. Concourse area air systems should be considered for their flexibility of returning or exhausting air. The economics of this type of flexibility should be evaluated with regard to the associated problem of air balance and freeze-up in cold climates.

Ticket offices, restaurants, and similar facilities are often expected to be open during hours that the main arena is closed; and, therefore, separate systems should be considered for these areas.

Locker rooms require little treatment other than excellent ventilation, usually not less than 10 to 15 L/s per square metre. To reduce the outdoor air load, excess air from the main arena or stadium may be transferred into the locker rooms. However, reheat or recooling by water or primary air should be considered to maintain the locker room temperature. To maintain proper air balance under all conditions, locker rooms should have separate supply and exhaust systems.

When an **ice rink** is designed into the facility, the concerns of groundwater conditions, site drainage, structural foundations, insulation, and waterproofing become even more important, with the potential of freezing of soil or fill under the floor and subsequent expansion. The rink floor may have to be strong enough to support heavy trucks. The floor insulation also must be strong enough to take this load. Ice-melting pits of sufficient size with steam pipes may have to be furnished. If the arena is to be air conditioned, the possibility of combining the air-conditioning system with the ice rink system may be analyzed. The designer should be aware that both systems operate at vastly different temperatures and may operate at different capacity levels at any given time. The radiant effects of the ice on the people and of the heat from the roof and lights on the ice must be considered in the design and operation of the system. Also, low air velocity at the floor is related to minimizing the refrigeration load. High air velocities will cause moisture to be drawn from the air by the ice sheet. Fog is caused by the uncontrolled introduction of airborne moisture through ventilation with warm, moist outside air and generally develops within the boarded area (playing area). Fog can be controlled by reducing outdoor air ventilation rates, using appropriate air velocities to bring the air in contact with the ice, and using a dehumidification system. Air-conditioning systems have limited impact on reducing the dew-point temperature sufficiently to prevent fog.

The type of lighting used over ice rinks must be carefully considered when precooling is used prior to hockey games and between periods. Main lights should be capable of being turned off, if feasible. Incandescent lights require no warm-up time and are more applicable than types requiring warm-up. Low emissivity ceilings with reflective characteristics successfully reduce condensation on roof structures; they also reduce lighting requirements.

Gymnasiums

Smaller gymnasiums, such as those found in school buildings, are miniature versions of arenas and often incorporate multipurpose features. For further information, see Chapter 6, Educational Facilities.

Many school gymnasiums are not air conditioned. Low-intensity perimeter radiant heaters with central ventilation supplying four to six air changes per hour are effective and energy efficient. Unit heaters located in the ceiling area are also effective. Ventilation must be provided due to the high activity levels and the resulting odors.

Most gymnasiums are located in schools. However, public and private organizations and health centers may also have gymnasiums. During the day, gymnasiums are usually used for physical activities, but in the evening and on weekends, they may be used for sports events, social affairs, or meetings. Thus, their activities fall within the scope of those of a civic center. More gymnasiums are being considered for air conditioning to make them more suitable for civic center activities.

The design criteria are similar to arenas and civic centers when used for nonstudent training activities. However, for schooltime use, space temperatures are often kept between 18 and 20°C during the heating season. Occupancy and the degree of activity during daytime use does not usually require high quantities of outdoor air, but if used for other functions, system flexibility is required.

CONVENTION AND EXHIBITION CENTERS

Convention-exhibition centers schedule diverse functions similar to those at arenas and stadiums and present a unique challenge to the designer. The center generally is a high-bay, long-span space. These centers can be changed weekly, for example, from an enormous computer room into a gigantic kitchen, large machine shop, department store, automobile showroom, or miniature zoo. They can also be the site of gala banquets or used as major convention meeting rooms.

The income earned by these facilities is directly affected by the time it takes to change from one activity to the next, so highly flexible utility distribution and air conditioning equipment are needed.

Ancillary facilities include restaurants, bars, concession stands, parking garages, offices, television broadcasting rooms, and multiple meeting rooms varying in capacity from small (10 to 20 people) to large (hundreds or thousands of people). Often, an appropriately sized full-scale auditorium or arena is also incorporated.

By their nature, these facilities are much too large and diverse in their use to be served by a single air-handling system. Multiple air handlers with several chillers can be economical.

Load Characteristics

The main exhibition room is subject to a variety of loads, depending on the type of activity in progress. Industrial shows provide the highest sensible loads, which may have a connected capacity of 215 W/m^2 along with one person per 3.7 to 4.6 m^2. Loads of this magnitude are seldom considered because large power-consuming equipment is seldom in continuous operation at full load. An adequate design accommodates (in addition to lighting load) about 108 W/m^2 and one person per 3.7 to 4.6 m^2 as a maximum continuous load.

Alternative loads that are very different in character may be encountered. When the main hall is used as a meeting room, the load will be much more latent in character. Thus, multispeed fans or variable volume systems may provide a better balance of load during these high latent, low sensible periods of use. The determination of accurate occupancy and usage information is critical in any plan to design and operate such a facility efficiently and effectively.

System Applicability

The main exhibition hall is normally handled by one or more all-air systems. This equipment should be capable of operating on all outdoor air, because during set-up time, the hall may contain a number of highway-size trucks bringing in or removing exhibit materials. There are also occasions when the space is used for equipment that produces an unusual amount of fumes or odors, such as restaurant or printing industry displays. It is helpful to build some flues into the structure to duct fumes directly to the outside. Perimeter radiant ceiling heaters have been successfully applied to exhibition halls with large expanses of glass.

Smaller meeting rooms are best conditioned with either individual room air handlers, or with variable volume central systems, because these rooms have high individual peak loads but are not used frequently. Constant volume systems of the dual- or single-duct reheat type waste considerable energy when serving empty rooms, unless special design features are incorporated.

Offices and restaurants often operate for many more hours than the meeting areas or exhibition areas and should be served separately. Storage areas can generally be conditioned by exhausting excess air from the main exhibit hall through these spaces.

NATATORIUMS

Environmental Control

A natatorium requires year-round humidity levels between 40 and 60% for comfort, energy consumption, and building protection. The designer must address the following concerns: humidity

control, ventilation requirements for air quality (outdoor and exhaust air), air distribution, duct design, pool water chemistry, and evaporation rates. A humidity control system will not provide satisfactory results if any of these items are overlooked.

Humidity Control

Humans are very sensitive to relative humidity. Fluctuations in relative humidity outside the 40 to 60% range can increase levels of bacteria, viruses, fungi and other factors that reduce air quality. For swimmers, 50 to 60% rh is most comfortable. High relative humidity levels are destructive to building components. Mold and mildew can attack wall, floor, and ceiling coverings; and condensation can degrade many building materials. In the worst case, the roof could collapse due to corrosion from water condensing on the structure.

Load Estimation

Loads for a natatorium include building heat gains and losses from outdoor air, lighting, walls, roof, and glass. Internal latent loads are generally from people and evaporation. Evaporation loads in pools and spas are significant relative to other load elements and may vary widely depending on pool features, the areas of water and wet deck, water temperature, and activity level in the pool.

Evaporation. The rate of evaporation (Carrier 1918) can be estimated from empirical Equation (1). This equation is valid for pools at normal activity levels, allowing for splashing and a limited area of wetted deck. Other pool uses may have more or less evaporation (Smith et al. 1993).

$$w_p = \frac{A}{Y}(p_w - p_a)(0.089 + 0.0782V) \quad (1)$$

where

w_p = evaporation of water, kg/s
A = area of pool surface, m^2
V = air velocity over water surface, m/s
Y = latent heat required to change water to vapor at surface water temperature, kJ/kg
p_a = saturation pressure at room air dew point, kPa
p_w = saturation vapor pressure taken at surface water temperature, kPa

The units for the constant 0.089 are $W/(m^2 \cdot Pa)$. The units for the constant 0.0782 are $W \cdot s/(m^3 \cdot Pa)$.

Equation (1) may be modified by multiplying it by an activity factor F_a to alter the estimate of evaporation rate based on the level of activity supported. For Y values of about 2400 kJ/kg and V values ranging from 0.05 to 0.15 m/s, Equation (1) can be reduced to

$$w_p = 4 \times 10^{-5} A(p_w - p_a)F_a \quad (2)$$

The following activity factors should be applied to the areas of specific features, and not to the entire wetted area:

Type of Pool	Typical Activity Factor (F_a)
Residential pool	0.5
Condominium	0.65
Therapy	0.65
Hotel	0.8
Public, schools	1.0
Whirlpools, spas	1.0
Wavepools, water slides	1.5 (minimum)

The effectiveness of controlling the natatorium environment depends on the correct estimation of water evaporation rates. Applying the correct activity factors is extremely important in determining water evaporation rates.. The difference in peak evaporation rates between private pools and active public pools of comparable size may be more than 100%.

Table 1 Typical Natatorium Design Conditions

Type of Pool	Air Temperature, °C	Water Temperature, °C	Relative Humidity, %
Recreational	24 to 29	24 to 29	50 to 60
Therapeutic	27 to 29	29 to 35	50 to 60
Competition	26 to 29	24 to 28	50 to 60
Diving	27 to 29	27 to 32	50 to 60
Whirlpool/spa	27 to 29	36 to 40	50 to 60

Actual operating temperatures and relative humidity conditions should be established prior to design. How the area will be used usually dictates design. The elderly prefer significantly warmer operating temperatures than those listed Table 1.

Air temperatures in public and institutional pools should be maintained 1 to 2 K above the water temperature (but not above the comfort threshold of 30°C) to reduce the evaporation rate and avoid chill effects on swimmers.

Ventilation Requirements

Air Quality. Outdoor air ventilation rates prescribed by ASHRAE *Standard* 62 are intended to provide acceptable air quality conditions for the average pool using chlorine for its primary disinfection process. The ventilation requirement may be excessive for private pools and installations with low use. They may also prove inadequate for high occupancy public installations.

Air quality problems in pools and spas are caused by water quality problems, so simply increasing ventilation rates may prove both expensive and ineffective. Water quality conditions are a direct function of pool use and the type and effectiveness of the water disinfection process used.

Because an indoor pool usually has a high ceiling, temperature stratification can have a detrimental effect on indoor air quality. Care must be taken with duct layout to ensure that the space receives the proper air changes and homogeneous air quality throughout. Some air movement at the deck and pool water level is essential to ensure acceptable air quality. Complaints from swimmers tend to indicate that the greatest chloramine (see the section on Pool Water Chemistry) concentrations occur at the water surface. Children are especially vulnerable to chloramine poisoning.

Exhaust air from pool is rich in moisture and may contain high levels of chloramine compounds. While most codes permit pool air to be used as makeup for showers, toilets, and locker rooms, these spaces should be provided with separate ventilation and maintained at a positive pressure with respect to the pool.

Pool and spa areas should be maintained at a negative pressure of 15 to 40 Pa relative to adjacent areas of the building to prevent moisture and chloramine odor migration. Active methods of pressure control may prove more effective than static balancing and may be necessary where outdoor air is used as a part of an active humidity control strategy. Openings from the pool to other areas should be minimized and controlled. Passageways should be equipped with doors with automatic closers to inhibit migration of moisture and air.

Air Delivery Rates. Total airflow should be determined by a psychrometric analysis. Most codes require a minimum of six (6) air changes per hour, except where mechanical cooling is used. This rate may prove inadequate for some anticipated conditions of occupancy and use.

Where mechanical cooling is provided, air delivery rates should be established to maintain appropriate conditions of temperature and humidity. The following rates are typically desired:

Pools with no spectator areas	4 to 6 air changes per hour
Spectator areas	6 to 8 air changes per hour
Therapeutic pools	4 to 6 air changes per hour

Outdoor air delivery rates may be constant or variable, depending on the design. Minimum rates, however, must provide adequate dilution of contaminants generated by pool water and must maintain acceptable ventilation for occupancy.

Where a minimum outdoor air ventilation rate is established to protect against condensation in a building's structural elements, the rates are typically used for 100% outdoor air systems. These rates usually result in excessive humidity levels under most operating conditions and are generally not adequate to produce acceptable indoor air quality, especially in public facilities subject to heavy use.

Duct Design

As with any installation, proper duct design and installation is necessary for proper equipment performance. Poorly installed return duct connections, for example, can significantly reduce the performance of a dehumidifier. The following duct construction practices apply to natatoriums:

- Fiberglass duct liner should not be used. Where condensation may occur the insulation must be applied to the exterior of the duct.
- Duct materials and hardware must be resistant to chemical corrosion from the pool atmosphere. The 400 series stainless steels are readily attacked by chlorides in moist environments. The 300 series stainless steel, painted galvanized, or aluminum sheet metal may be used for exposed duct systems. Buried ductwork should be constructed from non-metallic fiberglass reinforced or PVC materials due to the difficulty of replacing damaged materials.
- Grilles, registers and diffusers should be constructed from aluminum. They should be selected for low static pressure loss and for appropriate throws for proper air distribution.
- Supply air should be directed against interior envelope surfaces prone to condensation (walls, glass, and doors). A portion of the supply air should be directed over the water surface to move contaminated air toward an exhaust point and control chloramines released at the water surface.
- Return air inlets should be located to recover the warm humid air and return it to the ventilation system for treatment, to prevent the supply air from short-circuiting, and minimize recirculation of chloramines.
- Exhaust air inlets should be located to maximize capture effectiveness and minimize the recirculation of chloramines. Exhausting from directly above whirlpools is also desirable. Exhaust air should be taken directly to the outside, through heat recovery devices where provided.
- Filtration should be selected to provide 45 to 65% efficiencies (as defined in ASHRAE *Standard* 52.1) and be installed in locations selected to prevent condensation in the filter bank. Filter media and support materials should be resistant to moisture degradation.
- Air systems may be designed for noise levels of NC 45-50, however, wall, floor, and ceiling surfaces should be evaluated for their attenuation effect.

Envelope Design

Glazing in exterior walls becomes susceptible to condensation when the outdoor temperature drops below the pool room dew point. The design goal is to maintain the surface temperature of the glass and the window frames a minimum of 3 K above the pool room dew point. Windows must allow unobstructed air movement on inside surfaces. Thermal break frames should be used. Recessed windows and protruding window frames should be avoided. Skylights are especially vulnerable and attention should be given to control condensation on them. Wall and roof vapor retarder designs should be carefully reviewed, especially at wall-to-wall and wall-to-roof junctures and at window, door, and duct penetrations. The pool enclosure must be suitable for year round operation at 50 to 60% relative humidity. A vapor barrier analysis (as in Figure 11 in Chapter 22 of the 1997 *ASHRAE Handbook—Fundamentals*) should be prepared. Failure to install an effective vapor retarder will result in condensation forming in the structure and potentially serious damage.

Pool Water Chemistry

Failure to maintain proper chemistry in the pool water causes serious air quality problems and deterioration of mechanical and building systems. Water treatment equipment should be installed in a separate, dedicated, well-ventilated space that is under negative pressure. Pool water treatment consists of primary disinfection, pH control, water filtration and purging, and water heating. For further information, refer to Kowalsky (1990).

Air quality problems are usually caused by the reaction of chlorine with biological wastes, and particularly with ammonia, which is a by-product of the breakdown of urine and perspiration. Chlorine reacts with these wastes, creating chloramines (monochloramine, dichloramine, and nitrogen trichloride) that are commonly measured as combined chlorine. The addition of chemicals to pool water increases total contaminant levels. In high occupancy pools, water contaminant levels can double in a single day of operation.

The reduction of ammonia by chlorine is affected by several factors including water temperature, water pH, total chlorine concentration, and the level of dissolved solids in the water. Because of their higher operating temperature and higher ratio of occupancy per unit water volume, spas produce greater quantities of air contaminants than pools.

The following measures have demonstrated a potential to reduce chloramine concentrations in the air and water:

- **Ozonation.** In low concentrations, ozone has substantially reduced the concentration of combined chlorine in the water. In high concentrations, ozone can replace chlorine as the primary disinfection process, however, ozone is unable to maintain sufficient residual levels in the water to maintain a latent biocidal effect. This necessitates the maintenance of chlorine as a residual process at concentrations of 0.5 to 1.5 mg/kg.
- **Water Exchange Rates.** High concentrations of dissolved solids in water have been shown to directly contribute to high combined chlorine (chloramine) levels. Adequate water exchange rates are necessary to prevent the buildup of biological wastes and their oxidized components in pool and spa water. Conductivity measurement is an effective method to control the exchange rate of water in pools and spas to effectively maintain water quality and minimize water use. In high-occupancy pools, heat recovery may prove useful in reducing water heating energy requirements.

Energy Considerations

Natatoriums can be major energy burden on facilities, so they represent a significant opportunity for energy conservation. Several design solutions are possible using both dehumidification and ventilation strategies. When evaluating a system, the energy consumed by all elements should be considered, including primary heating and cooling systems, fan motors, water heaters, and pumps.

Natatoriums with fixed outdoor air ventilation rates without dehumidification generally have seasonally fluctuating space temperature and humidity levels. Systems designed to provide minimum ventilation rates without dehumidification are unable to maintain relative humidity conditions within prescribed limits. These systems may facilitate mold and mildew growth and may be unable to provide acceptable indoor air quality. Peak dehumidification loads vary with activity levels and during the cooling season when ventilation air becomes an additional dehumidification load to the space.

FAIRS AND OTHER TEMPORARY EXHIBITS

Occasionally, large-scale exhibits are constructed to stimulate business, present new ideas, and provide cultural exchanges. Fairs of this type take years to construct, are open from several months to

several years, and are sometimes designed considering future use of some of the buildings. Fairs, carnivals, or exhibits, which may consist of prefabricated shelters and tents that are moved from place to place and remain in a given location for only a few days or weeks, are not covered here because they seldom require the involvement of architects and engineers.

Design Concepts

One consultant or agency should be responsible for setting uniform utility service regulations and practices to ensure proper organization and operation of all exhibits. Exhibits that are open only during the intermediate spring or fall months require a much smaller heating or cooling plant than those designed for for peak summer or winter design conditions. This information is required in the earliest planning stages so that system and space requirements can be properly analyzed.

Occupancy

Fair buildings have heavy occupancy during visiting hours, but patrons seldom stay in any one building for a long period. The length of time that patrons stay in a building determines the air-conditioning design. The shorter the anticipated stay, the greater the leeway in designing for less-than-optimum comfort, equipment, and duct layout. Also, whether patrons wear coats and jackets while in the building influences operating design conditions.

Equipment and Maintenance

Heating and cooling equipment used solely for maintaining comfort and not for exhibit purposes may be secondhand or leased, if available and of the proper capacity. Another possibility is to rent the air-conditioning equipment to reduce the capital investment and eliminate disposal problems when the fair is over.

Depending on the size of the fair, the length of time it will operate, the types of exhibitors, and the policies of the fair sponsors, it may be desirable to analyze the potential for a centralized heating and cooling plant versus individual plants for each exhibit. The proportionate cost of a central plant to each exhibitor, including utility and maintenance costs, may be considerably less than having to furnish space and plant utility and maintenance costs. The larger the fair, the more savings may result. It may be practical to make the plant a showcase, suitable for exhibit and possibly added revenue. A central plant may also form the nucleus for the commercial or industrial development of the area after the fair is over.

If exhibitors furnish their own air-conditioning plants, it is advisable to analyze shortcuts that may be taken to reduce equipment space and maintenance aids. For a 6-month to 2-year maximum operating period, for example, tube pull or equipment removal space is not needed or may be drastically reduced. Higher fan and pump motor power and smaller equipment is permissible to save on initial costs. Ductwork and piping costs should be kept as low as possible because these are usually the most difficult items to salvage; cheaper materials may be substituted wherever possible. The job must be thoroughly analyzed to eliminate all unnecessary items and reduce all others to bare essentials.

The central plant may be designed for short-term use as well. However, if the plant is to be used after the fair closes, the central plant should be designed in accordance with the best practice for long-life plants. It is difficult to determine how much of the piping distribution system can be used effectively for permanent installations. For that reason, piping should be simply designed initially, preferably in a grid, loop, or modular layout, so that future additions can be made easily and economically.

Air Cleanliness

The efficiency of the filters needed for each exhibit is determined by the nature of the area served. Because the life of an exhibit is very short, it is desirable to furnish the least expensive filtering system. If possible, one set of filters should be selected to last for the life of the exhibit. In general, the filtering efficiencies do not have to exceed 30% (see ASHRAE *Standard* 52.1).

System Applicability

If a central air-conditioning plant is not built, the equipment installed in each building should be the least costly to install and operate for the life of the exhibit. These units and systems should be designed and installed to occupy the minimum usable space.

Whenever feasible, heating and cooling should be performed by one medium, preferably air, to avoid running a separate piping and radiation system for heating and a duct system for cooling. Air curtains used on an extensive scale may, on analysis, simplify the building structure and lower total costs.

Another possibility when both heating and cooling are required is a heat pump system, which may be less costly than separate heating and cooling plants. Economical operation may be possible, depending on the building characteristics, lighting load, and occupant load. If well or other water is available, it may produce a more economical installation than an air-source heat pump.

ATRIUMS

Atriums have diverse functions and occupancies. An atrium may (1) connect buildings; (2) serve as an architectural feature, leisure space, greenhouse, and/or smoke reservoir; and (3) afford energy and lighting conservation. The temperature, humidity, and hours of usage of an atrium are directly related to those of the adjacent buildings. Glass window walls and skylights are common. Atriums are generally large in volume with relatively small floor areas. The temperature and humidity conditions, air distribution, impact from adjacent buildings, and fenestration loads to the space must be considered in the design of an atrium.

Perimeter radiant heating (e.g., overhead radiant type, wall finned-tube or radiant type, floor radiant type, or combinations thereof) is commonly used for the expansive glass windows and skylights. Air-conditioning systems can heat, cool, and control smoke. The distribution of air across windows and skylights can also control heat transfer and condensation. Low supply and high return air distribution can control heat stratification, as well as wind and stack effects. Some atrium designs include a combination of high/low supply and high/low return air distribution to control heat transfer, condensation, stratification, and wind/stack effects.

The energy use of an atrium can be reduced by installing double- and triple-panel glass and mullions with thermal breaks, as well as shading devices such as external, internal, and interior screens, shades, and louvers.

Extensive landscaping is common in atriums. Humidity levels are generally maintained between 10 and 35%. Hot and cold air should not be distributed directly onto plants and trees.

CHAPTER 5

HOTELS, MOTELS, AND DORMITORIES

Load Characteristics 5.1
Design Concepts and Criteria 5.1
Systems 5.1
Hotels and Motels 5.3
Dormitories 5.8
Multiple-Use Complexes 5.8

HOTELS, motels, and dormitories may be single-room or multiroom, long- or short-term dwelling (or residence) units; they may be stacked sideways and/or vertically. Information in the first three sections of the chapter applies generally; the last three sections are devoted to the individual types of facilities.

LOAD CHARACTERISTICS

1. Ideally each room served by an HVAC unit should be able to be ventilated, cooled, heated, or dehumidified independently of any other room. If not, air conditioning for each room will be compromised.
2. Typically, the space is not occupied at all times. For adequate flexibility, each unit's ventilation and cooling should be able to be shut off (except when humidity control is required), and its heating to be shut off or turned down.
3. Concentrations of lighting and occupancy are typically low; activity is generally sedentary or light. Occupancy is transient in nature, with greater use of bedrooms at night.
4. Kitchens, whether integrated with or separate from residential quarters, have the potential for high appliance loads, odor generation, and large exhaust requirements.
5. Rooms generally have an exterior exposure, kitchens, toilets, and dressing rooms may not. The building as a whole usually has multiple exposures, as may many individual dwelling units.
6. Toilet, washing, and bathing facilities are almost always incorporated in the dwelling units. Exhaust air is usually incorporated in each toilet area.
7. The building has a relatively high hot water demand, generally for periods of an hour or two, several times a day. This demand can vary from a fairly moderate and consistent daily load profile in a senior citizens building to sharp, unusually high peaks at about 6:00 P.M. in dormitories. Chapter 48 includes details on service water heating.
8. Load characteristics of rooms, dwelling units, and buildings can be well defined with little need to anticipate future changes to the design loads, other than the addition of a service such as cooling that may not have been incorporated originally.
9. The prevalence of shifting, transient interior loads and exterior exposures with glass results in high diversity factors; the long-hour usage results in fairly high load factors.

DESIGN CONCEPTS AND CRITERIA

Wide load swings and diversity within and between rooms require the design of a flexible system for 24-hour comfort. Besides opening windows, the only method of providing flexible temperature control is having individual room components under individual room control that can cool, heat, and ventilate independently of the equipment in other rooms.

The preparation of this chapter is assigned to TC 9.8, Large Building Air-Conditioning Applications.

In some climates, summer humidity becomes objectionable because of the low internal sensible loads that result when cooling is on-off controlled. Modulated cooling and/or reheat may be required to achieve comfort. Reheat should be avoided unless some sort of heat recovery is involved.

Dehumidification can be achieved by lowering cooling coil temperatures and reducing airflow. Another means of dehumidification is desiccant dehumidifiers.

Some people have a noise threshold low enough that certain types of equipment disturb their sleep. Higher noise levels may be acceptable in areas where there is little need for air conditioning. Medium and better quality equipment is available with noise criteria (NC) 35 levels at 3 to 4 m in medium to soft rooms and little sound change when the compressor cycles.

Perimeter fan coils are usually quieter than unitary systems, but unitary systems provide more redundancy in case of failure.

SYSTEMS

Energy-Efficient Systems

The most efficient systems generally include water-source and air-source heat pumps. In areas with ample solar radiation, water-source heat pumps may be solar assisted. Energy-efficient equipment generally has the lowest operating cost and is relatively simple, an important factor where skilled operating personnel are unlikely to be available. Most systems allow individual operation and thermostatic control. The typical system allows individual metering so that most, if not all, of the cooling and heating costs can be metered directly to the occupant (McClelland 1983). Existing buildings can be retrofitted with heat flow meters and timers on fan motors for individual metering.

The water-loop heat pump has a lower operating cost than air-cooled unitary equipment, especially where electric heat is used. The lower installed cost encourages its use in mid- and high-rise buildings where individual dwelling units have floor areas of 75 m^2 or larger. Some systems incorporate sprinkler piping as the water loop.

Except for the central circulating pump, heat rejector fans, and supplementary heater, the water-loop heat pump is predominantly decentralized; individual metering allows most of the operating cost to be paid by the occupant. Its life should be longer than for other unitary systems because most of the mechanical equipment is in the building and not exposed to outdoor conditions. Also, the load on the refrigeration circuit is not as severe because the water temperature is controlled for optimum operation. Operating costs are low due to the energy conservation inherent in the system. Excess heat may be stored during the day for the following night, and heat may be transferred from one part of the building to another.

While heating is required in many areas during cool weather, cooling may be needed in rooms having high solar or internal loads. On a mild day, surplus heat throughout the building is frequently transferred into the hot water loop by water-cooled condensers on

cooling cycle so that water temperature rises. The heat remains stored in water from which it can be extracted at night; a water heater is not needed. This heat storage is improved by the presence of a greater mass of water in the pipe loop; some systems include a storage tank for this reason. Because the system is designed to operate during the heating season with water supplied at a temperature as low as 15°C, the water-loop heat pump lends itself to solar assist; relatively high solar collector efficiencies result from the low water temperature.

The installed cost of the water-loop heat pump is higher in very small buildings. In severe cold climates with prolonged heating seasons, even where natural gas or fossil fuels are available at reasonable cost, the operating cost advantages of this system may diminish unless heat can be recovered from some another source, such as solar collectors, geothermal, or internal heat from a commercial area served by the same system.

Energy-Neutral Systems

Energy-neutral systems do not allow simultaneous cooling and heating. Some examples are (1) packaged terminal air conditioners (PTACs) (through-the-wall units), (2) window units or radiant ceiling panels for cooling combined with finned or baseboard radiation for heating, (3) unitary air conditioners with an integrated heating system, (4) fan coils with remote condensing units, and (5) variable air volume (VAV) systems with either perimeter radiant panel heating or baseboard heating. To qualify as energy-neutral, a system must have controls that prevent simultaneous operation of the cooling and heating cycles. For unitary equipment, control may be as simple as a heat-cool switch. For other types, dead-band thermostatic control may be required.

PTACs are frequently installed to serve one or two rooms in buildings with mostly small, individual units. In a common two-room arrangement, a supply plenum diverts a portion of the conditioned air serving one room into the second, usually smaller, room. Multiple PTAC units allow additional zoning in dwellings having more rooms. Additional radiation heat is sometimes needed around the perimeter in cold climates.

Heat for a PTAC may be supplied either by electric resistance heaters or by hot water or steam heating coils. Initial costs are lower for a decentralized system using electric resistance heat. Operating costs are lower for coils heated by combustion fuels. Despite having relatively inefficient refrigeration circuits, the operating cost of a PTAC is quite reasonable, mostly because individual thermostatic control each machine, which eliminates the use of reheat while preventing the space from being overheated or overcooled. Also, because the equipment is located in the space being served, little power is devoted to circulating the room air. Servicing is simple—a defective machine is replaced by a spare chassis and forwarded to a service organization for repair. Thus, building maintenance requires relatively unskilled personnel.

Noise levels are generally no higher than NC 40, but some units are noisier than others. Installations near a seacoast should be specially constructed (usually with stainless steel or special coatings) to avoid the accelerated corrosion to aluminum and steel components caused by salt. In high-rise buildings of more than 12 stories, special care is required, both in the design and construction of outside partitions and in the installation of air conditioners, to avoid operating problems associated with leakage (caused by stack effect) around and through the machines.

Frequently, the least expensive installation is finned or baseboard radiation for heating and window-type room air conditioners for cooling. The window units are often purchased individually by the building occupants. This choice offers a reasonable operating cost and is relatively simple to maintain. However, window units have the shortest equipment life, the highest operating noise level, and the poorest distribution of conditioned air of any of the systems discussed in this section.

Fan coils with remote condensing units are used in smaller buildings. Fan coil units are located in closets, and the ductwork distributes air to the rooms in the dwelling. Condensing units may be located on roofs, at ground level, or on balconies.

Low capacity residential warm air furnaces may be used for heating, but with gas- or oil-fired units, the products of combustion must be vented. In a one- or two-story structure, it is possible to use individual chimneys or flue pipes, but in a high-rise structure requires a multiple-vent chimney or a manifold vent. Local codes should be consulted.

Sealed combustion furnaces draw all the combustion air from outside and discharge the flue products through a windproof vent to the outdoors. The unit must be located near an outside wall, and exhaust gases must be directed away from windows and intakes. In one- or two-story structures, outdoor units mounted on the roof or on a pad at ground level may also be used. All of these heating units can be obtained with cooling coils, either built-in or add-on. Evaporative-type cooling units are popular in motels, low-rise apartments, and residences in mild climates.

Desiccant dehumidification should be considered when independent control of temperature and humidity is required to avoid reheat.

Energy-Inefficient Systems

Energy-inefficient systems allow simultaneous cooling and heating. Examples include two-, three-, and four-pipe fan coil units, terminal reheat systems, and induction systems. Some units, such as the four-pipe fan coil, can be controlled so that they are energy-neutral. They are primarily used for humidity control.

Four-pipe systems and two-pipe systems with electric heaters can be designed for complete temperature and humidity flexibility during summer and intermediate season weather, although none provides winter humidity control. Both systems provide full dehumidification and cooling with chilled water, reserving the other two pipes or an electric coil for space heating or reheat. The equipment and necessary controls are expensive, and only the four-pipe system, if equipped with an internal-source heat-recovery design for the warm coil energy, can operate at low cost. When year-round comfort is essential, four-pipe systems or two-pipe systems with electric heat should be considered.

Total Energy Systems

A total energy system is an option for any multiple or large housing facility with large year-round service water heating requirements. Total energy systems are a form of cogeneration in which all or most electrical and thermal energy needs are met by on-site systems as described in Chapter 7 of the 2000 *ASHRAE Handbook—Systems and Equipment*. A detailed load profile must be analyzed to determine the merits of using a total energy system. The reliability and safety of the heat-recovery system must also be considered.

Any of the previously described systems can perform the HVAC function of a total energy system. The major considerations as they apply to total energy in choosing a HVAC system are as follows:

- Optimum use must be made of the thermal energy recoverable from the prime mover during all or most operating modes, not just during conditions of peak HVAC demand.
- Heat recoverable via the heat pump may become less useful because the heat required during many of its potential operating hours will be recovered from the prime mover. The additional investment for heat pump or heat recovery cycles may be more difficult to justify because operating savings are lower.
- The best application for recovered waste heat is for those services that use only heat (i.e., service hot water, laundry facilities, and space heating).

Special Considerations

Local building codes govern ventilation air quantities for most buildings. Where they do not, ASHRAE *Standard* 62 should be followed. The quantity of outdoor air introduced into the rooms or corridors is usually slightly in excess of the exhaust quantities to pressurize the building. To avoid adding any load to the individual systems, outdoor air should be treated to conform to indoor air temperature and humidity conditions. In humid climates, special attention must be given to controlling the humidity from outdoor air. Otherwise, the outdoor air may reach corridor temperature while still retaining a significant amount of moisture.

In buildings having a centrally controlled exhaust and supply, the system is regulated by a time clock or a central management system for certain periods of the day. In other cases, the outside air may be reduced or shut off during extremely cold periods, although this practice is not recommended and may be prohibited by local codes. These factors should be considered when estimating heating load.

For buildings using exhaust and supply air on a 24 hour basis, air-to-air heat recovery devices may be merited (see Chapter 44 of the 2000 *ASHRAE Handbook—Systems and Equipment)*. Such recovery devices can reduce energy consumption by capturing 60 to 80% of the sensible and latent heat extracted from the air source.

Infiltration loads in high-rise buildings without ventilation openings for perimeter units are not controllable year-round by general building pressurization. When outer walls are pierced to supply outdoor air to unitary or fan-coil equipment, combined wind and thermal stack-effect forces create equipment operating problems. These factors must be considered for high-rise buildings (see Chapter 25 of the 1997 *ASHRAE Handbook—Fundamentals*).

Interior public corridors should have tempered supply air with transfer into individual area units, if necessary, to provide kitchen and toilet makeup air requirements. The transfer louvers need to be acoustically lined. Corridors, stairwells, and elevators should be pressurized for fire and smoke control (see Chapter 51).

Kitchen air can be recirculated through hoods with activated charcoal filters rather than exhausted. Toilet exhaust can be VAV with a damper operated by the light switch. A controlled source of supplementary heat in each bathroom is recommended to ensure comfort while bathing.

Air-conditioning equipment must be isolated to reduce noise generation or transmission. The cooling tower or condensing unit must be designed and located to avoid disturbing occupants of the building or of adjacent buildings.

An important but frequently overlooked load is the heat gain from piping for hot water services. Insulation thickness should conform to the latest local energy codes and standards at a minimum. In large, luxury-type buildings, a central energy or building management system allows supervision of individual air-conditioning units for operation and maintenance.

Some facilities achieve energy conservation by reducing the indoor temperature during the heating season. Such a strategy should be pursued with caution because it could affect the competitiveness of the hotel/motel, for example.

HOTELS AND MOTELS

Hotel and motel accommodations are usually single guest rooms with a toilet and bath adjacent to a corridor, and flanked on both sides by other guest rooms. The building may be single-story, low-rise, or high-rise. Multipurpose subsidiary facilities range from stores and offices to ballrooms, dining rooms, kitchens, lounges, auditoriums, and meeting halls. Luxury motels may be built with similar facilities. Occasional variations are seen, such as kitchenettes, multiroom suites, and outside doors to patios and balconies. Hotel classes range from the deluxe hotel to the economy hotel/motel as outlined in Table 1.

A hotel can be divided into three main areas:

1. Guest rooms
2. Public areas
   - Lobby, atrium, and lounges
   - Ballrooms
   - Meeting rooms
   - Restaurants and dining rooms
   - Stores
   - Swimming pools
   - Health clubs
3. Back-of-the-house (BOTH) areas
   - Kitchens
   - Storage areas
   - Laundry
   - Offices
   - Service areas and equipment rooms

The two main areas of use are the guest rooms and the public areas. Maximum comfort in these areas is critical to the success of any hotel. Normally the BOTH spaces are less critical than the remainder of the hotel with the exception of a few spaces where a controlled environment is required or recommended.

Guest Rooms

Air conditioning in hotel rooms should be quiet, easily adjustable, and draft free. It must also provide ample outside air. Because the hotel business is so competitive and space is at a premium, systems that require little space and have low total owning and operating costs should be selected.

Design Concepts and Criteria. Table 2 lists design criteria for hotel guest rooms. In addition, the design criteria for hotel room HVAC services must consider the following factors:

Table 1 Hotel Classes

Type of Facility	Typical Occupancy, Persons per Room	Characteristics
Deluxe hotel	1.2	Large rooms, suites, specialty restaurants
Luxury/first class, full-service hotel	1.2 to1.3	Large rooms, large public areas, business center, pool and health club, several restaurants
Mid-scale, full-service hotel	1.2 to 1.3	Large public areas, business center, several restaurants
Convention hotel	1.4 to 1.6	Large number of rooms, very large public areas, extensive special areas, rapid shifting of peak loads
Limited-service hotel	1.1	Limited public areas, few restaurants, may have no laundry
Upscale, all-suites hotel	2.0	Rooms are two construction bays, in-room pantries, limited public areas, few restaurants
Economy, all-suites hotel	2.0 to 2.2	Smaller suites, limited public areas and restaurants
Resort hotel	1.9 to 2.4	Extensive public areas, numerous special and sport areas, several restaurants
Conference center	1.3 to 1.4	Numerous special meeting spaces, limited dining options
Casino hotel	1.5 to 1.6	Larger rooms, large gaming spaces, extensive entertainment facilities, numerous restaurants
Economy hotel/motel	1.6 to 1.8	No public areas, little or no dining, usually no laundry

Table 2 Hotel Design Criteria[a,b]

Category	Inside Design Conditions: Winter Temperature	Winter Relative Humidity[c]	Summer Temperature	Summer Relative Humidity	Ventilation[d]	Exhaust[d,e]	Filter Efficiency[f]	Noise, RC Level
Guest rooms	23 to 24°C	30 to 35%	23 to 26°C	50 to 60%	15 to 30 L/s per room	10 to 25 L/s per room	10 to 15%	25 to 35
Lobbies	20 to 23°C	30 to 35%	23 to 26°C	40 to 60%	8 L/s per person	–	35% or better	35 to 45
Conference/ Meeting rooms	20 to 23°C	30 to 35%	23 to 26°C	40 to 60%	10 L/s per person	–	35% or better	25 to 35
Assembly rooms	20 to 23°C	30 to 35%	23 to 26°C	40 to 60%	8 L/s per person	–	35% or better	25 to 35

[a] This table should not be used as the only source for design criteria. The data contained here can be determined from ASHRAE handbooks, standards, and governing local codes.
[b] Design criteria for stores, restaurants, and swimming pools are in Chapters 2, 3, and 4, respectively.
[c] Minimum recommended humidity.
[d] As per ASHRAE *Standard* 62, Ventilation for Acceptable Indoor Air Quality.
[e] Air exhaust from bath and toilet area.
[f] As per ASHRAE *Standard* 52.1, Gravimetric and Dust-Spot Procedures for Testing Air-Cleaning Devices Used in General Ventilation for Removing Particulate Matter.

- Individual and quick responding temperature control
- Draft-free air distribution
- Toilet room exhaust
- Ventilation (makeup) air supply
- Humidity control
- Acceptable noise level
- Simple controls
- Reliability
- Ease of maintenance
- Operating efficiency
- Use of space

Load Characteristics. The great diversity in the design, purpose, and use of hotels and motels makes analysis and load studies very important. The fact that guest rooms have a transient occupancy and the diversity associated with the operation of the support facilities provides an opportunity to take advantage of load diversification.

The envelope cooling and heating load is dominant because the guest rooms normally have exterior exposures. Other load sources such as people, lights, appliances, etc. are a relatively small portion of the space sensible and latent loads. The ventilation load can represent up to 15% of the total cooling load.

Because of the nature of the changing envelope sensible load and the transient occupancy of the guest room, large fluctuations in the space sensible load in a one-day cycle are common. The ventilation sensible cooling load can vary from 0 to 100% in a single day, whereas the ventilation latent load can remain almost constant for the entire day. A low sensible heat ratio is common in moderate to very humid climates. Usually the HVAC equipment must only handle part or low loads and peak loads rarely occur. For example, in humid climates, introducing untreated outside air directly into the guest room or into the return air plenum of the HVAC unit operating at part or low load creates a severe high-humidity problem, which is one of the causes of mold and mildew. The situation is further aggravated when the HVAC unit operates in on-off cycle during part- or low-load conditions.

Applicable Systems. Most hotels use all-water or unitary refrigerant-based equipment for guest rooms. All-water systems include

- Two-pipe fan coils
- Two-pipe fan coil with electric heat
- Four-pipe fan coils

Unitary refrigerant-based systems include

- Packaged terminal air conditioner or packaged terminal heat pump (with electric heat)
- Air to air heat pump (ductless, split)
- Water-source heat pump

With the exception of the two-pipe fan coil, all of these systems cool, heat, or dehumidify independently of any other room and regardless of the season. A two-pipe fan coil system should be selected only when economics and design objectives dictate a compromise to performance. Selection of a particular system should be based on

- First cost,
- Economical operation, especially at part load, and
- Maintainability.

Compared to unitary refrigerant-based units, all-water systems offer the following advantages:

- Reduced total installed cooling capacity due to load diversity
- Lower operating cost due to a more efficient central cooling plant
- Lower noise level (compared to PTAC and water-source heat pump)
- Longer service life
- Less equipment to be maintained in the occupied space
- Less water in circulation (compared to water-source heat pump)
- Smaller pipes and pumps (compared to water-source heat pump)

The unitary refrigerant-based system on the other hand offer the following advantages:

- Lower first cost
- Immediate all year availability of heating and cooling
- No seasonal changeover required
- Cooling available without operating a central refrigeration plant
- Can transfer energy from spaces being cooled to spaces being heated (with water-source heat pump)
- Range of circulated water temperature requires no pipe insulation (for water-source heat pump)
- Less dependence on a central plant for heating and cooling
- Simplicity, which results in lower operating and maintenance staff costs

The type of facility, sophistication, and quality desired by the owner/operator, as well as possible code requirements typically influence the selection. An economic analysis (life-cycle cost) is particularly important when selecting the most cost-effective system. Chapter 35 has further information on economic analysis techniques. Computer software like the NIST Building Life-Cycle Cost Program (BLCC) performs life-cycle cost analyses quickly and accurately (NIST 1994).

Chapter 3 and Chapter 5 of the 2000 *ASHRAE Handbook—Systems and Equipment* provide additional information about all-water systems and unitary refrigerant-based systems.

Room fan coils and room unitary refrigerant-based units are available in many configurations including horizontal, vertical, exposed, and concealed. The unit should be located in the guest room so that it provides excellent air diffusion without creating

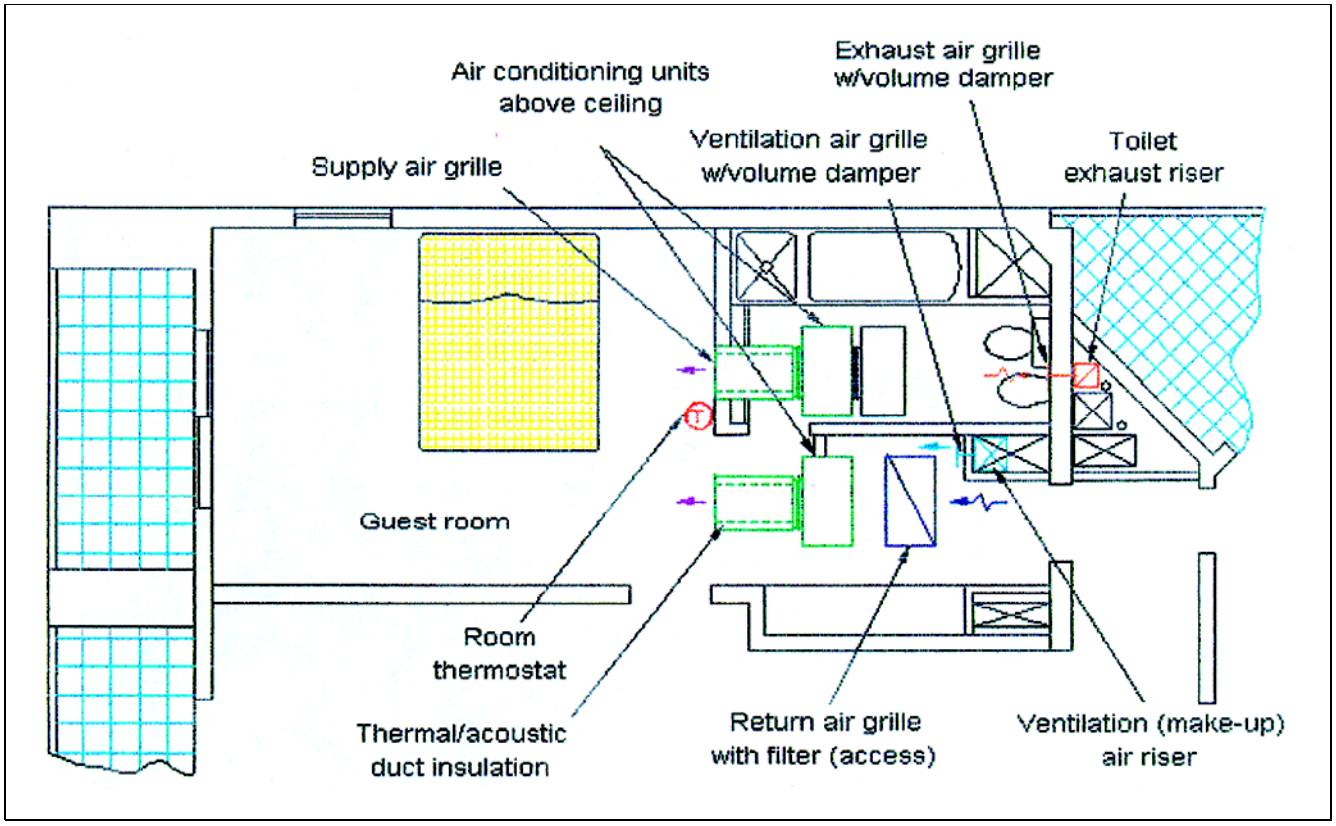

Fig. 1 Alternate Location for Hotel Guest Room Air Conditioning Unit above Hung Ceiling

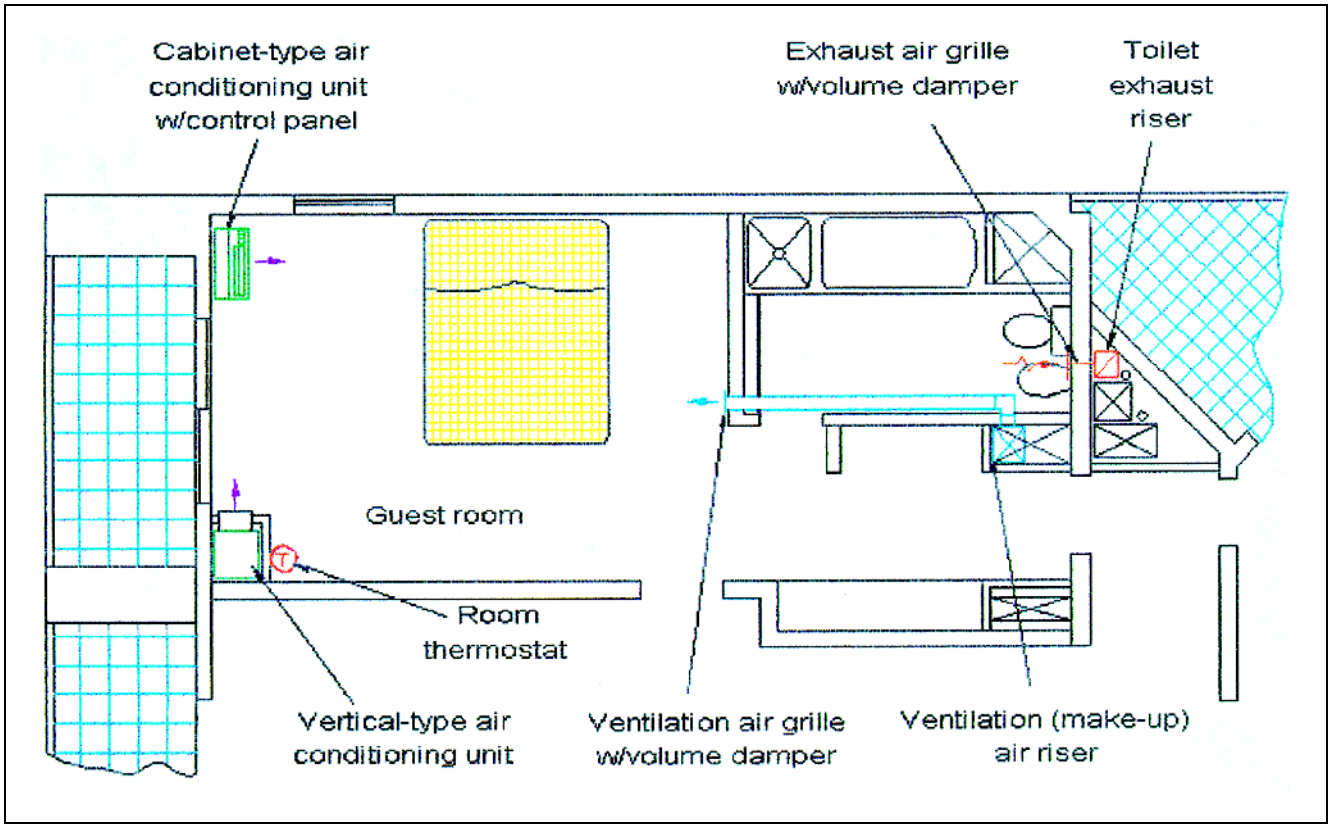

Fig. 2 Alternate Location for Hotel Guest Room Air Conditioning Unit on Room Perimeter and Chase-Enclosed

unpleasant drafts. Air should not discharge directly over the head of the bed in order to keep cold air away from a sleeping guest. The fan-coil/heat pump unit is most commonly located

- Above the ceiling in the guest room entry corridor or above the bathroom ceiling (horizontal air discharge),
- On the room's perimeter wall (vertical air discharge), or
- In a floor to ceiling enclosed chase (horizontal air discharge).

Locating the unit above the entry corridor is preferred because air can flow directly along the ceiling and the unit is in a relatively accessible location for maintenance (see Figure 1 and Figure 2).

Most units are designed for free-air discharge. The supply air grille should be selected according to the manufacturer recommendations for noise and air diffusion. Also, the airflow should not interfere with the room drapes or other wall treatment.

Other factors that should be considered include

- Sound levels at all operating modes, particularly with units that cycle on and off
- Adequately sized return air grille
- Access for maintenance, repair, and filter replacement

Ventilation (makeup) supply and exhaust rates must meet local code requirements. Ventilation rates vary and the load imposed by ventilation must be considered.

Providing conditioned ventilation air directly to the guest room is the preferred approach. Normally outside air is conditioned in a primary makeup air unit and distributed via a primary air duct to every guest room. This approach controls the supply air conditions, ensures satisfactory room conditions and room air balance (room pressurization) even during part or no load conditions, and controls mold and mildew.

Other ventilation techniques are to

- Transfer conditioned ventilation air from the corridor to each guest room. This approach controls ventilation air conditions better; however, the air balance (makeup versus exhaust) in the guest room may be compromised. This approach is prohibited under many code jurisdictions.
- Introduce unconditioned outside air directly to the air-conditioning unit's return air plenum (perimeter wall installations). This approach can cause mold and mildew and should be avoided. During periods of part or low load, which occur during most of the cooling season, the thermostatically-controlled air conditioner does not adequately condition the constant flow of outside air because the cooling coil valve closes and/or the compressor cycles off. As a result the humidity level in the room increases. Also, when the air conditioner's fan is off, outside air infiltrates through the ventilation opening and again elevates the room humidity level.

Guest-room HVAC units are normally controlled by a room thermostat. Thermostats for fan coils normally control valves in two-pipe, four-pipe, and two-pipe chilled water with electric heat systems. The control should include dead-band operation to separate the heating and cooling set points. Two-pipe system control valves are normally equipped with automatic changeover, which senses the water temperature and changes the mode of operation from heating to cooling. The thermostat may provide modulation or two-position control of the water control valve. The fan can be adjusted to high, medium, or low speed on most units.

Typical unitary refrigerant-based units have a push button off/fan/heat/cool selector switch, adjustable thermostat, and fan cycle switch. Heat pumps include a defrost cycle to remove ice from the outdoor coil. Chapter 45 has more information on control for fan coils.

Public Areas

The public areas are generally the showcase of a hotel. Special attention must be paid to incorporating a satisfactory system into the interior design. The location of supply diffusers, grilles. air outlets. etc. must be coordinated to satisfy the architect. The HVAC designer must pay attention to access doors for servicing fire dampers, volume dampers. valves, and variable-air-volume (VAV) terminals.

Design Concepts and Criteria. Design criteria for public areas is given in Table 2. In addition, the following design criteria must be considered:

- Year round availability of heating and cooling
- Independent unit for each main public area
- Economical and satisfactory operation at part-load and low-load conditions
- Coordination with adjacent back-of-the-house (BOTH) areas to insure proper air pressurization (i.e., restaurants and kitchens)

Load Characteristics. The hours each public area is used varies widely. In many cases the load is due to internal sources from people, lights, and equipment. The main lobby normally is operational 24 hours per day. Areas like restaurants, meeting rooms, and retail areas have intermittent use, so the load changes frequently. HVAC systems that respond effectively and economically must be selected for these areas.

Applicable Systems. All-air systems, single-duct constant-volume, and VAV are most frequently used for public areas. Chapter 2 of the 2000 *ASHRAE Handbook—Systems and Equipment* has more information on these systems while Chapter 45 in this volume covers control for all-air VAV systems.

Back-of-the-House (BOTH) Areas

The BOTH area is normally considered a service or support area. The climatic conditions in these areas are typically less critical than in the remainder of the hotel. However, a few spaces require special attention.

Design Concepts and Criteria. Recommended design criteria for several areas in the BOTH are shown in Table 3.

Special Concerns

Humidity, Mildew, Moisture Control, and IAQ. Humidity control is critical to ensure satisfactory air quality and to minimize costly mold and mildew problem in hotels. Moisture can be introduced and infiltrate into the guest rooms in the following ways:

Table 3 Design Criteria for Hotel Back-of-the-House Areas[a]

Category	Inside Design Conditions	Comments
Kitchen (general)[b]	28°C	Provide spot cooling
Kitchen (pastry)[b]	24°C	
Kitchen (chef's office)[b]	23 to 26°C 50 to 60% rh (summer) 30 to 35% rh (winter)	Fully air conditioned
Housekeeper's office	23 to 26°C 50 to 60% rh (summer) 30 to 35% rh (winter)	Fully air conditioned
Telephone equipment room	Per equipment criteria	Stand-alone air conditioner; air conditioned all year
Wine storage	Per food and beverage manager criteria	Air conditioned all year
Laundry		Spot cooling as required at workstations

[a] Governing local codes must be followed for design of the HVAC.
[b] Consult Chapter 30 for details on kitchen ventilation.

1. Unconditioned ventilation air is delivered directly into the guest room through the HVAC unit. At part or low sensible loads or in situations where the unit cycles on and off, the air-conditioning unit will not dehumidify the air adequately to remove the excess moisture.
2. Outdoor humid air infiltrates through openings, cracks, gaps. shafts, etc. due to insufficient space pressurization.
3. Moisture migrates through external walls and building elements due to a vapor pressure differential.
4. An internal latent load or moisture is generated.

Removing water vapor from the air is the most feasible way to control mold and mildew, particularly when the problem spreads to walls and carpeting. Good moisture control can be achieved by applying the following techniques:

1. Introduce adequately dried ventilation (makeup) air [i.e., with a dew point of 11°C (8.2 g/kg of dry air) or less] directly to the guest room.
2. Maintain slightly positive pressure in the guest room to minimize infiltration of hot and humid air into the room. Before a new HVAC system is accepted by the owner, a certified air balance contractor should be engaged to demonstrate that the volume of dry makeup air exceeds the volume of exhaust air. As the building ages, it is important to maintain this slight positive pressure; otherwise humid air that infiltrates into the building cavities will be absorbed regardless of how dry the room in maintained (Banks 1992).
3. Provide additional dehumidification capability to the ventilation (makeup air) by dehumidifying the air to a lower level than the desired space humidity ratio. For example, introducing 30 L/s of makeup air at 8 g/kg can provide approximately 120 W of internal latent cooling (assuming 9.5 g/kg is a desirable space humidity ratio).
4. Allow air conditioning to operate in unoccupied rooms instead of turning the units off, especially in humid areas.
5. Improve the room envelope by increasing its vapor and infiltration resistance.

Method 3 allows the ventilation air to handle part of the internal latent load (people, internal moisture generation, and moisture migration from external walls and building elements). In addition, this method can separate the internal sensible cooling, internal latent cooling, and ventilation loads. Independent ventilation/dehumidification allows room pressurization and space humidity control regardless of the mode of operation or magnitude of the air-conditioning load. Desiccant dehumidifiers can be retrofitted to solve existing moisture problems.

Ventilation (Makeup) Air Units. Makeup air units are designed to condition ventilation air introduced into a space and to replace air exhausted from the building. The geographic location and class of the hotel dictate the functions of the makeup air units, which may filter, heat, cool, humidify, and/or dehumidify the ventilation air. Makeup air may be treated directly or by air-to-air heat recovery (sensible or combined sensible and latent) and other heat recovery techniques. Equipment to condition the air by air-to-air heat recovery and final heating, cooling, humidification, and/or dehumidification is also available.

Chapter 26 of the 1997 *ASHRAE Handbook—Fundamentals* provides design weather data for ventilation. Analyzing and selecting the proper makeup unit for the full range of entering conditions are critical for an efficient and sufficient all-year operation. Air-to-air heat recovery helps stabilize the entering conditions, which helps provide an efficient and stable operation. However, heat recovery may not always be feasible. Often, exhaust air comes from many individual stacks. In this case, the cost of combining many exhausts for heat recovery may not be warranted.

Table 4 Design Criteria for Hotel Guest Room Makeup Air Units

Supply Air Conditions				Filter Efficiency (ASHRAE *Std.* 52.1)
Winter		Summer		
Temperature	Relative Humidity	Temperature	Relative Humidity	
20 to 24°C	30 to 45%	23 to 26°C	40 to 50%	30%

Notes:
1. Follow local codes when applicable.
2. The building location may dictate the optimum supply condition in the recommended range.

Typical design criteria for ventilation (makeup) air units are listed in Table 4.

Makeup air units can be stand alone packaged (unitary) or integrated in an air handler. A typical makeup air unit usually has the following features:

- Heating, cooling, and dehumidification
  - Chilled/hot water or steam coils in the air handling unit
  - Unitary refrigerant-based unit (direct-expansion cooling and gas furnace or electric heat)
  - Air-to-air energy recovery combined with mechanical cooling (DX or chilled water) and heating
  - Desiccant-based dehumidifier combined with air-to-air energy recovery, indirect/direct evaporative cooling and supplementary mechanical cooling and heating
- Heating only
  - Hot water or steam coils in the air handling unit
  - Stand alone gas-fired or electric makeup units
  - Air-to-air energy recovery with supplement heat

Humidification should be considered for all cold climates. The HVAC designer must also consider avoiding coil freeze up in water based systems. Chapter 31 and Chapter 44 of the 2000 *ASHRAE Handbook—Systems and Equipment* provide information about makeup air units and air-to-air energy recovery, respectively.

Hotel location, environmental quality desired by the owner, and design sophistication determines the system selected. For example, in locations with cool summers, dehumidification with mechanical cooling only is satisfactory. For humid locations or where enhanced dehumidification is required, a desiccant-based unit can provide lower supply air humidity. Such a unit can help prevent mold and mildew and provide internal latent cooling.

Central Mechanical Plant. Designing a reliable and energy efficient mechanical plant is essential element toward ensuring a profitable hotel. The chiller plant must operate efficiently at part load conditions. Some redundancy should be considered in case of equipment failure. Designs often include spare critical equipment where spare parts and qualified service are not readily available. Chillers with multistage compressors should be considered because they provide partial cooling during failures and enhance part-load operation. When using two chillers, each should provide at least 60% of the total load. Combinations of three chillers providing 40% each or four chillers providing 30% each are better for tracking part-load conditions. Cooling towers, pumps, etc. can be sized in a similar manner.

The heating plant should be designed to accommodate the heating load during the winter end could provide domestic hot water, swimming pool heating, and service to kitchens and laundries as well. The type of fuel used depends on location, availability, use, and cost.

Multipurpose boiler design for the kitchen and laundry should offer redundancy, effective part-load handling, and efficient operation during the summer when the HVAC heating load does not exist.

In areas with mild winters, a two-pipe system or an air-to-water heat pump chiller/heater can be considered. In any event, the HVAC

designer must understand the need for all-year cooling and heating availability in the public areas. In this case a combination of air-to-water heat pump, chiller/heater for the guest rooms and independent heat pumps for the public areas can be installed.

Acoustics and Noise Control. The sound level in guest room and public areas is a major design element. Both the level and constancy of the noise generated by the HVAC unit are of concern. Normally, packaged-terminal air conditioners/heat pumps and water-source heat pumps are noisier due to the compressor. Some equipment, however, has extra sound insulation, which reduces the noise significantly.

Lowering the fan speed, which is usually acceptable, can reduce fan noise levels. On/off cycling of the fan and the compressor can be objectionable even if the generated noise is low. Temperature control by cycling the fan only (no flow control valve) should not be used.

Another source of noise is sound that transfers between guest rooms through the toilet exhaust duct. Internal duct lining and sound attenuators are commonly used to minimize this problem.

Noise from equipment located on the roof or in a mechanical room located next to a guest room should be avoided. Proper selection of vibration isolators should prevent vibration transmission. In critical cases, an acoustician must be consulted.

New Technology in Hotels. Modern hotels are implementing new techniques to enhance comfort and convenience. For example, the telephone, radio, TV, communications, lighting, and air-conditioning unit are being integrated into one control system. Occupancy sensors are being used to conserve energy by resetting the temperature control when the room is occupied or when the guests leave. As soon as a new guest checks in at the front desk, the room temperature is automatically reset. But even with this improved technology, it is important to remember that temperature reset may create humidity problems.

DORMITORIES

Dormitory buildings frequently have large commercial dining and kitchen facilities, laundering facilities, and common areas for indoor recreation and bathing. Such ancillary loads may make heat pump or total energy systems appropriate, economical alternatives, especially on campuses with year-round activity.

When dormitories are shut down during cold weather, the heating system must supply sufficient heat to prevent freeze-up. If the dormitory contains non-dwelling areas such as administrative offices or eating facilities, these facilities should be designed as a separate zone or with a separate system for flexibility, economy, and odor control.

Subsidiary facilities should be controlled separately for flexibility and shutoff capability, but they may share common refrigeration and heating plants. With internal-source heat pumps, this interdependence of unitary systems permits the reclamation of all internal heat usable for building heating, domestic water preheating, and snow melting. It is easier and less expensive to place heat reclaim coils in the building's exhaust than to use air-to-air heat recovery devices. Heat reclaim can easily be sequence controlled to add heat to the building's chilled water system when required.

MULTIPLE-USE COMPLEXES

Multiple-use complexes combine retail facilities, office space, hotel space, residential space, and/or other commercial space into a single site. The peak HVAC demands of the various facilities may occur at different times of the day and year. Loads should be determined independently for each occupancy. Where a central plant is considered, a block load should also be determined.

Separate air handling and distribution should serve the separate facilities. However, heating and cooling units can be combined economically into a central plant. A central plant provides good opportunities for heat recovery, thermal storage, and other techniques that may not be economical in a single-use facility. A multiple-use complex is a good candidate for central fire and smoke control, security, remote monitoring, billing for central facility use, maintenance control, building operations control, and energy management.

CHAPTER 6

EDUCATIONAL FACILITIES

General Considerations 6.1
Energy Considerations 6.1
Design Considerations 6.2
Equipment and System Selection 6.4

THIS chapter contains technical and environmental factors and considerations that will assist the design engineer in the proper application of heating, ventilating, and air-conditioning systems and equipment for educational facilities. For further information on the HVAC systems mentioned in this chapter, see the 2000 *ASHRAE Handbook—Systems and Equipment*.

GENERAL CONSIDERATIONS

All forms of educational facilities require an efficiently controlled atmosphere for a proper learning environment. This involves the selection of heating, ventilating, and air-conditioning systems, equipment, and controls to provide adequate ventilation, comfort, and a quiet atmosphere. The system must also be easily maintained by the facility's maintenance staff.

The selection of the HVAC equipment and systems depends upon whether the facility is new or existing and whether it is to be totally or partially renovated. For minor renovations, existing HVAC systems are often expanded in compliance with current codes and standards with equipment that matches the existing types. For major renovations or new construction, new HVAC systems and equipment can be installed if the budget allows. The remaining useful life of existing equipment and distribution systems should be considered.

HVAC systems and equipment energy use and associated lifecycle costs should be evaluated. Energy analysis may justify new HVAC equipment and systems when a good return on investments can be shown. The engineer must take care to review all assumptions in the energy analysis with the school administration. Assumptions, especially as they relate to hard-to-measure items such as infiltration and part-load factors, can have a significant influence on the energy use calculated.

Other considerations for existing facilities are (1) whether the central plant is of adequate capacity to handle the additional loads of new or renovated facilities, (2) the age and condition of the existing equipment, pipes, and controls, and (3) the capital and operating costs of new equipment. Educational facilities usually have very limited budgets. Any savings in capital expenditures and energy costs may be available for the maintenance and upkeep of the HVAC systems and equipment and for other facility needs.

When new facilities are built or major renovations to existing facilities are made, seismic bracing of the HVAC equipment should be considered. Refer to Chapter 53, Seismic and Wind Restraint Design, for further information. Seismic codes may also apply in areas where tornados and hurricanes necessitate additional bracing. This consideration is especially important if there is an agreement with local officials to let the facility be used as a disaster relief shelter.

The type of HVAC equipment selected also depends upon the climate and the months of operation. In hot, dry climates, for instance, evaporative cooling may be the primary type of cooling; some school districts may choose not to provide air conditioning. In hot, humid climates, it is recommended that air conditioning or dehumidification be operated year-round to prevent the growth of mold and mildew.

The preparation of this chapter is assigned to TC 9.8, Large Building Air-Conditioning Applications.

ENERGY CONSIDERATIONS

Most new buildings and renovated portions of existing buildings must comply with the energy codes and standards enforced by local code officials. Use of energy-efficient equipment, systems, and building envelope materials should always be considered and evaluated. Methods of reducing energy usage should be discussed by the design team.

Outdoor air economizer cycles use cool outdoor air to accommodate high internal loads for many hours of the year, as dry- and wet-bulb temperatures permit. A relief air system sized to remove up to 100% of the outdoor air that could be supplied is required. Some packaged rooftop air-conditioning units do not have adequate relief air outlets, which could lead to overpressurization of the space. Additional relief vents or an exhaust system may be necessary.

Night setback, activated by a time clock controller and controlled by night setback thermostats, conserves energy by resetting the heating and cooling space temperatures during unoccupied hours. Intermittent use of educational facilities sometimes requires that individual systems have their own night setback control times and settings.

Coupled with night setback is **morning warm-up and cool-down**. This allows the space temperatures to be reset for normal occupancy at a predetermined time. This can be achieved either by setting a time clock for approximately one hour before occupancy or through the optimization program of a central energy management system. Such a program determines the warm-up or cool-down time based on the mass of the building, the outdoor air temperature, and a historical log of building occupancy.

Hot water temperature reset can save energy by resetting the building hot water temperature based upon outdoor air temperature. Care must be taken to not lower the water temperature below that recommended by the boiler manufacturer.

During cool weather, **cooling-tower free cooling** uses the cooling towers and either chiller refrigerant migration or a heat exchanger to cool the chilled water system without using the chillers. This system is useful for facilities with high internal heat loads.

Heat recovery systems can save energy when coupled to systems that generate a substantial amount of exhaust air. A study must be performed to determine whether a heat recovery system is cost-effective. Various heat recovery systems include runaround loops, heat wheels, and heat exchangers.

Boiler economizers can save energy by recovering the heat lost in the stacks of large boilers or in central plants. The recovered heat can be used to preheat the boiler makeup water or combustion air. Care should be exercised not to reduce the stack temperature enough to cause condensation. Special stack materials are required for systems in which condensation may occur.

Variable-speed drives for large fans and pumps can save energy, especially if coupled with energy-efficient motors. The

HVAC systems should be evaluated to determine whether there is enough variation in the airflows or water flows to justify the application of these devices. A cost analysis should also be performed.

Passive solar techniques, such as the use of external shading devices at fenestrations, can be incorporated into the building design. Coordination with the owner and design team is essential for this strategy. A life-cycle cost analysis may be necessary to evaluate the cost-effectiveness of this method.

Solar energy systems can either supplement other energy sources or be the sole energy source for an HVAC system. A life-cycle cost analysis should be performed to evaluate the cost-effectiveness of such a system.

DESIGN CONSIDERATIONS

Climate control systems for educational facilities may be similar to those of other types of buildings. To suit the mechanical systems to an educational facility, the designer must understand not only the operation of the various systems but also the functions of the school. Year-round school programs, adult education, night classes, and community functions put ever-increasing demands on these facilities; the environmental control system must be designed carefully to meet these needs. When occupied, classrooms, lecture rooms, and assembly rooms have uniformly dense occupancies. Gymnasiums, cafeterias, laboratories, shops, and similar functional spaces have variable occupancies and varying ventilation and temperature requirements. Many schools use gymnasiums as auditoriums and community meeting rooms. Wide variation in use and occupancy makes flexibility important in these multiuse rooms.

Design considerations for the indoor environment of educational facilities include heat loss, heat gain, humidity, air movement, ventilation methods, ventilation rates, noise, and vibration. Winter and summer design dry-bulb temperatures for the various spaces in schools are given in Table 1. These values should be evaluated for each application to avoid energy waste while ensuring comfort.

Sound levels are also an important consideration in the design of educational facilities. Typical ranges of sound design levels are given in Table 2. Whenever possible and as the budget allows, the design sound level should be at the lower end of these ranges. For additional information, see Chapter 46, Sound and Vibration Control.

Proper ventilation can control odors and inhibit the spread of respiratory diseases. Refer to ASHRAE *Standard* 62 for the ventilation rates required for various spaces within educational facilities.

Equipment for school facilities should be reliable and require minimal maintenance. Equipment location is also an important consideration. The easier equipment is to access and maintain, the more promptly it will be serviced. Roof hatches, ladders, and walkways should be provided for access to rooftop equipment.

Controls. Controls for most educational facilities should be kept as simple as possible because a wide variety of people need to use, understand, and maintain them. The different demands of the various spaces indicate the need for individual controls within each space. However, unless each space is served by its own self-contained unit, this approach is usually not practical. Many times, a group of similar spaces will be served by a single thermostat controlling one heating or cooling unit. Rooms grouped together should have similar occupancy schedules and the same outside wall orientation so that their cooling loads peak at approximately the same time.

Because most facilities are unoccupied at night and on weekends, night setback, boiler optimization, and hot water temperature reset controls are usually incorporated. When setbacks are used, morning warm-up and cool-down controls should be considered. After morning warm-up, automatic controls should change systems from heating to cooling as spaces heat up due to light and occupancy loads.

Table 1 Recommended Winter and Summer Design Dry-Bulb Temperatures for Various Spaces Common in Schools[a]

Space	Winter Design, °C	Summer Design, °C
Laboratories	22	26[d]
Auditoriums, libraries administrative areas, etc.	22	26
Classrooms		
Pre-K through 3rd	24	26
4th through 12th	22	26
Shops	22	26[b]
Locker, shower rooms	24[d]	[c,d]
Toilets	22	[c]
Storage	18	[c,d]
Mechanical rooms	16	[c]
Corridors	20	27[b]

[a]For spaces of high population density and where sensible heat factors are 0.75 or less, lower dry-bulb temperatures will result in generation of less latent heat, which may reduce the need for reheat and thus save energy. Therefore, optimum dry-bulb temperatures should be the subject of detailed design analysis.
[b]Frequently not air conditioned.
[c]Usually not air conditioned.
[d]Provide ventilation for odor control.

Table 2 Typical Ranges of Sound Design Levels

Space	A-Sound Levels, dB	Desired NC (Noise Criteria)
Libraries, classrooms	35-45	30-40
Laboratories, shops	40-50	35-45
Gyms, multipurpose corridors	40-55	35-50
Kitchens	45-55	40-55

Computerized systems are desirable. They can do much more than start and stop equipment; capabilities include resetting water temperatures, optimizing chillers and boilers, and keeping maintenance logs. See Chapter 38, Computer Applications, for more information about computerized management systems. For further information on controls, see Chapter 45.

Preschools

Commercially operated preschools are generally provided with a standard architectural layout based on owner-furnished designs. This may include the HVAC systems and equipment. All preschool facilities require quiet and economical systems. The equipment should be easy to operate and maintain. The design should provide for warm floors and no drafts. Radiant floor heating systems can be highly effective. Consideration should be given to the fact that the children are smaller and will play on the floor, while the teacher is taller and will be walking around. The teacher also requires a place for desk work; the designer should consider treating this area as a separate zone.

Preschool facilities generally operate on weekdays from early in the morning to 6:00 or 7:00 P.M. This schedule usually coincides with the normal working hours of the children's parents. The HVAC systems will therefore operate 12 to 14 hours per work day and be either off or on night setback at night and on weekends.

Supply air outlets should be located so that the floor area is maintained at about 24°C without the introduction of drafts. Both supply and return air outlets should be placed where they will not be blocked by furniture positioned along the walls. Coordination with the architect about the location of these outlets is essential. Proper ventilation is essential for controlling odors and helping prevent the spread of diseases among the children.

The use of floor-mounted heating equipment, such as electric baseboard heaters, should be avoided, as children must be prevented from coming in contact with hot surfaces or electrical devices.

Elementary Schools

Elementary schools are similar to preschools except that they have more facilities, such as gymnasiums and cafeterias. Such facilities are generally occupied from about 7:00 A.M to about 3:00 P.M. Peak cooling loads usually occur at the end of the school day. Peak heating is usually early in the day, when classrooms begin to be occupied and outdoor air is introduced into the facility. The following are facilities found in elementary schools:

Classrooms. Each classroom should at a minimum be heated and ventilated. Air conditioning should be seriously considered for school districts that have year-round classes in warm, humid climates. In humid climates, serious consideration should be given to providing dehumidification during the summer months, when the school is unoccupied, to prevent the growth of mold and mildew. Economizer systems during the winter months, to provide cooling and ventilation after morning warm-up cycles, should also be considered.

Gymnasiums. Gyms may be used after regular school hours for evening classes, meetings, and other functions. There may also be weekend use for group activities. The loads for these occasional uses should be considered when selecting and sizing the systems and equipment. Independent gymnasium HVAC systems with control capability allow for flexibility with smaller part load conditions.

Administrative Areas. The school's office area should be set up for individual control because it is usually occupied after school hours. As the offices are also occupied before school starts in the fall, air conditioning for the area should be considered or provisions should be allowed for the future.

Science Classrooms. Science rooms are now being provided for elementary schools. Although the children do not usually perform experiments, odors may be generated if the teacher demonstrates an experiment or if animals are kept in the classroom. Under these conditions, adequate ventilation for science classrooms is essential along with an exhaust fan with a local on-off switch for the occasional removal of excessive odors.

Libraries. If possible, libraries should be air conditioned to preserve the books and materials stored in them. See Chapter 3, Commercial and Public Buildings, for additional information.

Middle and Secondary Schools

Middle and secondary schools are usually occupied for longer periods of time than elementary schools, and they have additional special facilities. The following are typical special facilities for these schools:

Auditoriums. These facilities require a quiet atmosphere as well as heating, ventilating, and in some cases, air conditioning. Auditoriums are not often used with exception for special assemblies, practice for special programs, and special events. For other considerations see Chapter 4, Places of Assembly.

Computer Classrooms. These facilities have a high sensible heat load due to the computer equipment. Computer rooms may require additional cooling equipment such as small spot-cooling units to offset the additional load. Humidification may also be required. See Chapter 16, Data Processing and Electronic Office Areas, for additional information.

Science Classrooms. Science facilities in middle and secondary schools may require fume hoods with special exhaust systems. A makeup air system may be required if there are several fume hoods within a room. If there are no fume hoods, a room exhaust system is recommended for odor removal, depending on the type of experiments conducted in the room and whether animals are kept within the room. Any associated storage and preparation rooms are generally exhausted continuously to remove odors and vapors emanating from stored materials. The amount of exhaust and the location of exhaust grilles may be dictated by local or National Fire Protection Association (NFPA) codes. See Chapter 13, Laboratories, for further information.

Auto Repair Shops. These facilities require outdoor air ventilation to remove odors and fumes and to provide makeup air for exhaust systems. The shop is usually heated and ventilated but not air conditioned. To contain odors and fumes, return air should not be supplied to other spaces, and the shop should be kept at a negative pressure relative to the surrounding spaces. Special exhaust systems such as welding exhaust or direct-connected carbon monoxide exhaust systems may be required. See Chapter 29, Industrial Local Exhaust Systems, for further information.

Ice Rinks. These facilities require special air-conditioning and dehumidification systems to keep the spectators comfortable, maintain the ice surface at freezing conditions, and prevent the formation of fog at the surface. See Chapter 4, Places of Assembly, and Chapter 34 of the 1998 *ASHRAE Handbook—Refrigeration* for further discussion of these systems.

School Stores. These facilities contain school supplies and paraphernalia and are usually open for short periods of time. The heating and air-conditioning systems serving these areas should be able to be shut off when the store is closed to save energy.

Natatoriums. These facilities, like ice rinks, require special humidity control systems. In addition, special materials of construction are required. See Chapter 4, Places of Assembly, for further information.

Industrial Shops. These facilities are similar to auto repair shops and have special exhaust requirements for welding, soldering, and paint booths. In addition, a dust collection system is sometimes provided and the collected air is returned to the space. Industrial shops have a high sensible load due to the operation of the shop equipment. When calculating loads, the design engineer should consult the shop teacher about the shop operation, and where possible, diversity factors should be applied. See Chapter 29, Industrial Local Exhaust Systems, for more information.

Locker Rooms. Model building codes in the United States require that these facilities be exhausted directly to the outside when they contain toilets and/or showers. They are usually heated and ventilated only. Makeup air is required; the exhaust and makeup air systems should be coordinated and should operate only when required.

Home Economics Rooms. These rooms usually have a high sensible heat load due to appliances such as washing machines, dryers, stoves, ovens, and sewing machines. Different options should be considered for the exhaust of the stoves and dryers. If local codes allow, residential-style range hoods may be installed over the stoves. A central exhaust system could be applied to the dryers as well as to the stoves. If enough appliances are located within the room, a makeup air system may be required. These areas should be maintained at negative pressure in relationship to adjacent classrooms and administrative areas. See Chapter 30, Kitchen Ventilation, for more information.

Colleges and Universities

College and university facilities are similar to those of middle and secondary schools, except that there are more of them, and they may be located in several buildings on the campus. Some colleges and universities have satellite campuses scattered throughout a city or a state. The design criteria for each building are established by the requirements of the users. The following is a list of major facilities commonly found on college and university campuses but not in middle and secondary schools:

Administrative Buildings. These buildings should be treated as office buildings. They usually have a constant interior load and additional part-time loads associated with such spaces as conference rooms.

Animal Facilities. These spaces are commonly associated with laboratories, but usually have their own separate areas. Animal facilities need close temperature control and require a significant amount of outdoor air ventilation to control odors and prevent the spread of disease among the animals. Discussion of animal facilities is found in Chapter 13, Laboratories.

Dormitory Buildings. A discussion of dormitories can be found in Chapter 5, Hotels, Motels, and Dormitories.

Storage Buildings. These buildings are usually heated and ventilated only; however, a portion of the facility may require temperature and humidity control, depending upon the materials stored there.

Student and Faculty Apartment Buildings. A discussion of these facilities can be found in Chapter 5.

Large Gymnasiums. These facilities are discussed in Chapter 4, Places of Assembly.

Laboratory Buildings. These buildings house research facilities and may contain fume hoods, machinery, lasers, animal facilities, areas with controlled environments, and departmental offices. The HVAC systems and controls must be able to accommodate the diverse functions of the facility, which has the potential for 24-hour, year-round operation, and yet be easy to service and quick to repair. Variable air volume (VAV) systems can be used in laboratory buildings, but a proper control system should be applied to introduce the required quantities of outdoor air. Significant energy savings can be achieved by recovering the energy from the exhaust air and tempering the outdoor makeup air. Some other energy-saving systems employed for laboratory buildings are (1) ice storage, (2) economizer cycles, (3) heat reclaim chillers to produce domestic hot water or hot water for booster coils in the summer, and (4) cooling-tower free cooling.

The design engineer should discuss expected contaminants and concentrations with the owner to determine which materials of construction should be used for fume hoods and fume exhaust systems. Backup or standby systems for emergency use should be considered, as should alarms on critical systems. The maintenance staff should be thoroughly trained in the upkeep and repair of all systems, components, and controls. See Chapter 13, Laboratories, for additional information.

Museums. These facilities are discussed in Chapter 20, Museums, Libraries, and Archives.

Central Plants. These facilities contain the generating equipment and other supporting machinery for campus heating and air conditioning. Central plants are generally heated and ventilated only. Central plants are covered in Chapter 11 of the 2000 *ASHRAE Handbook—Systems and Equipment*.

Television and Radio Studios. A discussion of these facilities can be found in Chapter 3, Commercial and Public Buildings.

Hospitals. Hospitals are discussed in Chapter 7, Health Care Facilities.

Chapels. A discussion of these facilities can be found in Chapter 4, Places of Assembly.

Student Unions. These facilities may contain a dining room, a kitchen, meeting rooms, lounges, and game rooms. Student unions are generally open every day from early in the morning to late at night. An HVAC system such as VAV cooling with perimeter heating may be suitable. Extra ventilation air is required as makeup air for the kitchen systems and due to the high occupancy of the building. See Chapter 3, Commercial and Public Buildings, and Chapter 30, Kitchen Ventilation, for additional information.

Lecture Halls. These spaces house large numbers of students for a few hours several times a day and are vacant the rest of the time, so heat loads vary throughout the day. The systems that serve lecture halls must respond to these load variations. In addition, because the rooms are configured such that students at the rear of the room are seated near the ceiling, the systems must be quiet and must not produce any drafts. Coordination with the design team is essential for determining the optimal location of diffusers and return grilles and registers. Placement of the supply diffusers at the front of the room and the return air grilles and registers near the front and rear of the room or under the seats should be considered. An analysis of the system noise levels expected in the hall is recommended. See Chapter 46, Sound and Vibration Control, for further information.

EQUIPMENT AND SYSTEM SELECTION

The architectural configuration of an educational building has a considerable influence on the building's heating and cooling loads and therefore on the selection of its HVAC systems. Other influences on system selection are the budget and whether the project is to expand an existing system or to integrate an HVAC system into the design of a new building. ASHRAE *Standard* 100 has recommendations for energy conservation in existing institutional buildings. ASHRAE *Standard* 90.1 should be followed for the energy-efficient design of new buildings. ASHRAE *Standard* 62 addresses the criteria necessary to meet indoor air quality requirements.

The only trend evident in HVAC design for educational facilities is that air-conditioning systems are being installed whenever possible. In smaller single buildings, systems such as unit ventilators, heat pumps, small rooftop units, and VAV systems are being applied. In larger facilities, VAV systems, large rooftop units with perimeter heating systems, and heat pump systems coupled with central systems are utilized. When rooftop units are used, stairs to the roof or penthouses make maintenance easier.

Single-Duct with Reheat

Reheat systems are restricted from use by ASHRAE *Standard* 90.1 unless recovered energy is used as the reheat medium. Booster heating coils should be considered if the heat is to be applied after mechanical cooling has been turned off or locked out (e.g., during an economizer cycle). The booster heating coil system can use recovered energy to further reduce energy costs.

Multizone

The original multizone design, which simply heated or cooled by individual zones, is seldom used because mixing hot and cold airstreams is not energy-efficient. Multizone system units can be equipped with reset controllers that receive signals from zone thermostats, allowing them to maintain optimum hot and cold temperatures and minimize the mixing of airstreams.

Another energy-conserving technique for a multizone design is the incorporation of a neutral zone that mixes heated or cooled air with return air, but does not mix heated and cooled airstreams. This technique minimizes the energy-wasting practice of simultaneously producing both heating and cooling.

Multizone systems are also available that have individual heating and cooling within each zone, therefore avoiding simultaneous heating and cooling. The zone thermostats energize either the heating system or the cooling system as required.

Replacement multizone units with the energy-saving measures (see the section on Energy Considerations) are also available for existing systems. The replacement of multizone units with VAV systems described in the next section has been successful.

Variable Air Volume

Types of variable air volume systems include single-duct, single-duct with perimeter heating, and dual-duct systems. The supply air volumes from the primary air system are adjusted according to the space load requirements. VAV systems are most often zoned by exposure and occupancy schedules. The primary system usually provides supply air to the zones at a constant temperature either for cooling only or, in the case of dual-duct systems, for heating or cooling. To conserve energy, heating and cooling should not be provided simultaneously to the same zone. Heating should be pro-

vided only during economizer cooling or when mechanical cooling has been turned off or locked out.

Perimeter heating can be provided by duct-mounted heating coils, fan terminal units with duct- or unit-mounted heating coils, perimeter fin tubes, baseboard heaters, cabinet unit heaters, or convectors. Radiant ceiling or floor heating systems can also be applied around the perimeter. Each zone or exposure should be controlled to prevent overheating of the space. Perimeter air-distribution systems should be installed so that drafts are not created.

Fan terminal units are utilized when constant air motion is required. These units operate either constantly or only during heating periods. Noisy units should be avoided. A system of fan terminal units with heating coils allows the primary heating system to be shut off during night setback or unoccupied periods.

Packaged Units

Unit ventilators or through-the-wall packaged units with either split or integral direct-expansion cooling may serve one or two rooms with a common exposure. Heat pumps can also be used. When a single packaged unit covers more than one space, zoning is critical. As is the case for VAV systems, spaces with similar occupancy schedules are grouped together. If exterior spaces are to be served, exterior wall orientation must also match.

For water-source heat pumps, a constant flow of water is circulated to the units. This water is tempered by boilers for heating in the winter or by a fluid cooler provided for heat rejection (cooling). Heat rejection may be necessary for much of the school year, depending upon the internal loads. Certain operating conditions balance the water loop for water-source heat pumps, which could result in periods in which neither primary heating nor cooling is required. There may be simultaneous heating and cooling by different units throughout the facility, depending upon exposure and room loads. A water storage tank may be incorporated into the water loop to store heated water during the day for use at night.

Air-to-air heat pumps are also used in schools, as are small rooftop and self-contained unit ventilators featuring heat pump cycles.

HEALTH CARE FACILITIES

Air Conditioning in the Prevention and Treatment of Disease .. 7.1
HOSPITAL FACILITIES 7.2
Air Quality 7.2
Specific Design Criteria 7.6
Continuity of Service and Energy Concepts 7.10
OUTPATIENT HEALTH CARE FACILITIES 7.11
Diagnostic Clinics 7.11
Treatment Clinics 7.11
NURSING HOME FACILITIES 7.12
Design Concepts and Criteria 7.12
Applicability of Systems 7.12
DENTAL CARE FACILITIES 7.13

CONTINUAL advances in medicine and technology necessitate constant reevaluation of the air-conditioning needs of hospitals and medical facilities. While medical evidence has shown that proper air conditioning is helpful in the prevention and treatment of many conditions, the relatively high cost of air conditioning demands efficient design and operation to ensure economical energy management (Woods et al. 1986, Murray et al. 1988, Demling and Maly 1989, and Fitzgerald 1989).

Health care occupancy classification, based on the latest occupancy guidelines from the National Fire Protection Association (NFPA), should be considered early in the design phase of the project. Health care occupancy is important for fire protection (smoke zones, smoke control) and for the future adaptability of the HVAC system for a more restrictive occupancy.

Health care facilities are becoming increasingly diversified in response to a trend toward outpatient services. The term **clinic** may refer to any building from the ubiquitous residential doctor's office to a specialized cancer treatment center. Prepaid health maintenance provided by integrated regional health care organizations is becoming the model for medical care delivery. These organizations, as well as long-established hospitals, are constructing buildings that look less like hospitals and more like office buildings.

For the purpose of this chapter, health care facilities are divided into the following categories:

- Hospital facilities
- Outpatient health care facilities
- Nursing home facilities
- Dental care facilities

The specific environmental conditions required by a particular medical facility may vary from those in this chapter, depending on the agency responsible for the environmental standard. Among the agencies that may have standards for medical facilities are state and local health agencies, the U.S. Department of Health and Human Services, Indian Health Service, Public Health Service, Medicare/Medicaid, the U.S. Department of Defense, the U.S. Department of Veterans Affairs, and the Joint Commission on Accreditation of Healthcare Organizations. It is advisable to discuss infection control objectives with the hospital's infection control committee.

The general hospital was selected as the basis for the fundamentals outlined in the first section, Hospital Facilities, because of the variety of services it provides. Environmental conditions and design criteria apply to comparable areas in other health facilities.

The general acute care hospital has a core of critical care spaces, including operating rooms, labor rooms, delivery rooms, and a nursery. Usually the functions of radiology, laboratory, central sterile, and the pharmacy are located close to the critical care space. Inpatient nursing, including intensive care nursing, is in the complex. The facility also incorporates an emergency room, a kitchen, dining and food service, a morgue, and central housekeeping support.

Criteria for outpatient facilities are given in the second section, Outpatient Health Care Facilities. Outpatient surgery is performed with the anticipation that the patient will not stay overnight. An outpatient facility may be part of an acute care facility, a freestanding unit, or part of another medical facility such as a medical office building.

Nursing homes are addressed separately in the third section, Nursing Home Facilities, because their fundamental requirements differ greatly from those of other medical facilities.

Dental facilities are briefly discussed in the fourth section, Dental Facilities. Requirements for these facilities differ from those of other health care facilities because many procedures generate aerosols, dusts, and particulates.

The preparation of this chapter is assigned to TC 9.8, Large Building Air-Conditioning Applications.

AIR CONDITIONING IN THE PREVENTION AND TREATMENT OF DISEASE

Hospital air conditioning assumes a more important role than just the promotion of comfort. In many cases, proper air conditioning is a factor in patient therapy; in some instances, it is the major treatment.

Studies show that patients in controlled environments generally have more rapid physical improvement than do those in uncontrolled environments. Patients with thyrotoxicosis do not tolerate hot, humid conditions or heat waves very well. A cool, dry environment favors the loss of heat by radiation and evaporation from the skin and may save the life of the patient.

Cardiac patients may be unable to maintain the circulation necessary to ensure normal heat loss. Therefore, air conditioning cardiac wards and rooms of cardiac patients, particularly those with congestive heart failure, is necessary and considered therapeutic (Burch and Pasquale 1962). Individuals with head injuries, those subjected to brain operations, and those with barbiturate poisoning may have hyperthermia, especially in a hot environment, due to a disturbance in the heat regulatory center of the brain. Obviously, an important factor in recovery is an environment in which the patient can lose heat by radiation and evaporation—namely, a cool room with dehumidified air.

A hot, dry environment of 32°C dry bulb and 35% rh has been successfully used in treating patients with rheumatoid arthritis.

Dry conditions may constitute a hazard to the ill and debilitated by contributing to secondary infection or infection totally unrelated to the clinical condition causing hospitalization. Clinical areas devoted to upper respiratory disease treatment and acute care, as well as the general clinical areas of the entire hospital, should be maintained at a relative humidity of 30 to 60%.

Patients with chronic pulmonary disease often have viscous respiratory tract secretions. As these secretions accumulate and increase in viscosity, the patient's exchange of heat and water dwindles. Under these circumstances, the inspiration of warm,

humidified air is essential to prevent dehydration (Walker and Wells 1961).

Patients needing oxygen therapy and those with tracheotomies require special attention to ensure warm, humid supplies of inspired air. Cold, dry oxygen or the bypassing of the nasopharyngeal mucosa presents an extreme situation. Rebreathing techniques for anesthesia and enclosure in an incubator are special means of addressing impaired heat loss in therapeutic environments.

Burn patients need a hot environment and high relative humidity. A ward for severe burn victims should have temperature controls that permit adjusting the room temperature up to 32°C dry bulb and the relative humidity up to 95%.

HOSPITAL FACILITIES

Although proper air conditioning is helpful in the prevention and treatment of disease, the application of air conditioning to health facilities presents many problems not encountered in the usual comfort conditioning design.

The basic differences between air conditioning for hospitals (and related health facilities) and that for other building types stem from (1) the need to restrict air movement in and between the various departments; (2) the specific requirements for ventilation and filtration to dilute and remove contamination in the form of odor, airborne microorganisms and viruses, and hazardous chemical and radioactive substances; (3) the different temperature and humidity requirements for various areas; and (4) the design sophistication needed to permit accurate control of environmental conditions.

Infection Sources and Control Measures

Bacterial Infection. Examples of bacteria that are highly infectious and transported within air or air and water mixtures are *Mycobacterium tuberculosis* and *Legionella pneumophila* (Legionnaire's disease). Wells (1934) showed that droplets or infectious agents of 5 μm or less in size can remain airborne indefinitely. Isoard et al. (1980) and Luciano (1984) have shown that 99.9% of all bacteria present in a hospital are removed by 90 to 95% efficient filters (ASHRAE *Standard* 52.1). This is because bacteria are typically present in colony-forming units that are larger than 1 μm. Some authorities recommend the use of high efficiency particulate air (HEPA) filters having dioctyl phthalate (DOP) test filtering efficiencies of 99.97% in certain areas.

Viral Infection. Examples of viruses that are transported by and virulent within air are *Varicella* (chicken pox/shingles), *Rubella* (German measles), and *Rubeola* (regular measles). Epidemiological evidence and other studies indicate that many of the airborne viruses that transmit infection are submicron in size; thus, there is no known method to effectively eliminate 100% of the viable particles. HEPA and/or ultra low penetration (ULPA) filters provide the greatest efficiency currently available. Attempts to deactivate viruses with ultraviolet light and chemical sprays have not proven reliable or effective enough to be recommended by most codes as a primary infection control measure. Therefore, isolation rooms and isolation anterooms with appropriate ventilation-pressure relationships are the primary means used to prevent the spread of airborne viruses in the health care environment.

Molds. Evidence indicates that some molds such as *Aspergillis* can be fatal to advanced leukemia, bone marrow transplant, and other immunocompromised patients.

Outdoor Air Ventilation. If outdoor air intakes are properly located, and areas adjacent to outdoor air intakes are properly maintained, outdoor air, in comparison to room air, is virtually free of bacteria and viruses. Infection control problems frequently involve a bacterial or viral source within the hospital. Ventilation air dilutes the viral and bacterial contamination within a hospital. If ventilation systems are properly designed, constructed, and maintained to preserve the correct pressure relations between functional areas, they remove airborne infectious agents from the hospital environment.

Temperature and Humidity. These conditions can inhibit or promote the growth of bacteria and activate or deactivate viruses. Some bacteria such as *Legionella pneumophila* are basically waterborne and survive more readily in a humid environment. Codes and guidelines specify temperature and humidity range criteria in some hospital areas as a measure for infection control as well as comfort.

AIR QUALITY

Systems must also provide air virtually free of dust, dirt, odor, and chemical and radioactive pollutants. In some cases, outside air is hazardous to patients suffering from cardiopulmonary, respiratory, or pulmonary conditions. In such instances, systems that intermittently provide maximum allowable recirculated air should be considered.

Outdoor Intakes. These intakes should be located as far as practical (on directionally different exposures whenever possible), but not less than 9 m, from combustion equipment stack exhaust outlets, ventilation exhaust outlets from the hospital or adjoining buildings, medical-surgical vacuum systems, cooling towers, plumbing vent stacks, smoke control exhaust outlets, and areas that may collect vehicular exhaust and other noxious fumes. The bottom of outdoor air intakes serving central systems should be located as high as practical (3.6 m recommended) but not less than 1.8 m above ground level or, if installed above the roof, 0.9 m above the roof level.

Exhaust Outlets. These exhausts should be located a minimum of 3 m above ground level and away from doors, occupied areas, and operable windows. Preferred location for exhaust outlets is at roof level projecting upward or horizontally away from outdoor intakes. Care must be taken in locating highly contaminated exhausts (e.g., from engines, fume hoods, biological safety cabinets, kitchen hoods, and paint booths). Prevailing winds, adjacent buildings, and discharge velocities must be taken into account (see Chapter 15 of the 1997 *ASHRAE Handbook—Fundamentals*). In critical or complicated applications, wind tunnel studies or computer modeling may be appropriate.

Air Filters. A number of methods are available for determining the efficiency of filters in removing particulates from an airstream (see Chapter 24 of the 2000 *ASHRAE Handbook—Systems and Equipment*). All central ventilation or air-conditioning systems should be equipped with filters having efficiencies no lower than those indicated in Table 1. Where two filter beds are indicated, Filter Bed No. 1 should be located upstream of the air-conditioning equipment, and Filter Bed No. 2 should be downstream of the supply fan, any recirculating spray water systems, and water-reservoir type humidifiers. Appropriate precautions should be observed to prevent wetting of the filter media by free moisture from humidifiers. Where only one filter bed is indicated, it should be located upstream of the air-conditioning equipment. All filter efficiencies are based on ASHRAE *Standard* 52.1.

The following are guidelines for filter installations:

1. HEPA filters having DOP test efficiencies of 99.97% should be used on air supplies serving rooms for clinical treatment of patients with a high susceptibility to infection due to leukemia, burns, bone marrow transplant, organ transplant, or human immunodeficiency virus (HIV). HEPA filters should also be used on the discharge air from fume hoods or safety cabinets in which infectious or highly radioactive materials are processed. The filter system should be designed and equipped to permit safe removal, disposal, and replacement of contaminated filters.
2. All filters should be installed to prevent leakage between the filter segments and between the filter bed and its supporting frame. A small leak that permits any contaminated air to escape through the filter can destroy the usefulness of the best air cleaner.

Table 1 Filter Efficiencies for Central Ventilation and Air-Conditioning Systems in General Hospitals

1	Food preparation areas Laundries Administrative areas Bulk storage Soiled holding areas	25		

[a]Based on ASHRAE *Standard* 52.1.
[b]Based on DOP test.
[c]HEPA filters at air outlets.

3. A manometer should be installed in the filter system to measure the pressure drop across each filter bank. Visual observation is not an accurate method for determining filter loading.
4. High-efficiency filters should be installed in the system, with adequate facilities provided for maintenance without introducing contamination into the delivery system or the area served.
5. Because high-efficiency filters are expensive, the hospital should project the filter bed life and replacement costs and incorporate these into their operating budget.
6. During construction, openings in ductwork and diffusers should be sealed to prevent intrusion of dust, dirt, and hazardous materials. Such contamination is often permanent and provides a medium for the growth of infectious agents. Existing or new filters may rapidly become contaminated by construction dust.

Air Movement

The data given in Table 2 illustrate the degree to which contamination can be dispersed into the air of the hospital environment by one of the many routine activities for normal patient care. The bacterial counts in the hallway clearly indicate the spread of this contamination.

Because of the dispersal of bacteria resulting from such necessary activities, air-handling systems should provide air movement patterns that minimize the spread of contamination. Undesirable airflow between rooms and floors is often difficult to control because of open doors, movement of staff and patients, temperature differentials, and stack effect, which is accentuated by the vertical openings such as chutes, elevator shafts, stairwells, and mechanical shafts common to hospitals. While some of these factors are beyond practical control, the effect of others may be minimized by terminating shaft openings in enclosed rooms and by designing and balancing air systems to create positive or negative air pressure within certain rooms and areas.

Systems serving highly contaminated areas, such as autopsy and infectious isolation rooms, should maintain a negative air pressure within these rooms relative to adjoining rooms or the corridor (Murray et al. 1988). The negative pressure difference is obtained by supplying less air to the area than is exhausted from it (CDC 1994). This

Table 2 Influence of Bedmaking on Airborne Bacterial Count in Hospitals

Item	Count per Cubic Metre

pressure differential causes air to flow into the room through various leakage areas (e.g., the perimeter of doors and windows, utility/fixture penetrations, cracks, etc.) and prevents outward airflow. Protective isolation rooms exemplify positive pressure conditions or opposite conditions. Exceptions to normally established negative and positive pressure conditions include operating rooms where highly infectious patients may be treated (e.g., operating rooms in which bronchoscopy or lung surgery is performed) and infectious isolation rooms that house immunosuppressed patients with airborne infectious diseases such as tuberculosis (TB). These areas should include an anteroom between the operating or isolation room and the corridor or other contiguous space. The anteroom should either be positive to both the room and contiguous space or negative to both the room and the contiguous space, depending on local fire and smoke management regulations. Either technique minimizes cross contamination between the patient area and surrounding areas.

Differential air pressure can be maintained only in an entirely sealed room. Therefore, it is important to obtain a reasonably close fit of all doors and seal all wall and floor penetrations between pressurized areas. This is best accomplished by using weather stripping and drop bottoms on doors. The opening of a door between two areas instantaneously reduces any existing pressure differential between them to such a degree that its effectiveness is nullified. When such openings occur, a natural interchange of air takes place between the two rooms due to turbulence created by the door opening and closing combined with personnel ingress/egress.

For critical areas requiring both the maintenance of pressure differentials to adjacent spaces and personnel movement between the critical area and adjacent spaces, the use of appropriate air locks or anterooms is indicated.

Figure 1 shows the bacterial count in a surgery room and its adjoining rooms during a normal surgical procedure. These bacterial counts were taken simultaneously. The relatively low bacterial counts in the surgery room, compared with those of the adjoining rooms, are attributable to the lower level of activity and higher air pressure within operating rooms.

In general, outlets supplying air to sensitive ultraclean areas should be located on the ceiling, and perimeter or several exhaust outlets should be near the floor. This arrangement provides a downward movement of clean air through the breathing and working zones to the floor area for exhaust. Infectious isolation rooms should have supply air above and near the doorway and exhaust air from near the floor, behind the patient's bed. This arrangement is such that clean air first flows to parts of the room where workers or visitors are likely to be, and then flows across the infectious source and into the exhaust. Thus, noninfected persons are not positioned between the infectious source and the exhaust location (CDC 1994). The bottoms of the return or exhaust openings should be at least 75 mm above the floor.

The laminar airflow concept developed for industrial clean room use has attracted the interest of some medical authorities. There are advocates of both vertical and horizontal laminar airflow systems,

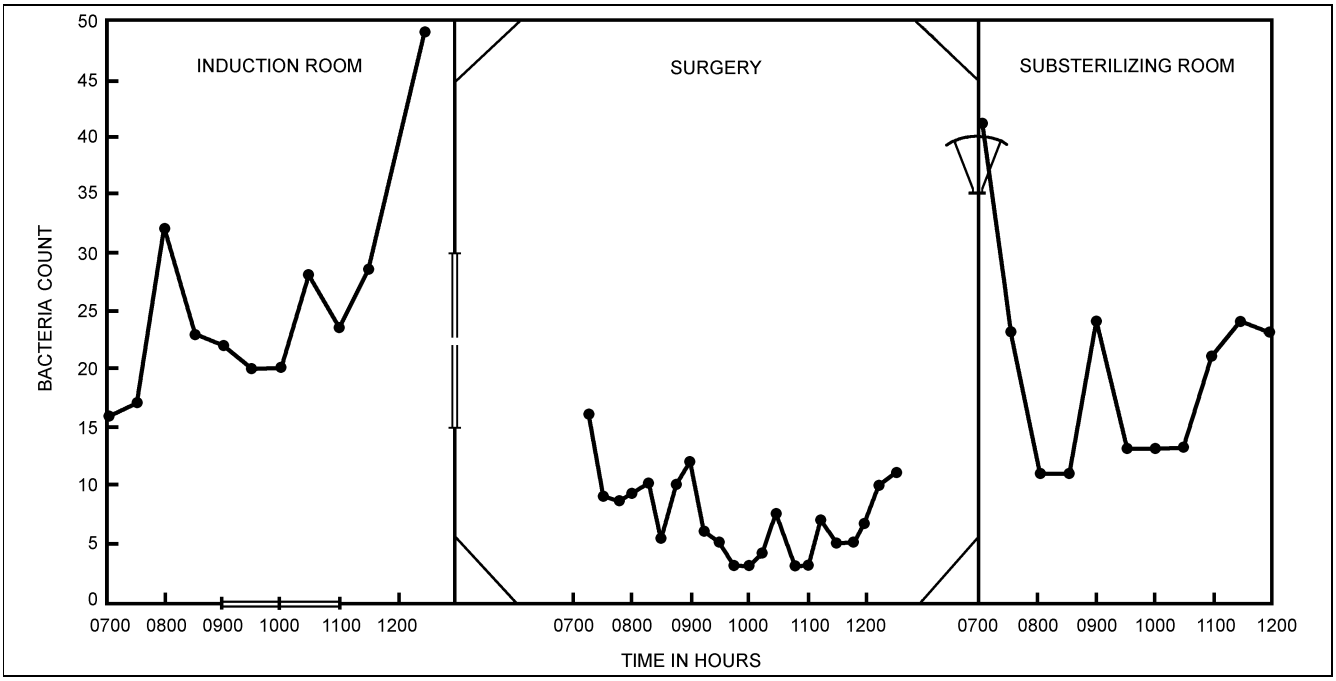

Fig. 1 Typical Airborne Contamination in Surgery and Adjacent Areas

with and without fixed or movable walls around the surgical team (Pfost 1981). Some medical authorities do not advocate laminar airflow for surgeries but encourage air systems similar to those described in this chapter.

Laminar airflow in surgical operating rooms is airflow that is predominantly unidirectional when not obstructed. The unidirectional laminar airflow pattern is commonly attained at a velocity of 0.45 ± 0.10 m/s.

Laminar airflow has shown promise in rooms used for the treatment of patients who are highly susceptible to infection (Michaelson et al. 1966). Among such patients would be the badly burned and those undergoing radiation therapy, concentrated chemotherapy, organ transplants, amputations, and joint replacement.

Temperature and Humidity

Specific recommendations for design temperatures and humidities are given in the next section, Specific Design Criteria. Temperature and humidity for other inpatient areas not covered should be 24°C or less and 30% to 60% rh.

Pressure Relationships and Ventilation

Table 3 covers ventilation recommendations for comfort, asepsis, and odor control in areas of acute care hospitals that directly affect patient care. Table 3 does not necessarily reflect the criteria of the American Institute of Architects (AIA) or any other group. If specific organizational criteria must be met, refer to that organization's literature. Ventilation in accordance with ASHRAE *Standard* 62, Ventilation for Acceptable Indoor Air Quality, should be used for areas where specific standards are not given. Where a higher outdoor air requirement is called for in ASHRAE *Standard* 62 than in Table 3, the higher value should be used. Specialized patient care areas, including organ transplant and burn units, should have additional ventilation provisions for air quality control as may be appropriate.

Design of the ventilation system must as much as possible provide air movement from clean to less clean areas. In critical care areas, constant volume systems should be employed to assure proper pressure relationships and ventilation, except in unoccupied rooms. In noncritical patient care areas and staff rooms, variable air volume (VAV) systems may be considered for energy conservation. When using VAV systems within the hospital, special care should be taken to ensure that minimum ventilation rates (as required by codes) are maintained and that pressure relationships between various spaces are maintained. With VAV systems, a method such as air volume tracking between supply, return, and exhaust could be used to control pressure relationships (Lewis 1988).

The number of air changes may be reduced to 25% of the indicated value, when the room is unoccupied, if provisions are made to ensure that (1) the number of air changes indicated is reestablished whenever the space is occupied, and (2) the pressure relationship with the surrounding rooms is maintained when the air changes are reduced.

In areas requiring no continuous directional control (±), ventilation systems may be shut down when the space is unoccupied and ventilation is not otherwise needed.

Because of the cleaning difficulty and potential for buildup of contamination, recirculating room heating and/or cooling units must not be used in areas marked "No." Note that the standard recirculating room unit may also be impractical for primary control where exhaust to the outside is required.

In rooms having hoods, extra air must be supplied for hood exhaust so that the designated pressure relationship is maintained. Refer to Chapter 13, Laboratories, for further discussion of laboratory ventilation.

For maximum energy conservation, use of recirculated air is preferred. If all-outdoor air is used, an efficient heat recovery method should be considered.

Smoke Control

As the ventilation design is developed, a proper smoke control strategy must be considered. Passive systems rely on fan shutdown, smoke and fire partitions, and operable windows. Proper treatment of duct penetrations must be observed.

Active smoke control systems use the ventilation system to create areas of positive and negative pressures that, along with fire and smoke partitions, limit the spread of smoke. The ventilation system may be used in a smoke removal mode in which the products of

P = Positive N = Negative E = Equal ± = Continuous directional control not required

[a]Where continuous directional control is not required, variations should be minimized, and in no case should a lack of directional control allow the spread of infection from one area to another. Boundaries between functional areas (wards or departments) should have directional control. Lewis (1988) describes methods for maintaining directional control by applying air-tracking controls.

[b]Ventilation in accordance with ASHRAE *Standard* 62, Ventilation for Acceptable Indoor Air Quality, should be used for areas for which specific ventilation rates are not given. Where a higher outdoor air requirement is called for in *Standard* 62 than in Table 3, the higher value should be used.

[c]Total air changes indicated should be either supplied or, where required, exhausted.

[d]Recirculating HEPA filter units used for infection control (without heating or cooling coils) are acceptable.

[e]For operating rooms, 100% outside air should be used only when codes require it and only if heat recovery devices are used.

[f]The term "trauma room" as used here is the first aid room and/or emergency room used for general initial treatment of accident victims. The operating room within the trauma center that is routinely used for emergency surgery should be treated as an operating room.

[g]See section on Patient Rooms for discussion on design of central toilet exhaust systems.

[h]The infectious isolation rooms described in this table are those that might be used for infectious patients in the average community hospital. The rooms are negatively pressurized. Some isolation rooms may have a separate anteroom. Refer to the discussion in the chapter for more detailed information. Where highly infectious respirable diseases such as tuberculosis are to be isolated, increased air change rates should be considered.

[i]Protective isolation rooms are those used for immunosuppressed patients. The room is positively pressurized to protect the patient. Anterooms are generally required and should be negatively pressurized with respect to the patient room.

[j]All air need not be exhausted if darkroom equipment has scavenging exhaust duct attached and meets ventilation standards of NIOSH, OSHA, and local employee exposure limits.

[k]The nonrefrigerated body-holding room is only for facilities that do not perform autopsies on-site and use the space for short periods while waiting for the body to be transferred.

[l]Food preparation centers should have an excess of air supply for positive pressure when hoods are not in operation. The number of air changes may be reduced or varied for odor control when the space is not in use. Minimum total air changes per hour should be that required to provide proper makeup air to kitchen exhaust systems. See Chapter 30, Kitchen Ventilation.

combustion are exhausted by mechanical means. As design of active smoke control systems continues to evolve, the engineer and code authority should carefully plan system operation and configuration. Refer to Chapter 51 and NFPA *Standards* 90A, 92A, 99, and 101.

SPECIFIC DESIGN CRITERIA

There are seven principal divisions of an acute care general hospital: (1) surgery and critical care, (2) nursing, (3) ancillary, (4) administration, (5) diagnostic and treatment, (6) sterilizing and supply, and (7) service. The environmental requirements of each of the departments/spaces within these divisions differ to some degree according to their function and the procedures carried out in them. This section describes the functions of these departments/spaces and covers details of design requirements. Close coordination with health care planners and medical equipment specialists in the mechanical design and construction of health facilities is essential to achieve the desired conditions.

Surgery and Critical Care

No area of the hospital requires more careful control of the aseptic condition of the environment than does the surgical suite. The systems serving the operating rooms, including cystoscopic and fracture rooms, require careful design to reduce to a minimum the concentration of airborne organisms.

The greatest amount of the bacteria found in the operating room comes from the surgical team and is a result of their activities during surgery. During an operation, most members of the surgical team are in the vicinity of the operating table, creating the undesirable situation of concentrating contamination in this highly sensitive area.

Operating Rooms. Studies of operating-room air distribution devices and observation of installations in industrial clean rooms indicate that delivery of the air from the ceiling, with a downward movement to several exhaust inlets located on opposite walls, is probably the most effective air movement pattern for maintaining the concentration of contamination at an acceptable level. Completely perforated ceilings, partially perforated ceilings, and ceiling-mounted diffusers have been applied successfully (Pfost 1981).

Operating room suites are typically in use no more than 8 to 12 h per day (excepting trauma centers and emergency departments). For energy conservation, the air-conditioning system should allow a reduction in the air supplied to some or all of the operating rooms when possible. Positive space pressure must be maintained at reduced air volumes to ensure sterile conditions. The time required for an inactive room to become usable again must be considered. Consultation with the hospital surgical staff will determine the feasibility of this feature.

A separate air exhaust system or special vacuum system should be provided for the removal of anesthetic trace gases (NIOSH 1975). Medical vacuum systems have been used for removal of nonflammable anesthetic gases (NFPA *Standard* 99). One or more outlets may be located in each operating room to permit connection of the anesthetic machine scavenger hose.

Although good results have been reported from air disinfection of operating rooms by irradiation, this method is seldom used. The reluctance to use irradiation may be attributed to the need for special designs for installation, protective measures for patients and personnel, constant monitoring of lamp efficiency, and maintenance.

The following conditions are recommended for operating, catheterization, cystoscopic, and fracture rooms:

1. The temperature set point should be adjustable by surgical staff over a range of 17 to 27°C.
2. Relative humidity should be kept between 45 and 55%.
3. Air pressure should be maintained positive with respect to any adjoining rooms by supplying 15% excess air.
4. Differential pressure indicating device should be installed to permit air pressure readings in the rooms. Thorough sealing of all wall, ceiling, and floor penetrations and tight-fitting doors is essential to maintaining readable pressure.
5. Humidity indicator and thermometers should be located for easy observation.
6. Filter efficiencies should be in accordance with Table 1.
7. Entire installation should conform to the requirements of NFPA *Standard* 99, Health Care Facilities.
8. All air should be supplied at the ceiling and exhausted or returned from at least two locations near the floor (see Table 3 for minimum ventilating rates). Bottom of exhaust outlets should be at least 75 mm above the floor. Supply diffusers should be of the unidirectional type. High-induction ceiling or sidewall diffusers should be avoided.
9. Acoustical materials should not be used as duct linings unless 90% efficient minimum terminal filters are installed downstream of the linings. Internal insulation of terminal units may be encapsulated with approved materials. Duct-mounted sound traps should be of the packless type or have polyester film linings over acoustical fill.
10. Any spray-applied insulation and fireproofing should be treated with fungi growth inhibitor.
11. Sufficient lengths of watertight, drained stainless steel duct should be installed downstream of humidification equipment to assure complete evaporation of water vapor before air is discharged into the room.

Control centers that monitor and permit adjustment of temperature, humidity, and air pressure may be located at the surgical supervisor's desk.

Obstetrical Areas. The pressure in the obstetrical department should be positive or equal to that in other areas.

Delivery Rooms. The design for the delivery room should conform to the requirements of operating rooms.

Recovery Rooms. Postoperative recovery rooms used in conjunction with the operating rooms should be maintained at a temperature of 24°C and a relative humidity between 45 and 55%. Because the smell of residual anesthesia sometimes creates odor problems in recovery rooms, ventilation is important, and a balanced air pressure relative to the air pressure of adjoining areas should be provided.

Nursery Suites. Air conditioning in nurseries provides the constant temperature and humidity conditions essential to care of the newborn in a hospital environment. Air movement patterns in nurseries should be carefully designed to reduce the possibility of drafts.

All air supplied to nurseries should enter at or near the ceiling and be removed near the floor with the bottom of exhaust openings located at least 75 mm above the floor. Air system filter efficiencies should conform to Table 1. Finned tube radiation and other forms of convection heating should not be used in nurseries.

Full-Term Nurseries. A temperature of 24°C and a relative humidity from 30 to 60% are recommended for full-term nurseries, examination rooms, and work spaces. The maternity nursing section should be controlled similarly to protect the infant during visits with the mother. The nursery should have a positive air pressure relative to the work space and examination room, and any rooms located between the nurseries and the corridor should be similarly pressurized relative to the corridor. This prevents the infiltration of contaminated air from outside areas.

Special Care Nurseries. These nurseries require a variable range temperature capability of 24 to 27°C and a relative humidity from 30 to 60%. This type of nursery is usually equipped with individual incubators to regulate temperature and humidity. It is desirable to maintain these same conditions within the nursery proper to accommodate both infants removed from the incubators and those not placed in incubators. The pressurization of special care nurseries should correspond to that of full-term nurseries.

Observation Nurseries. Temperature and humidity requirements for observation nurseries are similar to those for full-term nurseries. Because infants in these nurseries have unusual clinical symptoms, the air from this area should not enter other nurseries. A negative air pressure relative to the air pressure of the workroom should be maintained in the nursery. The workroom, usually located between the nursery and the corridor, should be pressurized relative to the corridor.

Emergency Rooms. Emergency rooms are typically the most highly contaminated areas in the hospital as a result of the soiled condition of many arriving patients and the relatively large number of persons accompanying them. Temperatures and humidities of offices and waiting spaces should be within the normal comfort range.

Trauma Rooms. Trauma rooms should be ventilated in accordance with requirements in Table 3. Emergency operating rooms located near the emergency department should have the same temperature, humidity, and ventilation requirements as those of operating rooms.

Anesthesia Storage Rooms. Anesthesia storage rooms must be ventilated in conformance with NFPA *Standard* 99. However, mechanical ventilation only is recommended.

Nursing

Patient Rooms. When central systems are used to air condition patients' rooms, the recommendations in Tables 1 and 3 for air filtration and air change rates should be followed to reduce cross-infection and to control odor. Rooms used for isolation of infected patients should have all air exhausted directly outdoors. A winter design temperature of 24°C with 30% rh is recommended; 24°C with 50% rh is recommended for summer. Each patient room should have individual temperature control. Air pressure in patient suites should be neutral in relation to other areas.

Most governmental design criteria and codes require that all air from toilet rooms be exhausted directly outdoors. The requirement appears to be based on odor control. Chaddock (1986) analyzed odor from central (patient) toilet exhaust systems of a hospital and found that large central exhaust systems generally have sufficient dilution to render the toilet exhaust practically odorless.

Where room unit systems are used, it is common practice to exhaust through the adjoining toilet room an amount of air equal to the amount of outdoor air brought into the room for ventilation. The ventilation of toilets, bedpan closets, bathrooms, and all interior rooms should conform to applicable codes.

Intensive Care Units. These units serve seriously ill patients, from postoperative to coronary patients. A variable range temperature capability of 24 to 27°C, a relative humidity of 30% minimum and 60% maximum, and positive air pressure are recommended.

Protective Isolation Units. Immunosuppressed patients (including bone marrow or organ transplant, leukemia, burn, and AIDS patients) are highly susceptible to diseases. Some physicians prefer an isolated laminar airflow unit to protect the patient; others are of the opinion that the conditions of the laminar cell have a psychologically harmful effect on the patient and prefer flushing out the room and reducing spores in the air. An air distribution of 15 air changes per hour supplied through a nonaspirating diffuser is often recommended. The sterile air is drawn across the patient and returned near the floor, at or near the door to the room.

In cases where the patient is immunosuppressed but not contagious, a positive pressure should be maintained between the patient room and adjacent area. Some jurisdictions may require an anteroom, which maintains a negative pressure relationship with respect to the adjacent isolation room and an equal pressure relationship with respect to the corridor, nurses' station, or common area. Exam and treatment rooms should be controlled in the same manner. A positive pressure should also be maintained between the entire unit and the adjacent areas to preserve sterile conditions.

When a patient is both immunosuppressed and contagious, isolation rooms within the unit may be designed and balanced to provide a permanent equal or negative pressure relationship with respect to the adjacent area or anteroom. Alternatively, when it is permitted by the jurisdictional authority, such isolation rooms may be equipped with controls that enable the room to be positive, equal, or negative in relation to the adjacent area. However, in such instances, controls in the adjacent area or anteroom must maintain the correct pressure relationship with respect to the other adjacent room(s).

A separate, dedicated air-handling system to serve the protective isolation unit simplifies pressure control and quality (Murray et al. 1988).

Infectious Isolation Unit. The infectious isolation room is used to protect the remainder of the hospital from the patients' infectious diseases. Recent multidrug-resistant strains of tuberculosis have increased the importance of pressurization, air change rates, filtration, and air distribution design in these rooms (Rousseau and Rhodes 1993). Temperatures and humidities should correspond to those specified for patient rooms.

The designer should work closely with health care planners and the code authority to determine the appropriate isolation room design. It may be desirable to provide more complete control, with a separate anteroom used as an air lock to minimize the potential that airborne particulates from the patients' area reach adjacent areas.

Switchable isolation rooms (rooms that can be set to function with either positive or negative pressure) have been installed in many facilities. AIA (1996) and CDC (1994) have, respectively, prohibited and recommend against this approach. The two difficulties associated with this approach are (1) maintaining the mechanical dampers and controls required to accurately provide the required pressures, and (2) that it provides a false sense of security on the part of staff who think that this provision is all that is required to change a room between protective isolation and infectious isolation, to the exclusion of other sanitizing procedures.

Floor Pantry. Ventilation requirements for this area depend on the type of food service adopted by the hospital. Where bulk food is dispensed and dishwashing facilities are provided in the pantry, the use of hoods above equipment, with exhaust to the outdoors, is recommended. Small pantries used for between-meal feedings require no special ventilation. The air pressure of the pantry should be in balance with that of adjoining areas to reduce the movement of air into or out of it.

Labor/Delivery/Recovery/Postpartum (LDRP). The procedures for normal childbirth are considered noninvasive, and rooms are controlled similarly to patient rooms. Some jurisdictions may require higher air change rates than in a typical patient room. It is expected that invasive procedures such as cesarean section are performed in a nearby delivery or operating room.

Ancillary

Radiology Department. Among the factors that affect the design of ventilation systems in these areas are the odorous characteristics of certain clinical treatments and the special construction designed to prevent radiation leakage. The fluoroscopic, radiographic, therapy, and darkroom areas require special attention.

Fluoroscopic, Radiographic, and Deep Therapy Rooms. These rooms require a temperature from 24 to 27°C and a relative humidity from 40 to 50%. Depending on the location of air supply outlets and exhaust intakes, lead lining may be required in supply and return ducts at the points of entry to the various clinical areas to prevent radiation leakage to other occupied areas.

The darkroom is normally in use for longer periods than the X-ray rooms, and it should have an independent system to exhaust the air to the outdoors. The exhaust from the film processor may be connected into the darkroom exhaust.

Laboratories. Air conditioning is necessary in laboratories for the comfort and safety of the technicians (Degenhardt and Pfost 1983). Chemical fumes, odors, vapors, heat from equipment, and the undesirability of open windows all contribute to this need.

Particular attention should be given to the size and type of equipment heat gain used in the various laboratories, as equipment heat gain usually constitutes the major portion of the cooling load.

The general air distribution and exhaust systems should be constructed of conventional materials following standard designs for the type of systems used. Exhaust systems serving hoods in which radioactive materials, volatile solvents, and strong oxidizing agents such as perchloric acid are used should be fabricated of stainless steel. Washdown facilities should be provided for hoods and ducts handling perchloric acid. Perchloric acid hoods should have dedicated exhaust fans.

Hood use may dictate other duct materials. Hoods in which radioactive or infectious materials are to be used must be equipped with ultrahigh efficiency filters at the exhaust outlet and have a procedure and equipment for the safe removal and replacement of contaminated filters. Exhaust duct routing should be as short as possible with a minimum of horizontal offsets. This applies especially to perchloric acid hoods because of the extremely hazardous, explosive nature of this material.

Determining the most effective, economical, and safe system of laboratory ventilation requires considerable study. Where the laboratory space ventilation air quantities approximate the air quantities required for ventilation of the hoods, the hood exhaust system may be used to exhaust all ventilation air from the laboratory areas. In situations where hood exhaust exceeds air supplied, a supplementary air supply may be used for hood makeup. The use of VAV supply/ exhaust systems in the laboratory has gained acceptance but requires special care in design and installation.

The supplementary air supply, which need not be completely conditioned, should be provided by a system that is independent of the normal ventilating system. The individual hood exhaust system should be interlocked with the supplementary air system. However, the hood exhaust system should not shut off if the supplementary air system fails. Chemical storage rooms must have a constantly operating exhaust air system with a terminal fan.

Exhaust fans serving hoods should be located at the discharge end of the duct system to prevent any possibility of exhaust products entering the building. For further information on laboratory air conditioning and hood exhaust systems, see Chapter 13; NFPA *Standard* 99; and Control of Hazardous Gases and Vapors in Selected Hospital Laboratories (Hagopian and Doyle 1984).

The exhaust air from the hoods in the biochemistry, histology, cytology, pathology, glass washing/sterilizing, and serology-bacteriology units should be discharged to the outdoors with no recirculation. Typically, exhaust fans discharge vertically at a minimum of 2.1 m above the roof at velocities up to 20 m/s. The serology-bacteriology unit should be pressurized relative to the adjoining areas to reduce the possibility of infiltration of aerosols that could contaminate the specimens being processed. The entire laboratory area should be under slight negative pressure to reduce the spread of odors or contamination to other hospital areas. Temperatures and humidities should be within the comfort range.

Bacteriology Laboratories. These units should not have undue air movement, so care should be exercised to limit air velocities to a minimum. The sterile transfer room, which may be within or adjoining the bacteriology laboratory, is a room where sterile media are distributed and where specimens are transferred to culture media. To maintain a sterile environment, an ultrahigh efficiency HEPA filter should be installed in the supply air duct near the point of entry to the room. The media room, essentially a kitchen, should be ventilated to remove odors and steam.

Infectious Disease and Virus Laboratories. These laboratories, found only in large hospitals, require special treatment. A minimum ventilation rate of 6 air changes per hour or makeup equal to hood exhaust volume is recommended for these laboratories, which should have a negative air pressure relative to any other area in the vicinity to prevent the exfiltration of any airborne contaminants. The exhaust air from fume hoods or safety cabinets must be sterilized before being exhausted to the outdoors. This may be accomplished by the use of electric or gas-fired heaters placed in series in the exhaust systems and designed to heat the exhaust air to 315°C. A more common and less expensive method of sterilizing the exhaust is to use HEPA filters in the system.

Nuclear Medicine Laboratories. Such laboratories administer radioisotopes to patients orally, intravenously, or by inhalation to facilitate diagnosis and treatment of disease. There is little opportunity in most cases for airborne contamination of the internal environment, but exceptions warrant special consideration.

One important exception involves the use of iodine 131 solution in capsules or vials to diagnose disorders of the thyroid gland. Another involves use of xenon 133 gas via inhalation to study patients with reduced lung function.

Capsules of iodine 131 occasionally leak part of their contents prior to use. Vials emit airborne contaminants when opened for preparation of a dose. It is common practice for vials to be opened and handled in a standard laboratory fume hood. A minimum face velocity of 0.5 m/s should be adequate for this purpose. This recommendation applies only where small quantities are handled in simple operations. Other circumstances may warrant provision of a glove box or similar confinement.

Use of xenon 133 for patient study involves a special instrument that permits the patient to inhale the gas and to exhale back into the instrument. The exhaled gas is passed through a charcoal trap mounted in lead and is often vented outdoors. The process suggests some potential for escape of the gas into the internal environment.

Due to the uniqueness of this operation and the specialized equipment involved, it is recommended that system designers determine the specific instrument to be used and contact the manufacturer for guidance. Other guidance is available in U.S. Nuclear Regulatory Commission Regulatory Guide 10.8 (NRC 1980). In particular, emergency procedures to be followed in case of accidental release of xenon 133 should include temporary evacuation of the area and/or increasing the ventilation rate of the area.

Recommendations concerning pressure relationships, supply air filtration, supply air volume, recirculation, and other attributes of supply and discharge systems for histology, pathology, and cytology laboratories are also relevant to nuclear medicine laboratories. There are, however, some special ventilation system requirements imposed by the NRC where radioactive materials are used. For example, NRC (1980) provides a computational procedure to estimate the airflow necessary to maintain xenon 133 gas concentration at or below specified levels. It also contains specific requirements as to the amount of radioactivity that may be vented to the atmosphere; the disposal method of choice is adsorption onto charcoal traps.

Autopsy Rooms. Susceptible to heavy bacterial contamination and odor, autopsy rooms, which are part of the hospital's pathology department, require special attention. Exhaust intakes should be located both at the ceiling and in the low sidewall. The exhaust system should discharge the air above the roof of the hospital. A negative air pressure relative to adjoining areas should be provided in the autopsy room to prevent the spread of contamination. Where large quantities of formaldehyde are used, special exhaust hoods may be needed to keep concentration below legal maximums.

In smaller hospitals where the autopsy room is used infrequently, local control of the ventilation system and an odor control system with either activated charcoal or potassium permanganate-impregnated activated alumina may be desirable.

Animal Quarters. Principally due to odor, animal quarters (found only in larger hospitals) require a mechanical exhaust system that discharges the contaminated air above the hospital roof. To prevent the spread of odor or other contaminants from the animal quarters to other areas, a negative air pressure of at least 25 Pa relative to adjoining areas must be maintained. Chapter 13 has further information on animal room air conditioning.

Pharmacies. Local ventilation may be required for chemotherapy hoods and chemical storage. Room air distribution and filtration must be coordinated with any laminar airflow benches that may be needed. See Chapter 13, Laboratories, for more information.

Administration

This department includes the main lobby and admitting, medical records, and business offices. Admissions and waiting rooms are areas where there are potential risks of the transmission of undiagnosed airborne infectious diseases. The use of local exhaust systems that move air toward the admitting patient should be considered. A separate air-handling system is considered desirable to segregate this area from the hospital proper because it is usually unoccupied at night.

Diagnostic and Treatment

Bronchoscopy, Sputum Collection, and Pentamidine Administration Areas. These spaces are remarkable due to the high potential for large discharges of possibly infectious water droplet nuclei into the room air. Although the procedures performed may indicate the use of a patient hood, the general room ventilation should be increased under the assumption that higher than normal levels of airborne infectious contaminants will be generated.

Magnetic Resonance Imaging (MRI) Rooms. These rooms should be treated as exam rooms in terms of temperature, humidity, and ventilation. However, special attention is required in the control room due to the high heat release of computer equipment; in the exam room, due to the cryogens used to cool the magnet.

Treatment Rooms. Patients are brought to these rooms for special treatments that cannot be conveniently administered in the patients' rooms. To accommodate the patient, who may be brought from bed, the rooms should have individual temperature and humidity control. Temperatures and humidities should correspond to those specified for patients' rooms.

Physical Therapy Department. The cooling load of the electrotherapy section is affected by the shortwave diathermy, infrared, and ultraviolet equipment used in this area.

Hydrotherapy Section. This section, with its various water treatment baths, is generally maintained at temperatures up to 27°C. The potential latent heat buildup in this area should not be overlooked. The exercise section requires no special treatment, and temperatures and humidities should be within the comfort zone. The air may be recirculated within the areas, and an odor control system is suggested.

Occupational Therapy Department. In this department, spaces for activities such as weaving, braiding, artwork, and sewing require no special ventilation treatment. Recirculation of the air in these areas using medium-grade filters in the system is permissible.

Larger hospitals and those specializing in rehabilitation offer patients a greater diversity of skills to learn and craft activities, including carpentry, metalwork, plastics, photography, ceramics, and painting. The air-conditioning and ventilation requirements of the various sections should conform to normal practice for such areas and to the codes relating to them. Temperatures and humidities should be maintained within the comfort zone.

Inhalation Therapy Department. This department treats pulmonary and other respiratory disorders. The air must be very clean, and the area should have a positive air pressure relative to adjacent areas.

Workrooms. Clean workrooms serve as storage and distribution centers for clean supplies and should be maintained at a positive air pressure relative to the corridor.

Soiled workrooms serve primarily as collection points for soiled utensils and materials. They are considered contaminated rooms and should have a negative air pressure relative to adjoining areas. Temperatures and humidities should be within the comfort range.

Sterilizing and Supply

Used and contaminated utensils, instruments, and equipment are brought to this unit for cleaning and sterilization prior to reuse. The unit usually consists of a cleaning area, a sterilizing area, and a storage area where supplies are kept until requisitioned. If these areas are in one large room, air should flow from the clean storage and sterilizing areas toward the contaminated cleaning area. The air pressure relationships should conform to those indicated in Table 3. Temperature and humidity should be within the comfort range.

The following guidelines are important in the central sterilizing and supply unit:

1. Insulate sterilizers to reduce heat load.
2. Amply ventilate sterilizer equipment closets to remove excess heat.
3. Where ethylene oxide (ETO) gas sterilizers are used, provide a separate exhaust system with terminal fan (Samuals and Eastin 1980). Provide adequate exhaust capture velocity in the vicinity of sources of ETO leakage. Install an exhaust at sterilizer doors and over the sterilizer drain. Exhaust aerator and service rooms. ETO concentration sensors, exhaust flow sensors, and alarms should also be provided. ETO sterilizers should be located in dedicated unoccupied rooms that have a highly negative pressure relationship to adjacent spaces and 10 air changes per hour. Many jurisdictions require that ETO exhaust systems have equipment to remove ETO from exhaust air. See OSHA 29 CFR, Part 1910.
4. Maintain storage areas for sterile supplies at a relative humidity of no more than 50%.

Service

Service areas include dietary, housekeeping, mechanical, and employee facilities. Whether these areas are air conditioned or not, adequate ventilation is important to provide sanitation and a wholesome environment. Ventilation of these areas cannot be limited to exhaust systems only; provision for supply air must be incorporated into the design. Such air must be filtered and delivered at controlled temperatures. The best-designed exhaust system may prove ineffective without an adequate air supply. Experience has shown that reliance on open windows results only in dissatisfaction, particularly during the heating season. The use of air-to-air heat exchangers in the general ventilation system offers possibilities for economical operation in these areas.

Dietary Facilities. These areas usually include the main kitchen, bakery, dietitian's office, dishwashing room, and dining space. Because of the various conditions encountered (i.e., high heat and moisture production and cooking odors), special attention in design is needed to provide an acceptable environment. Refer to Chapter 30 for information on kitchen facilities.

The dietitian's office is often located within the main kitchen or immediately adjacent to it. It is usually completely enclosed to ensure privacy and noise reduction. Air conditioning is recommended for the maintenance of normal comfort conditions.

The dishwashing room should be enclosed and minimally ventilated to equal the dishwasher hood exhaust. It is not uncommon for the dishwashing area to be divided into a soiled area and a clean area. In such cases, the soiled area should be kept at a negative pressure relative to the clean area.

Ventilation of the dining space should conform to local codes. The reuse of dining space air for ventilation and cooling of food preparation areas in the hospital is suggested, provided the reused air is passed through 80% efficient filters. Where cafeteria service is provided, serving areas and steam tables are usually hooded. The air-handling capacities of these hoods should be at least 380 L/s per square metre of perimeter area.

Kitchen Compressor/Condenser Spaces. Ventilation of these spaces should conform to all codes, with the following additional considerations: (1) 220 L/s of ventilating air per compressor kilowatt should be used for units located within the kitchen; (2) condensing units should operate optimally at 32°C maximum ambient temperature; and (3) where air temperature or air circulation is marginal, combination air- and water-cooled condensing units should be specified. It is often worthwhile to use condenser water coolers or remote condensers. Heat recovery from water-cooled condensers should be considered.

Laundry and Linen Facilities. Of these facilities, only the soiled linen storage room, the soiled linen sorting room, the soiled utility room, and the laundry processing area require special attention.

The room provided for storage of soiled linen prior to pickup by commercial laundry is odorous and contaminated and should be well ventilated and maintained at a negative air pressure.

The soiled utility room is provided for inpatient services and is normally contaminated with noxious odors. This room should be exhausted directly outside by mechanical means.

In the laundry processing area, equipment such as washers, flatwork ironers, and tumblers should have direct overhead exhaust to reduce humidity. Such equipment should be insulated or shielded whenever possible to reduce the high radiant heat effects. A canopy over the flatwork ironer and exhaust air outlets near other heat-producing equipment capture and remove heat best. The air supply inlets should be located to move air through the processing area toward the heat-producing equipment. The exhaust system from flatwork ironers and tumblers should be independent of the general exhaust system and equipped with lint filters. Air should exhaust above the roof or where it will not be obnoxious to occupants of other areas. Heat reclamation from the laundry exhaust air may be desirable and practicable.

Where air conditioning is contemplated, a separate supplementary air supply, similar to that recommended for kitchen hoods, may be located in the vicinity of the exhaust canopy over the ironer. Alternatively, spot cooling for the relief of personnel confined to specific areas may be considered.

Mechanical Facilities. The air supply to boiler rooms should provide both comfortable working conditions and the air quantities required for maximum rates of combustion of the particular fuel used. Boiler and burner ratings establish maximum combustion rates, so the air quantities can be computed according to the type of fuel. Sufficient air must be supplied to the boiler room to supply the exhaust fans as well as the boilers.

At workstations, the ventilation system should limit temperatures to 32°C effective temperature. When ambient outside air temperature is higher, indoor temperature may be that of the outside air up to a maximum of 36°C to protect motors from excessive heat.

Maintenance Shops. Carpentry, machine, electrical, and plumbing shops present no unusual ventilation requirements. Proper ventilation of paint shops and paint storage areas is important because of fire hazard and should conform to all applicable codes. Maintenance shops where welding occurs should have exhaust ventilation.

CONTINUITY OF SERVICE AND ENERGY CONCEPTS

Zoning

Zoning—using separate air systems for different departments—may be indicated to (1) compensate for exposures due to orientation or for other conditions imposed by a particular building configuration, (2) minimize recirculation between departments, (3) provide flexibility of operation, (4) simplify provisions for operation on emergency power, and (5) conserve energy.

By ducting the air supply from several air-handling units into a manifold, central systems can achieve a measure of standby capacity. When one unit is shut down, air is diverted from noncritical or intermittently operated areas to accommodate critical areas, which must operate continuously. This or other means of standby protection is essential if the air supply is not to be interrupted by routine maintenance or component failure.

Separation of supply, return, and exhaust systems by department is often desirable, particularly for surgical, obstetrical, pathological, and laboratory departments. The desired relative balance within critical areas should be maintained by interlocking the supply and exhaust fans. Thus, exhaust should cease when the supply airflow is stopped in areas otherwise maintained at positive or neutral pressure relative to adjacent spaces. Likewise, the supply air should be deactivated when exhaust airflow is stopped in spaces maintained at a negative pressure.

Heating and Hot Water Standby Service

The number and arrangement of boilers should be such that when one boiler breaks down or is temporarily taken out of service for routine maintenance, the capacity of the remaining boilers is sufficient to provide hot water service for clinical, dietary, and patient use; steam for sterilization and dietary purposes; and heating for operating, delivery, birthing, labor, recovery, intensive care, nursery, and general patient rooms. However, reserve capacity is not required in climates where a design dry-bulb temperature of –4°C is equaled or exceeded for 99.6% of the total hours in any one heating period as noted in the tables in Chapter 26 of the 1997 *ASHRAE Handbook—Fundamentals*.

Boiler feed pumps, heat circulation pumps, condensate return pumps, and fuel oil pumps should be connected and installed to provide both normal and standby service. Supply and return mains and risers for cooling, heating, and process steam systems should be valved to isolate the various sections. Each piece of equipment should be valved at the supply and return ends.

Some supply and exhaust systems for delivery and operating room suites should be designed to be independent of other fan systems and to operate from the hospital emergency power system in the event of power failure. The operating and delivery room suites should be ventilated such that the hospital facility retains some surgical and delivery capability in cases of ventilating system failure.

Boiler steam is often treated with chemicals that cannot be released in the air-handling units serving critical areas. In this case, a clean steam system should be considered for humidification.

Mechanical Cooling

The source of mechanical cooling for clinical and patient areas in a hospital should be carefully considered. The preferred method is to use an indirect refrigerating system using chilled water or antifreeze solutions. When using direct refrigerating systems, consult codes for specific limitations and prohibitions. Refer to ASHRAE *Standard* 15, Safety Code for Mechanical Refrigeration.

Insulation

All exposed hot piping, ducts, and equipment should be insulated to maintain the energy efficiency of all systems and protect building occupants. To prevent condensation, ducts, casings, piping, and equipment with outside surface temperature below ambient dew point should be covered with insulation having an external vapor barrier. Insulation, including finishes and adhesives on the exterior surfaces of ducts, pipes, and equipment, should have a flame spread rating of 25 or less and a smoke-developed rating of 50 or less, as

determined by an independent testing laboratory in accordance with NFPA *Standard* 255, as required by NFPA 90A. The smoke-developed rating for pipe insulation should not exceed 150 (DHHS 1984a).

Linings in air ducts and equipment should meet the erosion test method described in Underwriters Laboratories *Standard* 181. These linings, including coatings, adhesives, and insulation on exterior surfaces of pipes and ducts in building spaces used as air supply plenums, should have a flame spread rating of 25 or less and a smoke developed rating of 50 or less, as determined by an independent testing laboratory in accordance with ASTM *Standard* E 84.

Duct linings should not be used in systems supplying operating rooms, delivery rooms, recovery rooms, nurseries, burn care units, or intensive care units, unless terminal filters of at least 90% efficiency are installed downstream of linings. Duct lining should be used only for acoustical improvement; for thermal purposes, external insulation should be used.

When existing systems are modified, asbestos materials should be handled and disposed of in accordance with applicable regulations.

Energy

Health care is an energy-intensive, energy-dependent enterprise. Hospital facilities are different from other structures in that they operate 24 h a day year-round, require sophisticated backup systems in case of utility shutdowns, use large quantities of outside air to combat odors and to dilute microorganisms, and must deal with problems of infection and solid waste disposal. Similarly, large quantities of energy are required to power diagnostic, therapeutic, and monitoring equipment; and support services such as food storage, preparation, and service and laundry facilities.

Hospitals conserve energy in various ways, such as by using larger energy storage tanks and by using energy conversion devices that transfer energy from hot or cold building exhaust air to heat or cool incoming air. Heat pipes, runaround loops, and other forms of heat recovery are receiving increased attention. Solid waste incinerators, which generate exhaust heat to develop steam for laundries and hot water for patient care, are becoming increasingly common. Large health care campuses use central plant systems, which may include thermal storage, hydronic economizers, primary/secondary pumping, cogeneration, heat recovery boilers, and heat recovery incinerators.

The construction design of new facilities, including alterations of and additions to existing buildings, has a major influence on the amount of energy required to provide such services as heating, cooling, and lighting. The selection of building and system components for effective energy use requires careful planning and design. Integration of building waste heat into systems and use of renewable energy sources (e.g., solar under some climatic conditions) will provide substantial savings (Setty 1976).

OUTPATIENT HEALTH CARE FACILITIES

An outpatient health care facility may be a free-standing unit, part of an acute care facility, or part of a medical facility such as a medical office building (clinic). Any surgery is performed without anticipation of overnight stay by patients (i.e., the facility operates 8 to 10 h per day).

If physically connected to a hospital and served by the hospital's HVAC systems, spaces within the outpatient health care facility should conform to requirements in the section on Hospital Facilities. Outpatient health care facilities that are totally detached and have their own HVAC systems may be categorized as diagnostic clinics, treatment clinics, or both.

Table 4 Filter Efficiencies for Central Ventilation and Air-Conditioning Systems in Nursing Homes[a]

Area Designation	Minimum Number of Filter Beds	Filter Efficiency of Main Filter Bed, %
Patient care, treatment, diagnostic, and related areas	1	80
Food preparation areas and laundries	1	80
Administrative, bulk storage, and soiled holding areas	1	30

[a]Ratings based on ASHRAE *Standard* 52.1-92.

DIAGNOSTIC CLINICS

A diagnostic clinic is a facility where patients are regularly seen on an ambulatory basis for diagnostic services or minor treatment, but where major treatment requiring general anesthesia or surgery is not performed. Diagnostic clinic facilities have design criteria as shown in Tables 4 and 5 (see the section on Nursing Home Facilities).

TREATMENT CLINICS

A treatment clinic is a facility where major or minor procedures are performed on an outpatient basis. These procedures may render patients incapable of taking action for self-preservation under emergency conditions without assistance from others (NFPA *Standard* 101).

Design Criteria

The system designer should refer to the following paragraphs from the section on Hospital Facilities:

- Infection Sources and Control Measures
- Air Quality
- Air Movement
- Temperature and Humidity
- Pressure Relationships and Ventilation
- Smoke Control

Air-cleaning requirements correspond to those in Table 1 for operating rooms. A recovery area need not be considered a sensitive area. Infection control concerns are the same as in an acute care hospital. The minimum ventilation rates, desired pressure relationships, desired relative humidity, and design temperature ranges are similar to the requirements for hospitals shown in Table 3 except for operating rooms, which may meet the criteria for trauma rooms.

The following departments in a treatment clinic have design criteria similar to those in hospitals:

- Surgical—operating rooms, recovery rooms, and anesthesia storage rooms
- Ancillary
- Diagnostic and Treatment
- Sterilizing and Supply
- Service—soiled workrooms, mechanical facilities, and locker rooms

Continuity of Service and Energy Concepts

Some owners may desire that the heating, air-conditioning, and service hot water systems have standby or emergency service capability and that these systems be able to function after a natural disaster.

To reduce utility costs, facilities should include energy-conserving measures such as recovery devices, variable air volume, load shedding, or devices to shut down or reduce the ventilation of certain areas when unoccupied. Mechanical ventilation should take advantage of outside air by using an economizer cycle, when appropriate, to reduce heating and cooling loads.

Table 5 Pressure Relationships and Ventilation of Certain Areas of Nursing Homes

Function Area	Pressure Relationship to Adjacent Areas	Minimum Air Changes of Outdoor Air per Hour Supplied to Room	Minimum Total Air Changes per Hour Supplied to Room	All Air Exhausted Directly to Outdoors	Air Recirculated Within Room Units
PATIENT CARE					
Patient room	±	2	2	Optional	Optional
Patient area corridor	±	Optional	2	Optional	Optional
Toilet room	N	Optional	10	Yes	No

Bathroom	N	Optional	10	Yes	No

P = Positive N = Negative ± = Continuous directional control not required

The subsection on Continuity of Service and Energy Concepts in the section on Hospital Facilities includes information on zoning and insulation that applies to outpatient facilities as well.

NURSING HOME FACILITIES

Nursing homes may be classified as follows:

Extended care facilities are for the recuperation of hospital patients who no longer require hospital facilities but do require the therapeutic and rehabilitative services of skilled nurses. This type of facility is either a direct hospital adjunct or a separate facility having close ties with the hospital. Clientele may be of any age, usually stay from 35 to 40 days, and usually have only one diagnostic problem.

Skilled nursing homes are for the care of people who require assistance in daily activities; many of them are incontinent and nonambulatory, and some are disoriented. Clientele come directly from home or residential care homes, are generally elderly (with an average age of 80), stay an average of 47 months, and frequently have multiple diagnostic problems.

Residential care homes are generally for elderly people who are unable to cope with regular housekeeping chores but have no acute ailments and are able to care for all their personal needs, lead normal lives, and move freely in and out of the home and the community. These homes may or may not offer skilled nursing care. The average length of stay is four years or more.

Functionally, these buildings have five types of areas that are of concern to the HVAC designer: (1) administrative and supportive areas, inhabited by the staff, (2) patient areas that provide direct normal daily services, (3) treatment areas that provide special medical services, (4) clean workrooms for storage and distribution of clean supplies, and (5) soiled workrooms for collection of soiled and contaminated supplies and for sanitization of nonlaundry items.

DESIGN CONCEPTS AND CRITERIA

Controlling bacteria levels in nursing homes is not as critical as it is in acute care hospitals. Nevertheless, the designer should be aware of the necessity for odor control, filtration, and airflow control between certain areas.

Table 4 lists recommended filter efficiencies for air systems serving specific nursing home areas. Table 5 lists recommended minimum ventilation rates and desired pressure relationships for certain areas in nursing homes.

Recommended interior winter design temperature is 24°C for areas occupied by patients and 21°C for nonpatient areas. Provisions for maintenance of minimum humidity levels in winter depend on the severity of the climate and are best left to the judgment of the designer. Where air conditioning is provided, the recommended interior summer design temperature and humidity is 24°C, and 50% rh.

The general design criteria in the sections on Heating and Hot Water Standby Service, Insulation, and Energy for hospital facilities apply to nursing home facilities as well.

APPLICABILITY OF SYSTEMS

Nursing homes occupants are usually frail, and many are incontinent. Though some occupants are ambulatory, others are bedridden, suffering from the advanced stages of illnesses. The selected HVAC system must dilute and control odors and should not cause drafts. Local climatic conditions, costs, and designer judgment determine the extent and degree of air conditioning and humidification. Odor may be controlled with large volumes of outside air and some form of heat recovery. To conserve energy, odor may be controlled with activated carbon or potassium permanganate-impregnated activated alumina filters instead.

Temperature control should be on an individual room basis. In geographical areas with severe climates, patients' rooms should have supplementary heat along exposed walls. In moderate climates, i.e., where outside winter design conditions are –1°C or above, heating from overhead may be used.

DENTAL CARE FACILITIES

Institutional dental facilities include reception and waiting areas, treatment rooms (called operatories), and workrooms where supplies are stored and instruments are cleaned and sterilized; they may include laboratories where restorations are fabricated or repaired.

Many common dental procedures generate aerosols, dusts, and particulates (Ninomura and Byrns 1998). The aerosols/dusts may contain microorganisms (both pathogenic and nonpathogenic), metals (such as mercury fumes), and other substances (e.g., silicone dusts, latex allergens, etc.). Some measurements indicate that levels of bioaerosols during and immediately following a procedure can be extremely high (Earnest and Loesche 1991). Lab procedures have been shown to generate dusts and aerosols containing metals. At this time, only limited information and research is available regarding the level, nature, or persistence of bioaerosol and particulate contamination in dental facilities.

Nitrous oxide is used as an analgesic/anesthetic gas in many facilities. The design for the control of nitrous oxide should consider (1) that nitrous oxide is heavier than air and may accumulate near the floor if air mixing is inefficient, and (2) that nitrous oxide be exhausted directly outside. NIOSH (1996) includes recommendations for the ventilation/exhaust system.

FIXED GUIDEWAY VEHICLE AIR CONDITIONING 8.10

AUTOMOBILE AIR CONDITIONING

ENVIRONMENTAL control in modern automobiles consists of one or more of the following systems: (1) heater-defroster, (2) ventilation, and (3) cooling and dehumidifying (air-conditioning). All passenger cars sold in the United States must meet federal defroster requirements, so ventilation systems and heaters are included in the basic vehicle design. The integration of the heater-defroster and ventilation systems is common. Air conditioning remains an extra-cost option on many vehicles.

Heating

Outdoor air passes through a heater core, using engine coolant as a heat source. To avoid visibility-reducing condensation on the glass due to raised air dew point from occupant respiration and interior moisture gains, interior air should not recirculate through the heater.

Temperature control is achieved by either water flow regulation or heater air bypass and subsequent mixing. A combination of ram effect from forward movement of the car and the electrically driven blower provides the airflow.

Heater air is generally distributed into the lower forward compartment, under the front seat, and up into the rear compartment. Heater air exhausts through body leakage points. At higher vehicle speeds, the increased heater air quantity (ram assist through the ventilation system) partly compensates for the infiltration increase. Air exhausters are sometimes installed to increase airflow and reduce the noise of air escaping from the car.

The heater air distribution system is usually adjustable between the diffusers along the floor and on the dashboard. Supplementary ducts are sometimes required when consoles, panel-mounted air conditioners, or rear seat heaters are installed. Supplementary heaters are frequently available for third-seat passengers in station wagons and for the rear seats in limousines and luxury sedans.

Defrosting

Some heated outdoor air is ducted from the heater core to defroster outlets at the base of the windshield. This air absorbs moisture from the interior surface of the windshield and raises the glass temperature above the interior dew point. Induced outdoor air has a lower dew point than the air inside the vehicle, which absorbs moisture from the occupants and car interior. Heated air provides the energy necessary to melt or sublime ice and snow from the glass exterior. The defroster air distribution pattern on the windshield is developed by test for conformity with federal standards, satisfactory distribution, and rapid defrost.

Most automobiles operate the air-conditioning compressor to dry the induced outdoor air and/or to prevent a wet evaporator from increasing the dew point when the compressor is disengaged. Some vehicles are equipped with side window demisters that direct a small amount of heated air and/or air with lowered dew point to the front side windows. Rear windows are defrosted primarily by heating wires embedded in the glass.

Ventilation

Fresh air is introduced either by (1) ram air or (2) forced air. In both systems, air enters the vehicle through a screened opening in the cowl just forward of the base of the windshield. The cowl plenum is usually an integral part of the vehicle structure. Air entering this plenum can also supply the heater and evaporator cores.

In the ram air system, ventilation air flows back and up toward the front seat occupants' laps and then over the remainder of their bodies. Additional ventilation occurs by turbulence and air exchange through open windows. Directional control of ventilation air is frequently unavailable. Airflow rate varies with relative wind-vehicle velocity but may be adjusted with windows or vents.

Forced air ventilation is available in many automobiles. The cowl inlet plenum and heater/air-conditioning blower are used together with instrument panel outlets for directional control. Positive air pressure from the ventilation fan or blower helps reduce the amount of exterior pollutants entering the passenger compartment. In air-conditioned vehicles, the forced air ventilation system uses the air-conditioning outlets. Body air exhausts and vent windows exhaust air from the vehicle. With the increased popularity of air conditioning and forced ventilation, most late model vehicles are not equipped with vent windows.

Air Conditioning

Air conditioners are installed either with a combination evaporator-heater or as an add-on system. The combination evaporator-heater in conjunction with the ventilation system is the prevalent type of factory-installed air conditioning. This system is popular because (1) it permits dual use of components such as blower motors, outdoor air ducts, and structure; (2) it permits compromise standards where space considerations dictate (ventilation reduction on air-conditioned cars); (3) it generally reduces the number and complexity of driver controls; and (4) it typically features capacity control innovations such as automatic reheat.

Outlets in the instrument panel distribute air to the car interior. These are individually adjustable, and some have individual shut-offs. The dashboard end outlets are for the driver and front seat passenger; center outlets are primarily for rear seat passengers.

The dealer-installed add-on air conditioner is normally available only as a service or after-market installation. In recent designs, the air outlets, blower, and controls built into the automobile are used. Evaporator cases are styled to look like factory-installed units. These units are integrated with the heater as much as possible to provide outdoor air and to take advantage of existing air-mixing

The preparation of this chapter is assigned to TC 9.3, Transportation Air Conditioning.

dampers. Where it is not possible to use existing air ducts, custom ducts distribute the air in a manner similar to those in factory-installed units. On occasion, rather than installing a second duct, the dealer will create a slot in the existing duct to accept an evaporator.

As most of the air for the rear seat occupants flows through the center outlets of the front evaporator unit, a passenger in the center of the front seat impairs rear seat cooling. Supplemental trunk units for luxury sedans and roof units for station wagons improve the cooling of rear seat passengers.

The trunk unit is a blower-evaporator, complete with expansion valve, installed in the trunk of limousines and premium line vehicles. The unit uses the same high-side components as the front evaporator unit. Most auxiliary or rear units recirculate air from the passenger compartment.

DESIGN FACTORS

General considerations for design include ambient temperatures and contaminants, vehicle and engine concessions, flexibility, physical parameters, durability, electrical power, refrigeration capacity, occupants, infiltration, insulation, solar effect, and noise.

Ambient and Vehicle Criteria

Ambient Temperature. Heaters are evaluated for performance at temperatures from –40 to 21°C. Air-conditioning systems with reheat are evaluated from 4 to 43°C; add-on units are evaluated from 10 to 38°C, although ambient temperatures above 52°C are occasionally encountered. Because the system is an integral part of the vehicle detail, the effects of vehicle heat and local heating must be considered.

Ambient Contaminants. Airborne bacteria, pollutants, and corrosion agents must also be considered when selecting materials for seals and heat exchangers. Electronic air cleaners and filters have been installed in premium automobiles.

Vehicle Performance. Proper engine coolant temperature, freedom from gasoline vapor lock, adequate electrical charging system, acceptable vehicle ride, minimum surge due to compressor clutch cycling, and good handling must be maintained.

Flexibility. Engine coolant pressure at the heater core inlet ranges up to 280 kPa (gage) in cars and 380 kPa on trucks. The engine coolant thermostat remains closed until coolant temperature reaches 71 to 96°C. Coolant flow is a function of pressure differential and system restriction but ranges from 40 mL/s at idle to 630 mL/s at 100 km/h (lower for water valve regulated systems because of the added restriction).

Present-day antifreeze coolant solutions have specific heats from 2.7 to 4.2 kJ/(kg·K) and boiling points from 121 to 133°C (depending on concentration) when a 100 kPa radiator pressure cap is used.

Multiple-speed (usually four-speed) blowers supplement the ram air effect through the ventilation system and produce the necessary velocities for distribution. Heater air quantities range from 60 to 90 L/s. Defroster air quantities range from 42 to 68 L/s. Other considerations are (1) compressor/engine speed, from 8.3 to 92 rev/s; (2) drive ratio, from 0.89:1 to 1.41:1; (3) condenser air, from 10 to 50°C and from 150 to 1400 L/s (corrected for restriction and distribution factors); and (4) evaporator air, from 50 to 190 L/s (limits established by design but selective at operator's discretion) and from 2 to 66°C.

Physical Parameters

Parameters include engine rock, proximity to adverse environments, and durability.

Engine Rock. Relative to the rest of the car, the engine moves both fore and aft because of inertia and in rotation because of torque. Fore and aft movement may be as much as 6 mm; rotational movements at the compressor may be as much as 20 mm due to acceleration and 13 mm due to deceleration.

Proximity to Adverse Environments. Wiring, refrigerant lines, hoses, vacuum lines, and so forth, must be protected from exhaust manifold heat and sharp edges of sheet metal. Normal service items such as oil filler caps, power steering filler caps, and transmission dipsticks must be accessible. Air-conditioning components should not have to be removed for servicing other components.

Durability. Hours of operation are short compared to commercial systems (260 000 km ÷ 65 km/h = 4000 h), but the shock and vibration the vehicle receives or produces must not cause a malfunction or failure.

Equipment is designed to meet the recommendations of SAE *Recommended Practice* J 639, which states that the burst strength of those components subjected to high-side refrigerant pressure must be at least 2.5 times the venting pressure (or pressure equivalent to venting temperature) of the relief device. SAE J 639 also requires electrical cut-out of the clutch coil prior to pressure relief to prevent unnecessary refrigerant discharge. Components for the low-pressure side frequently have burst strengths in excess of 2 MPa. The relief device should be located as close as possible to the discharge gas side of the compressor, preferably in the compressor itself.

Power and Capacity

Fan size is kept to a minimum not only to save space and reduce weight, but also to reduce energy consumption. If a standard vehicle has a heater that draws 10 A, and the air conditioner requires 20 A, the alternator and wiring must be redesigned to supply this additional 10 A, with obvious cost and weight penalties.

The refrigeration capacity must be adequate to reduce the vehicle interior to a comfortable temperature quickly and then to maintain the selected temperature at reasonable humidity during all operating conditions and environments. A design may be established by mathematical modeling or empirical evaluation of all the known and predicted factors. A design tradeoff in capacity is sought relative to the vehicle's weight, component size, and fuel economy needs.

Occupancy per unit volume is high in automotive applications. The air conditioner (and auxiliary evaporators and systems) must be matched to the intended vehicle occupancy.

Other Concerns

Infiltration varies with relative wind-vehicle velocity. It also varies with assembly quality. Body sealing is part of air-conditioning design for automobiles. Occasionally, sealing beyond that required for dust, noise, and draft control is required.

Due to cost, insulation is seldom added to reduce thermal load. Insulation for sound control is generally considered adequate. Roof insulation is of questionable benefit, as it retards heat loss during the nonoperating, or soak, periods. Additional dashboard and floor insulation helps reduce cooling load. Typical maximum ambient temperatures are 90°C above mufflers and catalytic converters, 50°C for other floor areas, 63°C for dash and toe board, and 43°C for sides and top. The following three solar effects add to the cooling load:

Vertical. Maximum intensity occurs at or near noon. Solar heat gain through all glass surface area normal to the incident light is a substantial fraction of the cooling load.

Horizontal and Reflected Radiation. The intensity is significantly less, but the glass area is large enough to merit consideration.

Surface Heating. The temperature of the surface is a function of the solar energy absorbed, the interior and ambient temperatures, and the automobile's velocity.

The temperature control should not produce objectionable sounds. During maximum heating or cooling operation, a slightly higher noise level is acceptable. Thereafter, it should be possible to maintain comfort at a lower blower speed with an acceptable noise level. Compressor-induced vibrations, gas pulsations, and noise

must be kept to a minimum. Suction and discharge mufflers are often used to reduce noise. Belt-induced noises, engine torsional vibration, and compressor mounting all require particular attention.

COMPONENTS

Compressors

Scroll and piston compressors are used in mobile applications. They have the following characteristics:

Displacement. Fixed displacement compressors have displacements of 0.1 to 0.2 L/rev. Variable displacement compressors have a minimum displacement of about 0.016 L/rev, about 10% of their maximum displacement. A typical variable capacity scroll compressor has a maximum displacement of 0.12 L/rev and a minimum displacement of just 3% of the maximum.

Physical Size. Fuel economy, lower hood lines, and more engine accessories all decrease compressor installation space. These features, along with the fact that smaller engines have less accessory power available, promote the use of smaller compressors.

Speed Range. Because compressors are belt driven directly from the engine, they must withstand speeds of over 100 rev/s and remain smooth and quiet down to 8.3 rev/s. In the absence of a variable drive ratio, there are instances when the maximum compressor speed may need to be higher in order to achieve sufficient pumping capacity at idle.

Torque Requirements. Because torque pulsations cause or aggravate vibration problems, it is best to minimize them. Minimizing peak torque benefits the compressor drive and mount systems. Multicylinder reciprocating and rotary compressors aid in reducing vibration. An economical single-cylinder compressor reduces cost; however, any design must reduce peak torques and belt loads, which would normally be at a maximum in a single-cylinder design.

Compressor Drives. A magnetic clutch, energized by power from the car engine electrical system, drives the compressor. The clutch is always disengaged when air conditioning is not required. The clutch can also be used to control evaporator temperature (see the section on Controls).

Variable Displacement Compressors. Wobble plate compressors are used for automobile air conditioning. The angle of the wobble plate changes in response to the evaporator and discharge pressure to achieve a constant suction pressure just above freezing, regardless of load. A bellows valve or electronic sensor-controlled valve routes internal gas flow to control the wobble plate.

Refrigerants and Lubricants

New Vehicles. The phaseout of R-12 has led to the use of non-CFC alternatives in vehicles. The popular choice is R-134a because its physical and thermodynamic properties closely match those of R-12. Because its miscibility with mineral oil is poor, R-134a requires the use of synthetic lubricants such as polyalkylene glycol (PAG) or polyol ester (POE). PAGs are currently preferred. These lubricants—especially PAGs—are more hygroscopic than mineral oil; production and service procedures must emphasize the need for system dehydration and limited exposure of the lubricants to atmospheric moisture.

Older Vehicles. Vehicles originally equipped with R-12 do not require retrofit to another refrigerant as long as an affordable supply of new or reclaimed R-12 exists. When circumstances require it, most air conditioners can be modified to use R-134a and POE. When PAG oil is used in a retrofit, the remaining mineral oil should be removed to levels established by the original equipment manufacturer to prevent residual chlorides from breaking down the PAG.

R-22 is not suitable for topping off or retrofit in R-12 systems, as it will produce unacceptable discharge pressures (up to 4.5 MPa at idle) and temperatures. R-12 idle discharge pressures can reach 3.1 MPa; in addition, it may be incompatible with the elastomeric seals and hose materials.

Several blends of two or more refrigerants are being sold as "drop-in" replacements for R-12. They should not be used without a thorough investigation of their effect on performance and reliability under all operating conditions. Other concerns include (1) flammability, (2) fractionation, (3) evaporator temperature glide, (4) increased probability of adding the wrong refrigerant or oil in future service, and (5) compounded complexity of refrigerant reclaim.

Condensers

Condensers must be properly sized. High discharge pressures reduce the compressor capacity and increase power requirements. When the condenser is in series with the radiator, the air restriction must be compatible with the engine cooling fan and engine cooling requirements. Generally, the most critical condition occurs at engine idle under high load conditions. An undersized condenser can raise head pressures sufficiently to stall small displacement engines.

Automotive condensers must meet internal and external corrosion, pressure cycle, burst, and vibration requirements. They may be of the following designs: (1) tube-and-fin with mechanically bonded fins, (2) serpentine tube with brazed, multilouvered fins, and (3) header extruded tube brazed to multilouvered fins. Aluminum is popular for its low cost and mass.

An oversized condenser may produce condensing temperatures significantly below the engine compartment temperature. This can result in evaporation of refrigerant in the liquid line where the liquid line passes through the engine compartment (the condenser is ahead of the engine and the evaporator is behind it). Engine compartment air has not only been heated by the condenser but by the engine and radiator as well. Typically, this establishes a minimum condensing temperature of 17 K above ambient.

Liquid flashing occurs more often at reduced load, when the liquid line velocity decreases, allowing the liquid to be heated above saturation temperature before reaching the expansion valve. This is more apparent on cycling systems than on systems that have a continuous liquid flow. Liquid flashing is audibly detected as gas enters the expansion valve. This problem can be reduced by adding a subcooler or additional fan power to the condenser.

Condensers generally cover the entire radiator surface to prevent air bypass. Accessory systems designed to fit several different cars are occasionally over-designed. Internal pressure drop should be minimized to reduce power requirements. Condenser-to-radiator clearances as low as 6 mm have been used, but 13 mm is preferable. Primary-to-secondary surface area ratio varies from 8:1 to 16:1. Condensers are normally painted black so that they are not visible through the vehicle's grille.

A condenser ahead of the engine-cooling radiator not only restricts air but also heats the air entering the radiator. The addition of air conditioning requires supplementing the engine cooling system. Radiator capacity is increased by adding fins, depth, or face area or by raising pump speed to increase coolant flow. Pump cavitation at high speeds is a limiting factor. Also, increased coolant velocity may cause excessive tube erosion. In the case of direct fan drive, increasing the speed of the water pump increases the engine cooling fan speed, which not only supplements the engine cooling system but also provides more air for the condenser.

When air conditioning is installed in an automobile, fan size, number of blades, and blade width and pitch are frequently increased, and fan shrouds are often added. Increases in fan speed, diameter, and pitch raise the noise level and power consumption. Temperature- and torque-sensitive drives (viscous drives or couplings) or flex-fans reduce these increases in noise and power. They rely on the airflow produced by the forward motion of the car to reduce the amount of air the radiator fan must move to maintain adequate coolant temperatures. As vehicle speed increases, fan requirements drop.

Front-wheel-drive vehicles typically have electric motor-driven cooling fans. Some vehicles also have a side-by-side condenser and radiator, each with its own motor-driven fan.

Evaporators

Current automotive evaporator materials and construction include (1) copper or aluminum tube and aluminum fin, (2) brazed aluminum plate and fin, and (3) brazed serpentine tube and fin. Design parameters include air pressure drop, capacity, and condensate carryover. Fin spacing must permit adequate condensate drainage to the drain pan below the evaporator.

Condensate must drain outside the vehicle. At road speeds, the vehicle exterior is generally at a higher pressure than the interior by 250 to 500 Pa. Drains are usually on the high-pressure side of the blower; they sometimes incorporate a trap and are as small as possible. Drains can become plugged not only by contaminants but also by road splash. Vehicle attitude (slope of the road and inclines), acceleration, and deceleration must be considered when designing condensate systems.

High refrigerant pressure loss in the evaporator requires externally equalized expansion valves. A bulbless expansion valve, which provides external pressure equalization without the added expense of an external equalizer, is available. The evaporator must provide stable refrigerant flow under all operating conditions and have sufficient capacity to ensure rapid cool-down of the vehicle after it has been standing in the sun.

The conditions affecting evaporator size and design are different from those in residential and commercial installations in that the average operating time, from a hot-soaked condition, is less than 20 min. Inlet air temperature at the start of the operation can be as high as 65°C, and it decreases as the duct system is ventilated. In a recirculating system, the temperature of inlet air decreases as the car interior temperature decreases; in a system using outdoor air, inlet air temperature decreases to a few degrees above ambient (perpetual heating by the duct system). During longer periods of operation, the system is expected to cool the entire vehicle interior rather than just produce a flow of cool air.

During sustained operation, vehicle occupants want less air noise and velocity, so the air quantity must be reduced; however, sufficient capacity must be preserved to maintain satisfactory interior temperatures. Ducts must be kept as short as possible and should be insulated from engine compartment and solar-ambient heat loads. Thermal lag resulting from the added heat sink of ducts and housings increases cool-down time.

Filters and Hoses

Air filters are not common. Coarse screening prevents such objects as facial tissues, insects, and leaves from entering fresh-air ducts. Studies show that wet evaporator surfaces reduce the pollen count appreciably. In one test, an ambient of 23 to 96 mg/mm^3 showed 53 mg/mm^3 in a non-air-conditioned car and less than 3 mg/mm^3 in an air-conditioned car. Rubber hose assemblies are installed where flexible refrigerant transmission connections are needed due to relative motion between components or because stiffer connections cause installation difficulties and noise transmission. Refrigerant effusion through the hose wall is a design concern. Effusion occurs at a reasonably slow and predictable rate that increases as pressure and temperature increase. Hose with a nylon core is less flexible (pulsation dampening), has a smaller OD, is generally cleaner, and allows practically no effusion. It is recommended for Refrigerant 134a.

Heater Cores

The heat transfer surface in an automotive heater is generally either copper/brass cellular, aluminum tube and fin, or aluminum brazed tube and center. Each of these designs can currently be found in production in either straight-through or U-flow designs. The basics of each of the designs are outlined below.

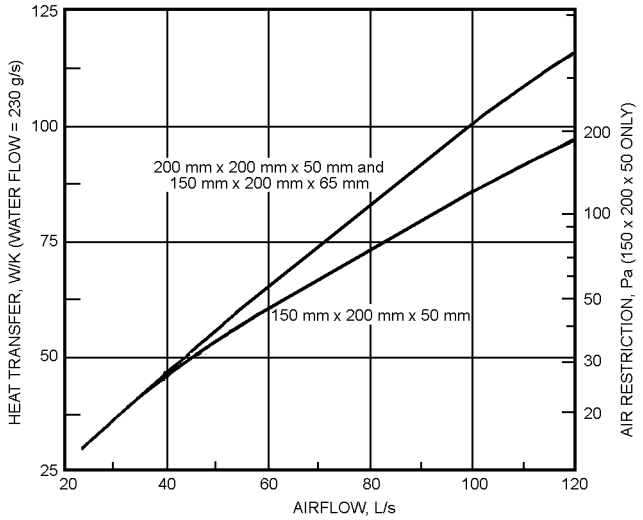

Fig. 1 Typical Copper-Brass Cellular Heater Core Capacity

The copper/brass cellular design (Figure 1) uses brass tube assemblies (0.15 to 0.4 mm) as the water course and convoluted copper fins (0.08 to 0.2 mm) held together with a lead-tin solder. The tanks and connecting pipes are usually brass (0.66 to 0.86 mm) and again are attached to the core by a lead-tin solder. Capacity is adjusted by varying the face area of the core to increase or decrease the heat transfer surface area.

The aluminum tube and fin design generally uses round copper or aluminum tubes mechanically joined to aluminum fins. U-tubes can take the place of a conventional return tank. The inlet/outlet tank and connecting pipes are generally plastic and clinched onto the core with a rubber gasket. Capacity can be adjusted by varying face area, adding coolant-side turbulators, or varying air-side surface geometry for turbulence and air restriction.

The aluminum brazed tube and center design uses flat aluminum tubes and convoluted fins or centers as the heat transfer surface. Tanks can be either plastic and clinched onto the core or aluminum and brazed to the core. Connecting pipes can be constructed of various materials and attached to the tanks a number of ways, including brazing, clinching with an o-ring, fastening with a gasket, and so forth. Capacity can be adjusted by varying face area, core depth, or air-side surface geometry.

Receiver-Drier Assembly

The receiver-drier assembly accommodates charge fluctuations from changes in system load (refrigerant flow and density). It accommodates an overcharge of refrigerant (0.25 to 0.5 kg) to compensate for system leaks and hose effusion. The assembly houses the high-side filter and desiccant. Several types of desiccant are used, the most common of which is spherical molecular sieves; silica gel is occasionally used. Mechanical integrity (freedom from powdering) is important because of the vibration to which the assembly is exposed. For this reason, molded desiccants have not obtained wide acceptance.

Moisture retention at elevated temperatures is also important. The rate of release with temperature increase and the reaction while accumulating high concentration should be considered. Design temperatures of at least 60°C should be used.

The receiver-drier often houses a sight glass that allows visual inspection of the system charge level. It houses safety devices such as fusible plugs, rupture disks, or high-pressure relief valves. High-pressure relief valves are gaining increasing acceptance because they do not vent the entire charge. Location of the relief devices is

important. Vented refrigerant should be directed so as not to endanger personnel.

Receivers are usually (though not always) mounted on or near the condenser. They should be located so that they are ventilated by ambient air. Pressure drops should be minimal.

Expansion Valves

Thermostatic expansion valves (TXVs) control the flow of refrigerant through the evaporator. These are applied as shown in Figures 4, 5, and 6. Both liquid- and gas-charged power elements are used. Internally and externally equalized valves are used as dictated by system design. Externally equalized valves are necessary where high evaporator pressure drops exist. A bulbless expansion valve, usually block-style, that senses evaporator outlet pressure without the need for an external equalizer, is now widely used. There is a trend toward variable compressor pumping rate expansion valves.

Orifice Tubes

An orifice tube instead of an expansion valve has come into widespread use to control refrigerant flow through the evaporator, primarily due to its lower cost. Components must be matched to obtain proper performance. Even so, under some conditions liquid refrigerant floods back to the compressor with this device. Chapter 45 of the 1998 *ASHRAE Handbook—Refrigeration* covers the design of orifice tubes.

Suction Line Accumulators

A suction line accumulator is required with an orifice tube to ensure uniform return of refrigerant and oil to the compressor to prevent slugging and to cool the compressor. It also stores excess refrigerant. A typical suction line accumulator is shown in Figure 2. A bleed hole at the bottom of the standpipe meters oil and liquid refrigerant back to the compressor. The filter and desiccant are contained in the accumulator because no receiver-drier is used with this system. The amount of refrigerant charge is more critical when a suction line accumulator is used than it is with a receiver-drier.

Refrigerant Flow Control

The cycling clutch designs shown in Figures 3 and 4 are common for both factory- and dealer-installed units. The clutch is cycled by a thermostat that senses evaporator temperature or by a pressure switch that senses evaporator pressure. Some dealer-installed units use an adjustable thermostat, which controls car temperature by controlling evaporator temperature. The thermostat also prevents evaporator icing. Most units use a fixed thermostat or pressure switch set to prevent evaporator icing. Temperature is then controlled by blending the air with warm air coming through the heater.

Cycling the clutch sometimes causes noticeable surges as the engine is loaded and unloaded by the compressor. This is more evident in cars with smaller engines. Reevaporation of condensate from the evaporator during the off-cycle may cause objectionable temperature fluctuation or odor. This system cools faster and at lower cost than a continuously running system.

In orifice tube-accumulator systems, the clutch cycling switch disengages at about 170 kPa and cuts in at about 310 kPa (gage). Thus, the evaporator defrosts on each off-cycle. The flooded evaporator has enough thermal inertia to prevent rapid clutch cycling. It is desirable to limit clutch cycling to a maximum of 4 cycles per minute because heat is generated by the clutch at engagement. The pressure switch can be used with a thermostatic expansion valve in a dry evaporator if the pressure switch is damped to prevent rapid cycling of the clutch.

Continuously running systems, once widely used, are rarely seen today because they require more power and, consequently, more fuel to operate. In a continuously running system, an evaporator pressure regulator (EPR) keeps the evaporator pressure above the condensate freezing level. Temperature is controlled by reheat or by blending the air with warm air from the heater core.

The continuously running system possesses neither of the previously mentioned disadvantages of the cycling clutch system, but it does increase the suction line pressure drop, which reduces performance slightly at maximum load. A solenoid version of this valve,

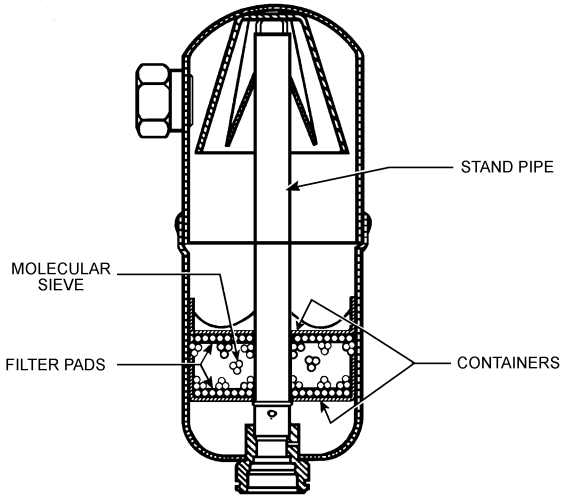

Fig. 2 Typical Suction Line Accumulator

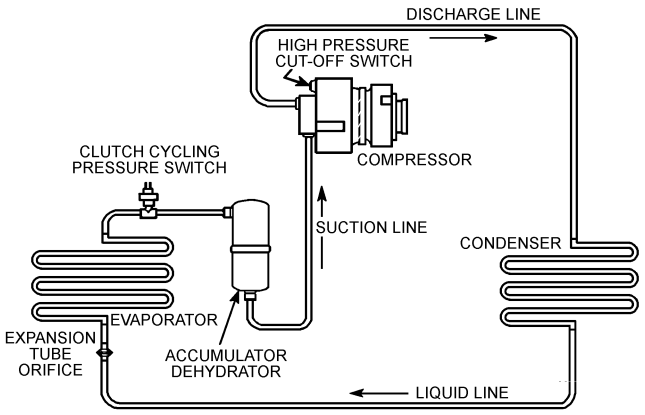

Fig. 3 Clutch Cycling Orifice Tube Air-Conditioning Schematic

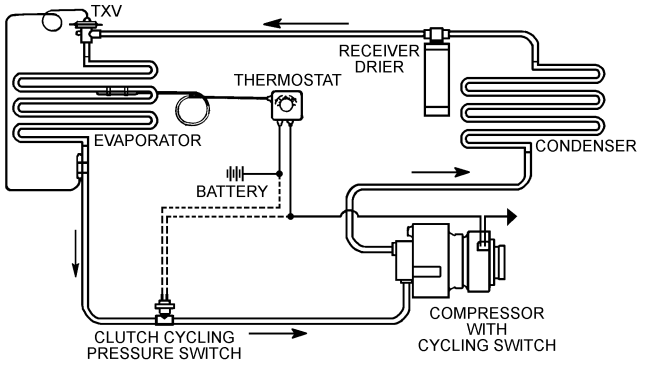

Fig. 4 Clutch Cycling System with Thermostatic Expansion Valve (TXV)

which is controlled by an antifreeze switch that senses evaporator fin temperature, has also been used.

Two refrigeration circuits use the EPR. Figure 5 shows a conventional dry circuit. Figure 6 shows a flooded evaporator circuit, which uses a plate-and-separator type of evaporator with a tank at the top and bottom. It also has a unique piping arrangement. The TXV external equalizer line is connected downstream from the EPR valve. Also, a small oil return line containing an internal pressure relief valve is connected downstream from the EPR. These two lines may be connected to the housing of the EPR valve downstream of its valve mechanism. This piping arrangement causes the TXV to open wide when the EPR throttles, thus flooding the evaporator and causing the EPR to act as an expansion valve. The system allows the air conditioner to run at ambients as low as 2°C to defog windows while maintaining adequate refrigerant flow and ensuring oil return to the compressor.

CONTROLS

Manual

The fundamental control mechanism is a flexible control cable that transmits linear motion with reasonable efficiency and little hysteresis. Rotary motion is obtained by a crank mechanism. Common applications are (1) movement of damper doors that blend air to control the discharge air temperature, (2) regulation of the amount of defrost bleed, and (3) regulation of valves to control the flow of engine coolant through the heater core.

Vacuum

Vacuum provides a silent, powerful method of manual control, requiring only the movement of a lever or a switch by the operator.

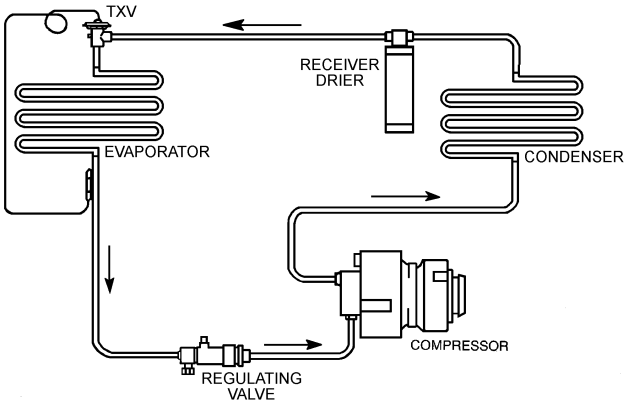

Fig. 5 Suction Line Regulation System

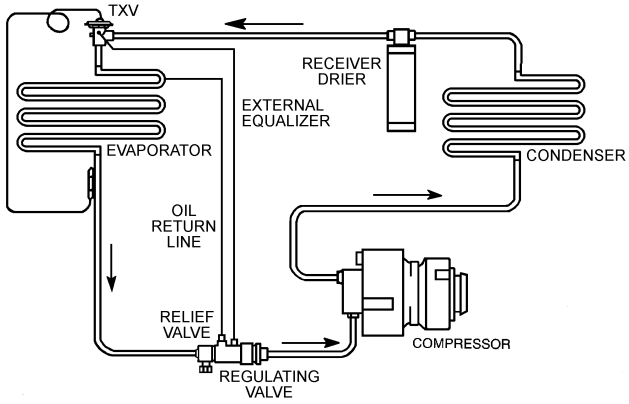

Fig. 6 Flooded Evaporator Suction Line Regulation System

Vacuum is obtained from the engine intake manifold. A vacuum reservoir (0.4 to 4 L) may be used to ensure an adequate source. Most systems are designed to function at a minimum vacuum of −17 to −20 kPa, although as much as −90 kPa may be available at times.

Linear or rotary slide valves select functions. Vacuum-modulating, temperature-compensating (bimetal) valves control thermostatic coolant valves. Occasionally, solenoid valves are used, but they are generally avoided because of their cost and associated wiring.

Electrical

Electrical controls regulate blower motors. Blowers have three or four speeds. The electrically operated compressor clutch frequently sees service as a secondary system control operated by function (mode) selection integration or evaporator temperature or pressure sensors.

Temperature Control

Air-conditioning capacity control to regulate car temperature is achieved in one of two ways—the clutch can be cycled in response to an adjustable thermostat sensing evaporator discharge air, or the evaporator discharge air can be blended with or reheated by air flowing through the heater core. The amount of reheat or blend is usually controlled by driver-adjusted damper doors.

Solid-state logic interprets system requirements and automatically adjusts to heating or air conditioning, depending on the operator's selection of temperature and on ambient temperature. Manual override enables the occupant to select the defrost function. The system not only regulates this function but also controls capacity and air quantity. An in-car thermistor measures the temperature of the air in the passenger compartment and compares it to the setting at the temperature selector. An ambient sensor, sometimes a thermistor, senses ambient temperature to prevent offset or droop. These elements, along with a vacuum supply line from an engine vacuum reservoir, are coupled to the control package, which consists of an electronic amplifier and a transducer. The output is a vacuum or electrical signal regulated by the temperature inputs.

This regulated signal is supplied to servo units that control the quantity of coolant flowing in the heater core, the position of the heater blending door, or both; the air-conditioning evaporator pressure; and the speed of the blower. The same regulated signal controls sequencing of damper doors, either resulting in the discharge of air at the occupant's feet or at waist level or causing the system to work on the recirculation of interior air. Several interlocking devices (1) prevent blower operation before the engine coolant is up to temperature, (2) prevent the air-conditioning compressor clutch from being energized at low ambient temperatures, and (3) provide other features for passenger comfort.

Other Controls

A pressure switch is located in the suction line at either the block valve or the accumulator to cycle the clutch off at pressures below, and on at pressures above, that at which water would freeze onto the evaporator surface. A cycling switch may be included to start an electric fan when insufficient ram air flows over the condenser. Other sophistications include a charge loss/low ambient switch, transducer evaporator pressure control, and thermistor control.

BUS AIR CONDITIONING

Providing a comfortable climate inside a bus passenger compartment is difficult because the occupancy rate per unit surface and volume is very high, the glazed area is very large, and outside conditions are highly variable. Designing for a specific climate is usually not cost-effective; therefore, the design should consider all likely climates, from the high ambient temperature of the desert to the high humidity of the tropics. Units should operate satisfactorily in ambient conditions up to 50°C. A unit designed for both extremes

has a greater sensible cooling capacity in hot, dry climates than in humid climates.

Ambient air quality must also be considered. Frequently, intakes are subjected to thermal contamination either from road surfaces, condenser air recirculation, or radiator air discharge. Vehicle motion also introduces pressure variables that affect condenser fan performance. In addition, engine speed affects compressor capacity. Bus air conditioners are initially performance-tested as units in small climate-controlled test cells. Larger test cells that can hold the whole bus are commonly used to verify as-installed performance.

Heat Load

The main parameters that must be considered in the design of a bus air conditioning system include:

- Occupancy data (number of passengers, distance traveled, distance traveled between stops, typical permanence time)
- Dimensions and optical properties of glass
- Outside weather conditions (temperature, relative humidity, solar radiation)
- Dimensions and thermal properties of materials in the bodies of the bus and indoor design conditions (temperature, humidity, and air velocity)

The heating or cooling load in a passenger bus may be estimated by summing the following loads:

- Heat flux from solid walls (side panels, roof, floor)
- Heat flux from glass (side, front and rear windows)
- Heat flux from passengers
- Heat flux from the engine, passengers, and ventilation (difference in enthalpy between outside and inside air)
- Heat flux from the air conditioner

The extreme loads for both summer and winter should be calculated. The cooling load is the most difficult load to handle; the heating load is normally handled by heat recovered from the engine. An exception is that an idling engine provides marginal heat in very cold climates. James and He (1993) and Andre et al. (1994) describe computational models for calculating the heat load in vehicles, as well as for simulating the thermal behavior of the passenger compartment.

The following conditions can be assumed for calculating the summer heat load in an interurban vehicle similar to that shown in Figure 7:

- Capacity of 50 passengers
- Insulation thickness of 25 to 40 mm
- Double-pane tinted windows
- Outdoor air intake of 190 L/s
- Road speed of 100 km/h
- Inside design temperatures of 27°C dry bulb and 19.5°C wet bulb, or 11 K lower than ambient

Loads from 12 to 35 kW are calculated, depending on the outside weather conditions and on the geographic location of the bus. The typical distribution of the different heat loads during a summer day at 40° North latitude is shown in Figure 8.

Inlets and Outlets

Correct positioning of external air inlets and outlets to the passenger compartment is important on interurban buses that operate mostly at a high, constant speed. Figure 9 shows the pressure coefficient distribution around a typical bus. The main features, resulting from the analysis of the figure are

- On the front surface, most of the pressure is positive, with the stagnation point located at 1/3 of the height.
- At the frontal leading edge, the pressure is strongly negative.

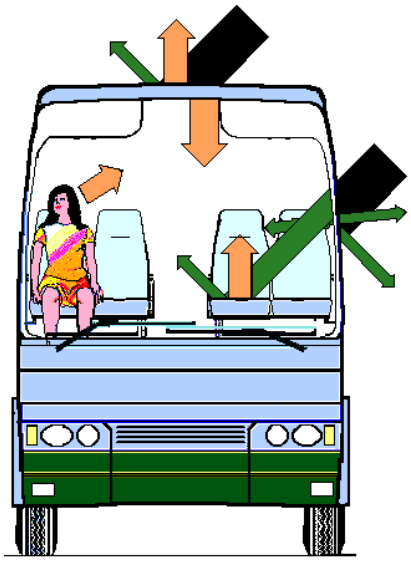

Fig. 7 Distribution of Heat Load (Summer)

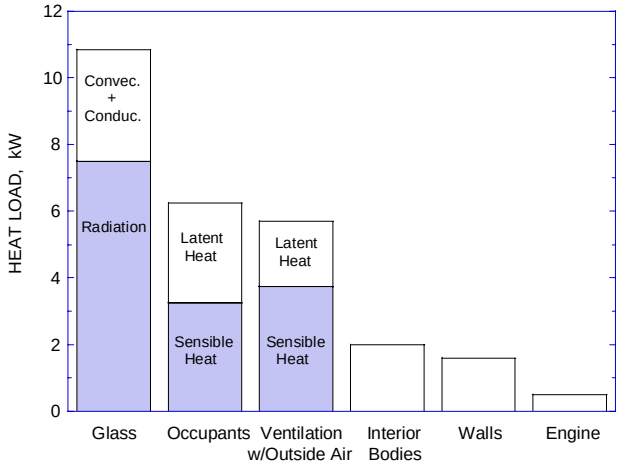

Fig. 8 Main Heat Fluxes in a Bus

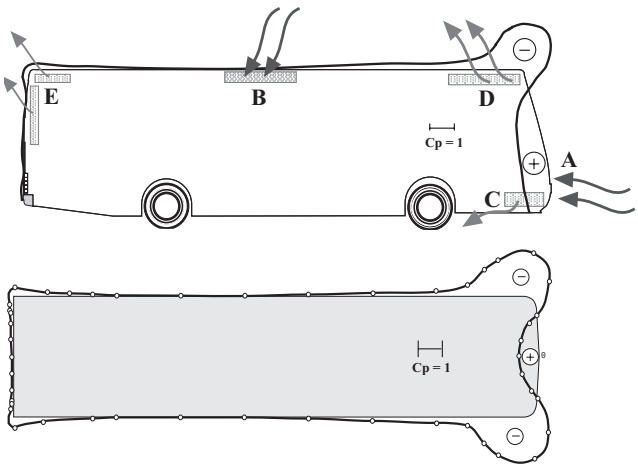

Fig. 9 Pressure Distribution Around a Moving Bus

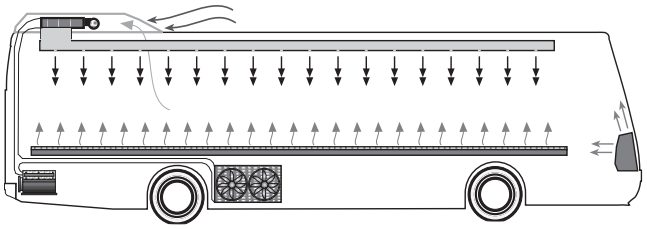

Fig. 10 Typical Arrangement of Air Conditioning in an Interurban Bus

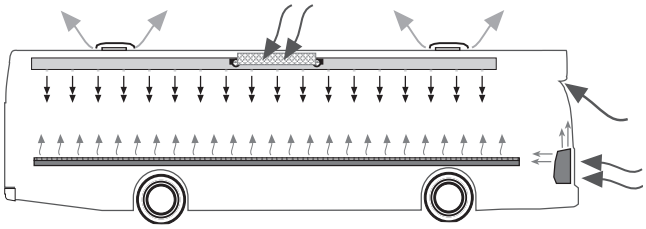

Fig. 11 Typical Arrangement of Air Conditioning in an Urban Bus

- Behind the recirculation bubble in the front, the pressure on the roof is nearly atmospheric.
- In the rear, the pressure coefficient is always slightly negative.

Thus, the best location for inlets is the lower part of the front surface (A). An alternative is near the top and center of the side (B), which is also out of any rain. The areas with strong negative pressure coefficients (C, D) in the side panels just behind the front, vertical pillars are the best locations for the outlets because vehicle movement drives the flow. Slightly negative pressure at the rear and near the rear lateral panels (E) also makes those areas a good location for outlets. Sometimes, the evaporator is inside an enclosure mounted on the roof.

Design Considerations

Figure 10 shows a typical arrangement of equipment in an **interurban bus**. The compressor is usually driven by the engine. Some interurban buses have a separate, engine-driven air conditioner to provide more constant performance; however, this unit is more complex and costly, and it requires more space and maintenance. The evaporator or evaporators may be placed in an upper rear compartment or inside the air distribution ducts concealed in the space between the roof and ceiling panels. Fans blow air through the evaporator to the longitudinal ducts. From there the air enters the passenger compartment in downward cold jets. To avoid strong drafts on passengers, the initial velocity of the jets should not exceed 4 to 5 m/s.

A damper valve in the fan area regulates the amount of fresh and recirculated air. To maintain its efficiency, the condenser should not be placed in an area with a negative pressure coefficient or high temperatures.

A heater for cold weather is also important to offset downdrafts. Hot coolant from the engine is usually used to heat convectors placed in the corners defined between the floor and the side walls. A front unit for defrosting the windshield and for the driver area should also be installed. For hot climates, window curtains are needed to reduce the large solar heat gain and to reduce discomfort due to high radiant temperature asymmetries.

Higher heat loads, for the same outdoor conditions must be considered in **urban buses** because of the high occupancy that can occur in these vehicles. On the other hand, passengers spend less time in urban buses, so they accept less comfortable conditions. In moderate climates, some urban buses only have heating and ventilation and no air conditioning. In all cases, the air exchange rate should be high enough to avoid complaints about air quality—typically between 12 and 30 air changes per hour, independent of vehicle speed. The worst situation for indoor air quality in buses occurs on rainy winter days when the vehicle is crowded and all openings must remain closed. Even with the vehicle stopped in traffic, a certain amount of air exchange should be achieved.

Figure 11 shows a typical arrangement of the heating and ventilation equipment in an urban bus. The air inlets can be placed in the front, just beneath the destination announcement box and under the windshield, or in the upper part of the lateral panels near the center of the bus. This location is preferred if some independence to vehicle speed is desirable. Roof ventilators can be used to extract air from the passenger compartment. Their rotation speed can not be very high to avoid noise complaints, which occur when noise exceeds 65 dB(A) at the passengers' head height when the engine is idling. Increasing the number of ventilators and decreasing their rotation speed can be a solution to the problem

RAILROAD AIR CONDITIONING

Passenger railcar air conditioners are generally electromechanical units with direct-expansion evaporators, usually using R-22 (an HCFC). As HCFCs are phased out, the most likely replacements are HFC-407C or HFC-410A. Because HFC-410A operates at a higher pressure, it is not a viable replacement refrigerant for existing R-22 systems. HFC-134a, a medium-pressure refrigerant, is being used in a few new applications and as a replacement refrigerant for existing R-12 equipment. But for the same reason that R-12 was limited (i.e., its lower density in the gas phase), R-134a is not usually chosen because it requires larger suction piping, heat exchangers, and compressor.

Electronic, automatic controls are common, with a trend toward microprocessor control with fault monitoring, logging, and feedback to a central car information system. Electric heating elements installed in the air-conditioning unit or supply duct temper outdoor air brought in for ventilation. They are often used to control humidity by reheating the conditioned supply air during partial cooling load conditions.

Passenger Car Construction

Passenger car design has emphasized lighter car construction to lower operating and maintenance costs. This trend has caused a reduction in the size and weight of air-conditioning equipment and other auxiliaries.

Vehicle Types

Mainline intercity passenger rail service generally operates single and bilevel cars hauled by a locomotive. Locomotive-driven alternators or static inverters distribute power via an intercar cable power bus to the air conditioners. A typical railcar has a control package and two air-conditioning systems. The units are usually either split, with the compressor/condenser units located in the car undercarriage area and the evaporator blower portion mounted in the ceiling area, or self contained packages mounted in interior equipment rooms. Underfloor and roof-mounted package units are less common.

Commuter cars operating around large cities are similar in size to mainline cars and generally have two evaporator-heater fan units mounted above the ceiling with a common or two separate under floor compressor-condenser unit(s) and a control package. These cars may be locomotive hauled and have air conditioning arrangements similar to mainline intercity cars; but they are often self propelled by high-voltage direct current (dc)

or alternating current (ac) power supplied from an overhead catenary or from a dc-supplied third rail system. On such cars, the air conditioning may operate on ac or dc power. Self-propelled diesel-driven vehicles still operate in a few areas that use onboard generated power for the air conditioners.

Subway and **elevated rapid-transit cars** usually operate on a third rail dc power supply. The car air conditioning operates on the normal dc supply voltage or on three-phase ac supply from an alternator or inverter mounted under the car. Split air-conditioning systems are common, with evaporators in the interior ceiling area and underfloor-mounted condensing sections.

Streetcars, light rail vehicles, and downtown **people movers** usually run on the city ac or dc power supply and have air-conditioning equipment similar to rapid transit cars. Roof-mounted packages are used more often than under car or split systems. This is partly because of the lack of undercar space availability and in cases, where a sufficient clearance envelope will allow, the roof mounted location offers the most convenient location for add-on systems and for modifying rail vehicles designed without HVAC.

Equipment Selection

The source and type of power dictate the type of air conditioning installed on a passenger railcar; weight, the type of vehicle, and the service parameters of the vehicle to which the system is applied are other major concerns. Thus, ac-powered, semi-hermetic reciprocating, vane, or scroll hermetic compressors, which are lighter than open machines with dc motor drives, are a common choice. However, each car design must be examined in this respect because dc/ac inverters may increase not only the total weight, but also the total power draw, due to conversion losses.

Other concerns in equipment selection include the space required, location, accessibility, reliability, and maintainability. Interior and exterior equipment noise levels must be considered both during the early stages of design and later, when the equipment is coordinated with the car builder's ductwork and grilles.

Design Limitations

Space underneath and inside a railroad car is at a premium, especially on self-propelled light rail vehicles and rapid transit and commuter cars; this generally rules out unitary interior or underfloor-mounted systems. Components are usually built to fit the configuration of the available space. Overall car height, roof profile, ceiling cavity, and undercar clearance restrictions determine the shape and size of equipment.

Because a mainline passenger railcar must operate in various parts of the country, the air conditioning must be designed to handle the national seasonal extreme design days. Commuter cars and rapid transit cars operate in a small geographical area, so only the local design temperatures and humidities need be considered.

Dirt and corrosion constitute an important design factor, especially if the equipment is beneath the car floor, where it is subject to extremes of weather and severe dirt conditions. For this reason, corrosion-resistant materials and coatings must be selected. Aluminum has not proved durable in exterior exposed applications; the sandblasting effect tends to degrade any surface treatment on it. Because dirt pickup cannot be avoided, the equipment must be designed for quick and easy cleaning; access doors are provided and evaporator and condenser fin spacing is usually limited to 2.5 to 3 mm. Closer spacing causes more rapid dirt buildup and higher cleaning costs. Dirt and severe environmental conditions must also be considered in selecting motors and controls.

Railroad HVAC equipment requires more maintenance and servicing than stationary units. A passenger railcar, having sealed windows and a well-insulated structure, becomes almost unusable if the air conditioning fails. The equipment therefore has many additional components to permit quick diagnosis and correction of a failure. Motors, compressors, control compartments, diagnostic test ports and other maintenance points must be easily accessible for inspection or repair. However, changes in maintenance strategies and environmental regulations have caused some users to move away from fully on-car serviceable air conditioners, and toward modular, self-contained units with hermetically sealed refrigerant systems. These units are designed for rapid removal and replacement and off-car repair in a dedicated air-conditioning service area. Microprocessor-based controls are designed to identify, log, and indicate system faults in a manner that facilitates expeditious diagnosis and repair.

Security of the air-conditioning equipment attachment to the vehicle must be considered, especially on equipment located beneath the car. Vibration isolators and supports should be designed to safely retain the equipment on the vehicle, even if the vibration isolators or fasteners fail completely. A piece of equipment that dangles or drops off could cause a train derailment. All belt drives and other revolving items must be safety guarded. High-voltage controls and equipment must be labeled by approved warning signs. Pressure vessels and coils must meet ASME test specifications for protection of the passengers and maintenance personnel. Materials selection criteria include low flammability, low toxicity, and low smoke emission.

The design, location, and installation of air-cooled condenser sections must allow for considerable discharge air recirculation and/or temporary extreme inlet air temperatures from adjacent equipment that may occur at passenger loading platforms or in tunnels. To prevent a total system shutdown due to high discharge pressure, a capacity reduction control device is typically used to reduce the cooling capacity, thus temporarily reducing discharge pressure.

Interior Comfort

Air-conditioning and heating comfort and ventilation parameters may be selected in accordance with ASHRAE *Standards* 55 and 62. The duration of exposure and the effect of prior passenger activity should also be considered. For example, a person running for a ride and/or waiting in a hot or cold climate prior to boarding for a 10 minute ride in clothing fit for outside is not a typical building occupant. Jones et al. (1994) evaluated the heat load imposed by people under transient weather and activity conditions as opposed to steady state metabolic rates traditionally used. An application program TRANMOD was developed that allows a designer to predict the thermal loads imposed by passengers (Jones and He 1993).

Door openings, ventilation air sources (ambient contamination), and loading profiles need to be considered when locating inlets and calculating the amount of makeup air. Evaporator sectional staging, variable compressor and evaporator fan speed control, and/or compressor cylinder unloading, coupled with electric reheat, are used to provide part-load humidity control. In winter, humidity control is usually not provided.

The dominant summer cooling load is due to passengers, followed by ventilation, car body transmission, solar gain, and internal heat. Heating loads are due to car body losses and ventilation. The heating load calculation does not credit heat from passengers and internal sources. Comfortable internal conditions in ventilated non-air-conditioned cars can be maintained only when ambient conditions permit. Interior conditions are difficult to maintain because the passenger and solar loads in mass transit cars vary continuously.

Air conditioners in North American cars are selected to maintain temperatures of 23 to 24.5°C, with a maximum relative humidity of 55 to 60%. In Europe and elsewhere, the conditions are usually set at a dry-bulb temperature approximately 5 K below ambient, with a

coincidental relative humidity of 50 to 66%. In the heating mode, the car interior is kept in the 18 to 21°C range.

Other Requirements

Most cars are equipped with both overhead and floor heat. The overhead heat raises the temperature of the recirculated and ventilation air mixture to slightly above the car design temperature. A duct limit thermostat is often used to prevent the supply air from overheating, which can cause passenger discomfort due to temperature stratification. The floor heat offsets heat loss through the car body. The times of maximum occupancy, outdoor ambient, and solar gain must be ascertained. The peak cooling load on urban transit cars usually coincides with the evening rush hour, while the peak load on intercity railcars occurs in the mid afternoon.

Heating capacity for the car depends on body construction, car size, and the design area-averaged relative wind-vehicle velocity. In some instances, minimum car warm-up time may be the governing factor. In long-distance trains, the toilets, galley, and lounges often have exhaust fans. Ventilation airflow must exceed forced exhaust air rates sufficiently to maintain positive car pressure. Ventilation air pressurizes the car and reduces infiltration.

Air Distribution

The most common air distribution system is a centerline supply duct running the length of the car in the space between the ceiling and the roof. The air outlets are usually ceiling-mounted linear slot air diffusers. Louvered or egg crate recirculation grilles are positioned in the ceiling beneath the evaporator units. The main supply duct must be insulated from the ceiling cavity to prevent thermal gain/loss and condensation. Taking ventilation air from both sides of the roof line helps overcome the effect of wind. Adequate snow and rain louvers, and in some cases internal baffles, must be installed on the outdoor air intakes. Separate outdoor air filters are usually paired with a return air filter. Disposable media or permanent, cleanable air filters are used and are usually serviced every month. Some long-haul cars, such as sleeper cars, require a network of delivered-air and return ducts. Duct design should consider noise and static pressure losses.

Piping Design

Standard refrigerant piping practice is followed. Pipe joints should be accessible for inspection and, on split systems, not concealed in car walls. Evacuation, leak testing, and dehydration must be completed successfully after installation and prior to charging. Piping should be supported adequately and installed without traps that could retard the flow of lubricant back to the compressor. Pipe sizing and arrangement should be in accordance with Chapter 2 of the 1998 *ASHRAE Handbook—Refrigeration*. Evacuation, dehydration and charging, should be performed as described in Chapter 46 of the 1998 *ASHRAE Handbook*. Piping on packaged units should also conform to these recommendations.

Control Requirements

Car HVAC systems are automatically controlled for year-round comfort. In split systems cooling load variations are usually handled by two-stage direct-expansion coils and compressors equipped with suction pressure unloaders, electric unloaders, or speed control. Unitary systems may have hot gas bypass to keep the compressor from cycling and reduce the cooling effect. Under low load conditions, cooling is provided by outdoor air supplied by ventilation. During part-load cooling, electric reheat maintains humidity. Under low loads not requiring humidity control, the system assumes the ventilation mode. A pump-down cycle and low ambient lockout are recommended on split systems to protect the compressor from damage caused by liquid slugging. In addition, the compressor may be fitted with a crankcase heater that is energized during the compressor off-cycle. During the heating mode, floor and overhead heaters are staged to maintain the car interior temperature. Today's controls use thermistors and solid-state electronics instead of electromechanical devices. The control circuits are normally powered by low-voltage DC or, occasionally, by single-phase AC.

Future Trends

Air cycle technology is being introduced in passenger railcar air conditioning in Germany (Giles et al. 1997); however, issues of greater weight, higher cost, and low efficiency need to be addressed before air-cycle equipment will be widely accepted. Other trends include the proliferation of hermetic scroll compressors, significantly increased self-diagnostic capabilities included in microprocessor-based controls, and continued efforts to identify the best refrigerant for the long term.

FIXED GUIDEWAY VEHICLE AIR CONDITIONING

Fixed guideway systems, commonly called people movers, can be monorails or rubber-tired cars running on an elevated or grade level guideway, as seen at airports and in urban areas such as Miami. The guideway directs and steers the vehicle and provides the electrical power to operate the car's traction motors, lighting, electronics, air conditioner, and heater. People movers are usually unmanned and computer controlled from a central point. Operations control determines vehicle speed and headway and the length of time doors stay open based on telemetry from the individual cars or trains. Therefore, reliable and effective environmental control is essential.

People movers are smaller than most other mass transit vehicles, generally having spaces for 20 to 40 seated passengers and generous floor space for standing passengers. Under some conditions of passenger loading, a 12 m car can accommodate 100 passengers. The wide range of passenger loading and the continual movement of the car from full sunlight to deep shade make it essential that the car's air conditioner be especially responsive to the amount of cooling required at a given moment.

System Types

The HVAC for a people mover is usually one of three types:

1. Conventional undercar condensing unit connected with refrigerant piping to an evaporator/blower unit mounted above the car ceiling
2. Packaged, roof-mounted unit having all components in one enclosure and mated to an air distribution system built into the car ceiling
3. Packaged, undercar-mounted unit mated to supply and return air ducts built into the car body

Two systems are usually installed in each car, one at each end; each system provides one-half of the maximum cooling requirement. The systems, whether unitary or split, operate on the guideway's power supply, which, in the United States, is usually 60 Hz, 460 to 600 V (ac).

Refrigeration Components

Because commercial electrical power is available, standard semihermetic motor-compressors and commercially available fan motors and other components can be used. Compressors generally have one or two stages of unloaders, and hot gas bypass is used to maintain cooling at low loads. Condenser and cooling coils are copper tube, copper, or aluminum fin units. Generally, flat fins are preferred for undercar systems to make it simpler to clean the coils. Evaporator/blower sections must often be designed for the specific

vehicle and fitted to its ceiling contours. The condensing units must also be arranged to fit in the limited space available and still ensure good airflow across the condenser coil. R-22 is used in almost all of these units.

Heating

Where heating must be provided, electric resistance heaters that operate on the guideway power supply are installed at the evaporator unit discharge. One or two stages of heat control are used, depending on the size of the heaters.

Controls

A solid-state control is usually used to maintain interior conditions. The cooling set point is typically between 23 and 24°C. For heating, the set point is 20°C or lower. Some controls provide humidity control by using the electric heat. Between the cooling and heating set points, blowers continue to operate on a ventilation cycle. Often, two-speed blower motors are used, switching to low speed for the heating cycle. Some controls have internal diagnostic capability; they are able to signal the operations center when a cooling or heating malfunction occurs.

Fresh Air

With overhead air-handling equipment, fresh air is introduced into the return airstream at the evaporator entrance. Fresh air is usually taken from a grilled or louvered opening in the end or side of the car and, depending on the configuration of components, filtered separately or directed so that the return air filter can handle both airstreams. For undercar systems, a similar procedure is used, except the air is introduced into the system through an intake in the undercar enclosure. In some cases, a separate fan is used to induce fresh air into the system.

The amount of mechanical outdoor air ventilation is usually expressed as L/s per passenger on a full load continuous basis. Passenger loading is not continuous at full load in this application, with the net result that more outside air is provided than indicated. The passengers may load and unload in groups, which causes additional air exchange with the outside. Frequent opening of doors, sometimes on both sides at once, allows additional natural ventilation. The effective outside air ventilation per passenger is a summation of all these factors. Some vehicles currently in service have no mechanical outside air supply. Others have up to 5 L/s per passenger. Lower values of mechanical ventilation, typically 2.5 L/s or less per passenger, are associated with travel times of less than 2 min and large passenger turnover. Longer rides justify higher rates of mechanical ventilation.

Air Distribution

With overhead equipment, air is distributed through linear ceiling diffusers that are often constructed as a part of the overhead lighting fixtures. Undercar equipment usually makes use of the void spaces in the sidewalls and below fixed seating. In all cases, the spaces used for air supply must be adequately insulated to prevent condensation on surfaces and, in the case of voids below seating, to avoid cold seating surfaces. The supply-air discharge from undercar systems is typically through a windowsill diffuser. Recirculation air from overhead equipment flows through ceiling-mounted grilles. For undercar systems, return air grilles are usually found in the door wells or beneath seats.

Because of the small size of the vehicle and its low ceilings, extreme care must be taken to design the air supply so that it does not blow directly on passengers' heads or shoulders. High rates of diffusion are needed, and diffuser placement and arrangement should cause the discharge to hug the ceiling and walls of the car. Total air quantity and discharge temperature must be carefully balanced to minimize cold drafts and air currents.

CHAPTER 9

AIRCRAFT

Regulations 9.1
Design Conditions 9.2
System Description 9.4
Typical Flight 9.7
Air Quality 9.9

ENVIRONMENTAL control system (ECS) is a generic term used in the aircraft industry for the systems and equipment associated with the ventilation, heating, cooling, humidity/contamination control, and pressurization in the occupied compartments, cargo compartments, and electronic equipment bays. The term ECS often encompasses other functions such as windshield defog, airfoil anti-ice, oxygen systems, and other pneumatic demands. The regulatory or design requirements of these related functions are not covered in this chapter.

Environmental control systems of various types and complexity are used in military and civil aircraft, helicopter, and spacecraft applications. This chapter applies to commercial transport aircraft that predominately use air-cycle air conditioning for the ECS.

Commercial users categorize their ECS equipment in accordance with the Air Transport Association of America *Specification No.* 100, Specification for Manufacturers Technical Data. The following ATAA 100 chapters define ECS functions and components:

- **Chapter 21**, Air Conditioning, includes heating, cooling, moisture/contaminant control, temperature control, distribution, and cabin pressure control. Common system names are the air-conditioning system (ACS) and the cabin pressure control system (CPCS).
- **Chapter 30**, Ice and Rain Protection, includes airfoil ice protection; engine cowl ice protection; and windshield ice, frost, or rain protection.
- **Chapter 35**, Oxygen, includes components that store, regulate, and deliver oxygen to the passengers and crew.
- **Chapter 36**, Pneumatic, covers ducts and components that deliver compressed air (bleed air) from a power source (main engine or auxiliary power unit) to connecting points for the using systems (Chapters 21, 30, and Chapter 80, Starting). The pneumatic system is also commonly called the engine bleed air system (EBAS).

REGULATIONS

The Federal Aviation Administration (FAA) regulates the design of transport category aircraft for operation in the United States under Federal Aviation Regulation (FAR) Part 25. ECS equipment and systems must meet these requirements, which are primarily related to health and safety of the occupants. Certification and operation of these aircraft in the U.S. is regulated by the FAA in FAR Part 121. Similar regulations are applied to European nations by the European Joint Aviation Authorities (JAA), which represents the combined requirements of the airworthiness authorities of the participating nations; the equivalent design regulation is JAR Part 25. Operating rules based on FAA or JAA regulations are applied individually by the nation of registry. Regulatory agencies may impose special conditions on the design, and compliance is mandatory.

The preparation of this chapter is assigned to TC 9.3, Transportation Air Conditioning.

Several FAR and JAR Part 25 paragraphs apply directly to transport category aircraft ECSs; those most germane to the ECS design requirements are as follows:

FAR/JAR 25.831	Ventilation
FAR 25.832	Cabin ozone concentration
FAR/JAR 25.841	Pressurized cabins
FAR/JAR 25.1309	Equipment, systems, and installations
FAR/JAR 25.1438	Pressurization and pneumatic systems
FAR/JAR 25.1461	Equipment containing high energy rotors

These regulatory requirements are summarized in the following sections; however, the applicable FAR and JAR paragraphs, amendments and advisory circulars should be consulted for the latest revisions and full extent of the rules.

Ventilation

FAR/JAR *Paragraph* 25.831

- Each passenger and crew compartment must be ventilated.
- Each crew member must have enough fresh air to perform their duties without undue fatigue or discomfort (minimum of 4.7 L/s).
- Crew and passenger compartment air must be free from hazardous concentration of gases and vapors:
  - Carbon monoxide limit is 1 part in 20 000 parts of air
  - Carbon dioxide limit is 3% by volume, sea level equivalent (An FAA amendment reduces the carbon dioxide limit to 0.5%)
  - Conditions must be met after reasonably probable failures
- Smoke evacuation from the cockpit must be readily accomplished without depressurization.
- The occupants of the flight deck, crew rest area, and other areas must be able to control the temperature and quantity of ventilating air to their compartments independently.

FAR *Amendment* No. 25-87:

- Under normal operating conditions and in the event of any probable failure, the ventilation system must be designed to provide each occupant with an airflow containing at least 0.25 kg of fresh air per minute (or about 5 L/s at 2400 m).
- The maximum exposure an any given temperature is specified as a function of the temperature exposure.

JAR ACJ (*Advisory Circular-Joint*) 25.831:

- The supply of fresh air in the event of loss of one source, should not be less than 3 g/s per person for any period exceeding 5 min. However, reductions below this flow rate may be accepted provided that the compartment environment can be maintained at a level that is not hazardous to the occupant.
- Where the air supply is supplemented by a recirculating system, it should be possible to stop the recirculating system.

Cabin Ozone Concentration

FAR 25.832 specifies the cabin ozone concentration during flight must be shown not to exceed:

- 0.25 ppm by volume (0.5 mg/m^3), sea level equivalent, at any time above 9800 m
- 0.10 ppm by volume (0.2 mg/m^3), sea level equivalent, time weighted average during any 3 h interval above 8200 m

At present, JAR 25 has no requirement for cabin ozone concentration.

Pressurized Cabins

FAR/JAR 25.841:

- Limits the maximum cabin pressure altitude to 2450 m at the maximum aircraft operating altitude under normal operating conditions.
- For operation above 7600 m, a cabin pressure altitude of not more than 4600 m must be maintained in the event of any reasonably probable failure or malfunction in the pressurization system.
- The makeup of the cabin pressure control components, instruments, and warning indication is specified to ensure the necessary redundancy and flight crew information.

FAR *Amendment* No. 25-87 imposes additional rules for high altitude operation.

Equipment, Systems, and Installations

FAR/JAR 25.1309:

- Systems and associated components must be designed such that occurrence of any failure that would prevent continued safe flight and landing is extremely improbable.
- The occurrence of any other failure that reduces the capability of the aircraft or the ability of the crew to cope with adverse operating conditions is improbable.
- Warning information must be provided to alert the crew to unsafe system operating conditions to enable them to take corrective action.
- Analysis in compliance with these requirements must consider possible failure modes, probability of multiple failures, undetected failures, current operating condition, crew warning, and fault detection.

FAR *Advisory Circular* AC 25.1309-1A and JAR ACJ *No.* 1 to JAR 25.1309 define the required failure probabilities for the various failure classifications: probable, improbable, and extremely improbable for the FAR requirements; and frequent, reasonably probable, remote, and extremely remote for the JAR requirements.

Pressurization and Pneumatic Systems

FAR 25.1438 specifies the proof and burst pressure factors for pressurization and pneumatic systems as follows:

- Pressurization system elements (air conditioning)
  - Burst pressure: 2.0 times maximum normal pressure
  - Proof pressure: 1.5 times max normal pressure
- Pneumatic system elements (bleed)
  - Burst pressure: 3.0 times maximum normal pressure
  - Proof pressure: 1.5 times maximum normal pressure

JAR 25.1438 and ACJ 25.1438 specify the proof and burst pressure factors for pressurization and pneumatic systems as follows:

- Proof pressure
  - 1.5 times worst normal operation
  - 1.33 times worst reasonable probable failure
  - 1.0 times worst remote failure
- Burst pressure
  - 3.0 times worst normal operation
  - 2.66 times worst reasonably probable failure
  - 2.0 times worst remote failure
  - 1.0 times worst extremely remote failure

Equipment Containing High-Energy Rotors

FAR/JAR 25.1461:

Equipment must comply with at least one of the following three requirements:

1. High-energy rotors contained in equipment must be able to withstand damage caused by malfunctions, vibration, and abnormal temperatures.
   - Auxiliary rotor cases must be able to contain damage caused by high-energy rotor blades.
   - Equipment control devices must reasonably ensure that no operating limitations affecting the integrity of high-energy rotors will be exceeded in service.
2. Testing must show that equipment containing high-energy rotors can contain any failure that occurs at the highest speed attainable with normal speed control devices inoperative.
3. Equipment containing high-energy rotors must be located where rotor failure will neither endanger the occupants nor adversely affect continued safe flight.

DESIGN CONDITIONS

Design conditions for aircraft applications differ in several ways from other HVAC applications. Commercial transport aircraft operate in a physical environment that is not survivable by unprotected humans. This requires a complex ECS to provide passengers and crew with safety and comfort without health risks.

Aircraft ECSs operate under unique conditions. Outside air at altitude is extremely cold, dry, and can contain high levels of ozone. On the ground outside air can be hot, humid, and contain many pollutants such as particulate matter, aerosols, and hydrocarbons. These ambient conditions change quickly from ground operations to flight. The hot-day, high-humidity ground condition usually dictates the size of air-conditioning equipment, and high altitude flight conditions determine the impedance necessary to provide adequate ventilation and pressurization bleed airflow. Maximum heating requirements can be determined by either cold day ground or flight operations.

In addition to essential safety requirements, the ECS should provide a comfortable environment for the passengers and crew. This presents a unique challenge because of the high density seating of the passengers and the changes in cabin pressure and the outside environment during flight. Also aircraft systems must be light, accessible for quick inspection and servicing, highly reliable, tolerant of a wide range of environmental conditions, able to withstand aircraft vibratory and maneuver loads, and able to accommodate failures occurring during flight.

Ambient Temperature, Humidity, and Pressure

Figure 1 shows typical design ambient temperature profiles for hot, standard, and cold days. The ambient temperatures used for the design of a particular aircraft may be higher or lower than those shown in Figure 1, depending on the regions in which the aircraft is to be operated. The design ambient moisture content at various altitudes that is recommended for commercial aircraft is shown in Figure 2. However, operation at moisture levels exceeding 30 g/kg of dry air is possible in some regions. The variation in ambient pressure with altitude is shown in Figure 3.

ECS Performance

The ECS is designed to provide a comfortable cabin temperature, acceptable ventilation, good airflow distribution across the cabin width, and sufficient bleed airflow to maintain cabin pressurization

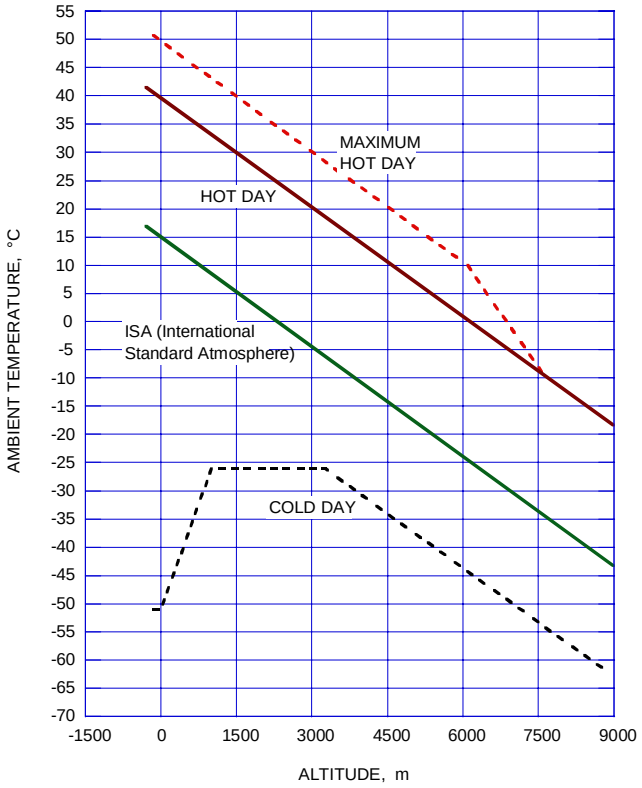

Fig. 1 Typical Ambient Temperature Profiles

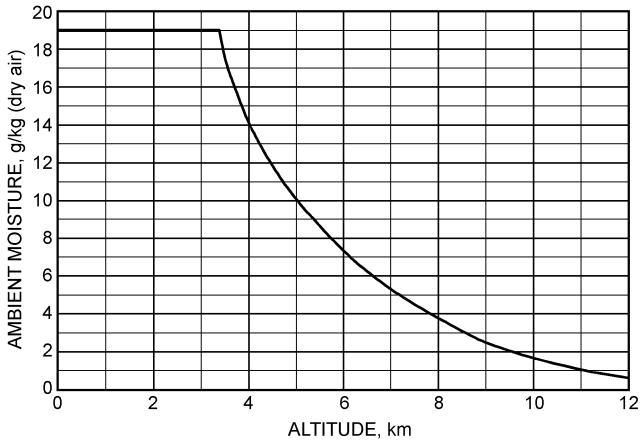

Fig. 2 Design Moisture for Equipment Performance

and repressurization during descent, while accounting for certain failure conditions. The ECS also includes provisions to dehumidify the cabin supply during cooling operations.

Load Determination. The steady-state cooling and heating loads for a particular aircraft model are determined by a heat transfer study of the several elements that comprise the air-conditioning load. The heat transfer involves the following factors:

- Convection between the boundary layer and the outer aircraft skin
- Radiation between the outer aircraft skin and the external environment
- Solar radiation through transparent areas
- Conduction through cabin walls and the aircraft structure
- Convection between the interior cabin surface and the cabin air
- Convection between the cabin air and occupants or equipment

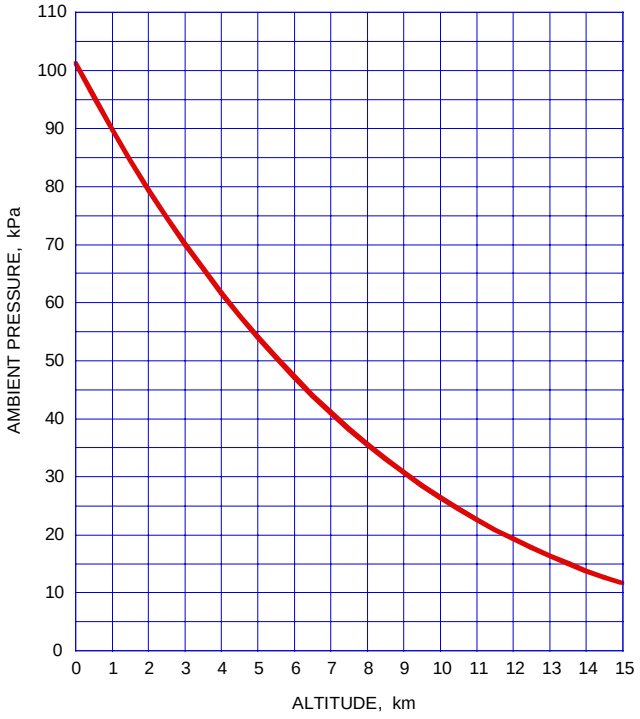

Fig. 3 Variation of Ambient Pressure with Altitude

- Convection and radiation from internal sources of heat such as electrical equipment

The heat transfer analysis should include all possible flow paths through the complex aircraft structure. Air film coefficients vary with altitude and should be considered. During flight, the increase in air temperature and pressure due to ram effects is appreciable and may be calculated from the following equations:

$$\Delta t_r = 0.2 M^2 T_a F_r$$

$$\Delta p_r = (1 + 0.2M^2)^{3.5} p_a - p_a$$

wherewhere

F_r = recovery factor, dimensionless
Δt_r = increase in temperature due to ram effect, K
M = Mach number, dimensionless
T_a = absolute static temperature of ambient air, K
Δp_r = increase in pressure due to ram effect, kPa
p_a = absolute static pressure of ambient air, kPa

The average increase in aircraft skin temperature for subsonic flight is generally based on a recovery factor F_r of 0.9.

Ground and flight requirements may be quite different. For an aircraft sitting on the ground in bright sunlight, surfaces that have high absorptivity and are perpendicular to the sun's rays may have much higher temperatures than ambient. This skin temperature is reduced considerably if a breeze blows across the aircraft. Other considerations for ground operations include cool-down or warm-up requirements, and the time that doors are open for passenger and galley servicing.

Cooling. The sizing criteria for the air conditioning is usually ground operation on a hot, humid day with the aircraft fully loaded and the doors closed. A second consideration is cool-down of a empty, heat-soaked aircraft prior to passenger loading; a cool-down time of less than 30 minutes is usually specified. A cabin

temperature of about 25°C is usually specified for these hot day ground design conditions. During cruise, the system should maintain a cabin temperature of 24°C with a full passenger load.

Heating. Heating requirements are based on a partially loaded aircraft on a very cold day; cabin temperature warm-up within 30 minutes for a cold-soaked aircraft is also considered. A cabin temperature of 21°C is usually specified for these cold day ground operating conditions. During cruise, the system should maintain a cabin temperature of 24°C with a 20% passenger load, a cargo compartment temperature above 5°C and cargo floor temperatures above 0°C to prevent the freezing of cargo.

Temperature Control. Commercial aircraft (over 19 passengers) have as few as two zones (cockpit and cabin) and as many as seven zones. These crew and passenger zones are individually temperature controlled to a crew selected temperature for each zone ranging from 18 to 30°C. Some systems have limited authority bias selectors in the passenger zones that can be adjusted by the flight attendants. The selected zone temperature is controlled to within 1 K and the temperature uniformity within the zone should be within 2.5 K. Separate temperature controls can be provided for cargo compartments.

Ventilation. Aircraft cabin ventilation systems can use all bleed air or a mixture of bleed and recirculated air. The bleed air source is engine compressor air that powers the air-cycle air-conditioning equipment and pressurizes the aircraft cabin. A typical ventilation system supplies 5 L/s of bleed air per occupant, which satisfies regulatory (FAA/JAA) requirements for ventilation and concentrations of carbon monoxide and carbon dioxide.

An equal amount of filtered, recirculated cabin air can be provided for improved distribution and circulation. The use of filtered, recirculated air reduces the bleed air penalty and increases cabin humidity. Most systems have no filtration of the engine bleed air supply, although bleed air centrifugal cleaners are sometimes offered as optional equipment. Some aircraft that fly where high ambient ozone levels can be expected require catalytic ozone converters.

Particulate filters are used to filter the recirculated cabin air. High-efficiency particulate air (HEPA) filters are preferred. Charcoal filters are sometimes offered as optional equipment, and are installed in series with the particulate filters. The demand for charcoal filters is low for domestic carriers because of the smoking ban on domestic flights. Their use worldwide is also limited due to cost, frequency of maintenance (replacement), and disposal requirements.

Pressurization. Cabin pressurization achieves the required partial pressures of oxygen for the crew and passengers during high altitude flight. While the aircraft operates at altitudes above 12 000 m, the occupied cabin must be pressurized to an equivalent altitude of 2400 m or less to permit normal physiological functions without supplemental oxygen. The maximum pressure difference between the cabin and the outside environment is limited by aircraft structural design limits. The differential pressure control provides a cabin pressure based on the flight altitude of the aircraft. A typical cabin altitude schedule is shown in Figure 4. The cabin pressure control must also limit the normal maximum rates of change of cabin pressure; the recommended limits are 150 m/min for increasing altitude (ascent) and 90 m/min for decreasing altitude (descent). Provisions separate from the normal cabin pressure controls must be provided for positive and negative pressure relief to protect the aircraft structure.

SYSTEM DESCRIPTION

The outside air supplied to the airplane cabin is provided by the engine compressors (or auxiliary power unit in the aircraft tailcone), cooled by **air-conditioning packs** located under the wing center section, and mixed with an equal quantity of filtered, recirculated

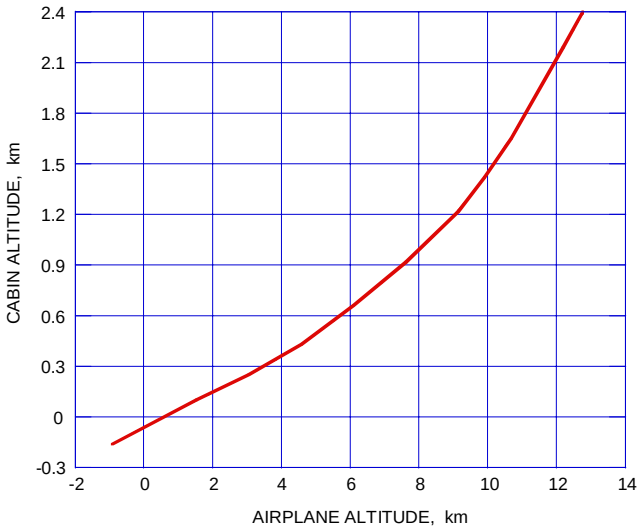

Fig. 4 Typical Cabin Altitude Schedule

air. An air-conditioning pack uses the compressed outside air passing through it and into the airplane as the refrigerant in an air-cycle refrigeration cycle.

Air is supplied and exhausted from the cabin on a continuous basis. As shown in Figure 5, air enters the passenger cabin from overhead distribution outlets that run the length of the cabin. The exhaust air leaves the cabin through return air grilles located in the sidewalls near the floor, and running the length of the cabin on both sides. The exhaust air is continuously extracted from below the cabin floor by recirculation fans that return part of the air to the distribution system and to an outflow valve that purges the remaining exhaust air overboard. The cabin ventilation system is designed and balanced so that air supplied at one seat row leaves at approximately the same seat row, thus minimizing airflow in the fore and aft directions.

The following basic systems comprise the typical aircraft ECS.

Pneumatic System

The pneumatic system or engine bleed air system extracts a small amount of the gas turbine engine compressor air to ventilate and pressurize the aircraft compartments. A schematic of a typical engine bleed air system is shown in Figure 6. During climb and cruise the bleed air is usually taken from the midstage engine bleed port for minimum bleed penalty. During idle descent it is taken from the high-stage engine bleed port where maximum available pressure is required to maintain cabin pressure and ventilation. The bleed air is pressure controlled to meet the requirements of the using system; and it is usually cooled to limit bleed manifold temperatures to be compatible with fuel safety requirements. In fan jets, the fan air is used as the heat sink for the bleed air heat exchanger (precooler); for turboprop engines, ram air is used, which usually requires an ejector or fan for static operation. Other components include bleed-shutoff and modulating valves, fan-air modulating valve, sensors, controllers, and ozone converters. The pneumatic system is also used intermittently for airfoil and engine cowl anti-icing, engine start, and several other pneumatic functions.

Each engine has an identical bleed air system for redundancy and to equalize the compressor air bled from the engines. The equipment is sized to provide the necessary temperature and airflow for airfoil and cowl anti-icing, or cabin pressurization and air conditioning with one system or engine inoperative. The bleed air used for airfoil anti-icing is controlled by valves feeding piccolo tubes

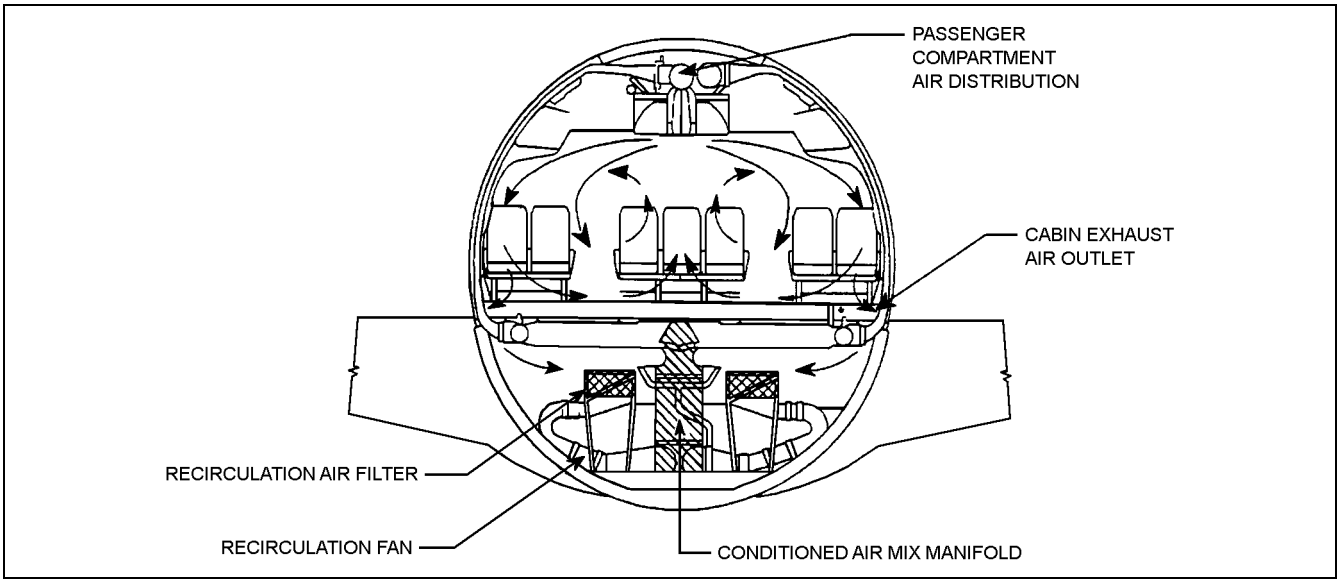

Fig. 5 Cabin Airflow Patterns
(Hunt et al. 1995)

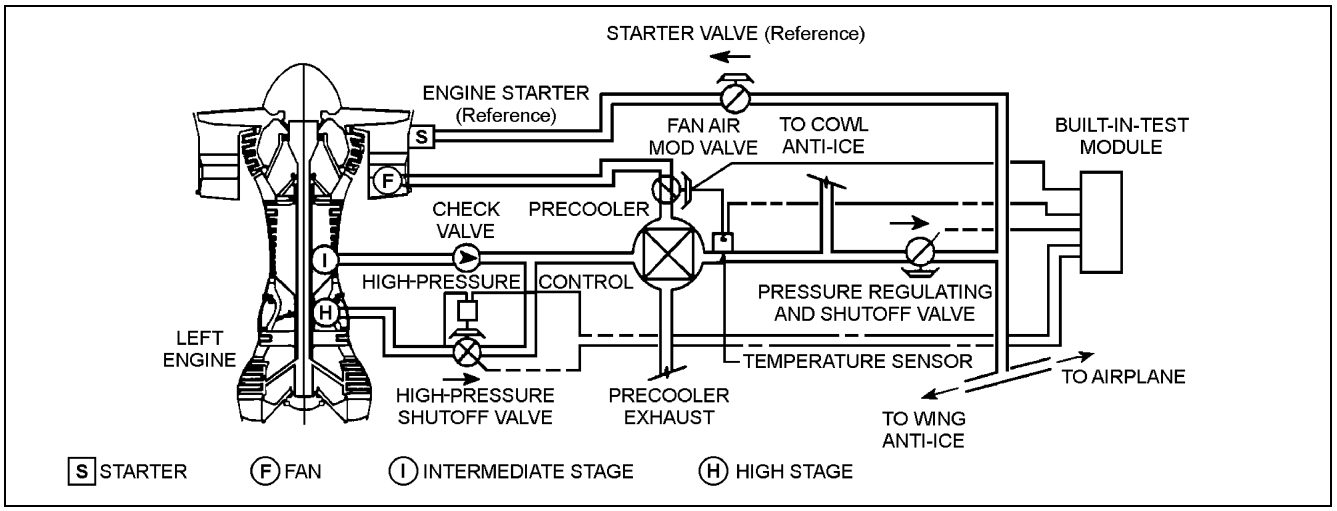

Fig. 6 Typical Engine Bleed Air System Schematic
(Hunt et al. 1995)

extending along the wing leading edge. Similar arrangements are used for anti-icing the engine cowl and tail section.

Air Conditioning

Air-cycle refrigeration is the predominant means of air conditioning for commercial and military aircraft. The reverse-Brayton cycle or Brayton refrigeration cycle is used as opposed to the Brayton power cycle that is used in gas turbine engines. The difference between the two cycles is that in the power cycle fuel in a combustion chamber adds heat, and in the refrigeration cycle a ram-air heat exchanger removes heat. The familiar Rankine vapor cycle, which is used in building and automotive air conditioning and in domestic and commercial refrigeration, has limited use for aircraft air conditioning. The Rankine cycle is used mostly in unpressurized helicopters and general aviation applications.

In an air cycle, compression of the ambient air by the gas turbine engine compressor provides the power input. The heat of compression is removed in a heat exchanger using ambient air as the heat sink. This cooled air is refrigerated by expansion across a turbine powered by the compressed bleed air. The turbine energy resulting from the isentropic expansion is absorbed by a second rotor, which is either a ram air fan, bleed air compressor, or both. This assembly is called an **air-cycle machine** (ACM). Moisture condensed during the refrigeration process is removed by a water separator.

The compartment supply temperature is controlled by mixing hot bleed air with the refrigerated air to satisfy the range of heating and cooling. Other more sophisticated means of temperature control are often used; these include ram air modulation, various bypass schemes in the air-conditioning pack, and downstream controls that add heat for individual zone temperature control.

The bleed airflow is controlled by a flow control or pressure regulating valve at the inlet of the air-conditioning pack. This valve controls bleed air used to minimize engine bleed penalties while satisfying the aircraft outside air ventilation requirements.

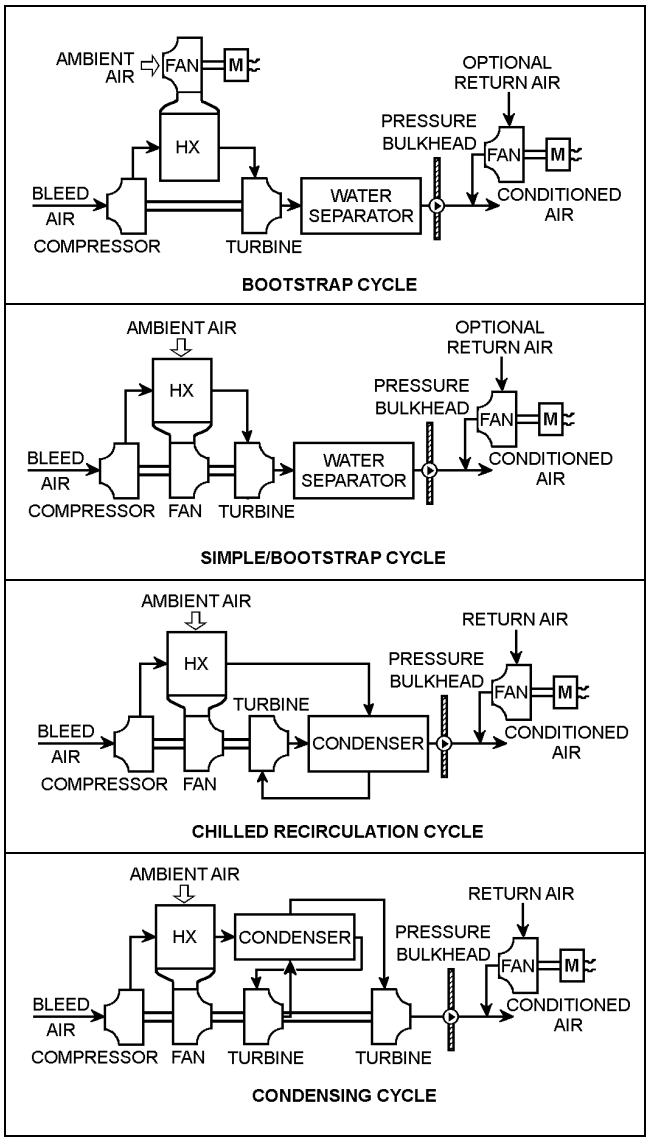

Fig. 7 Air-Conditioning Air-Cycle Configurations

Most aircraft use two or three air-cycle packs operating in parallel to compensate for failures during flight and to allow the aircraft to be dispatched with certain failures. However, many business and commuter aircraft use a single-pack air conditioner; high-altitude aircraft that have single pack also have emergency pressurization equipment that uses precooled bleed air.

The most common types of air-conditioning cycles in use on commercial transport aircraft are shown in Figure 7. All equipment in common use on commercial and military aircraft are open loop, although many commercial aircraft systems include various means of recirculating cabin air to minimize engine bleed air use without sacrificing cabin comfort. The basic differences between the systems are the type of air-cycle machine used and its means of water separation.

The most common air-cycle machines in use are the bootstrap ACM consisting of a turbine and compressor; the three-wheel ACM consisting of a turbine, compressor, and fan; and the four wheel ACM consisting of a two turbines, a compressor, and a fan. The bootstrap ACM is most commonly used for military applications, although many older commercial aircraft models use the bootstrap cycle. The three-wheel ACM (simple bootstrap cycle) is used on most of the newer commercial aircraft, including commuter aircraft and business aircraft. The four-wheel ACM (condensing cycle) was first applied in 777 aircraft.

Low-pressure water separation and high-pressure water separation are used. A **low-pressure water separator**, located downstream from the cooling turbine, has a coalescer cloth that agglomerates fine water particles entrained in the turbine discharge air into droplets. The droplets are collected, drained, and sprayed into the ram airstream using a bleed air powered ejector; this process increases pack cooling capacity by depressing the ram-air heat-sink temperature.

The **high-pressure water separator** condenses and removes moisture at high pressure upstream of the cooling turbine. A heat exchanger uses turbine discharge air to cool the high-pressure air sufficiently to condense most of the moisture present in the bleed air supply. The moisture is collected and sprayed into the ram airstream.

In the condensing cycle one turbine removes the high-pressure water and the second turbine does the final expansion to subfreezing temperature air that is to be mixed with filtered, recirculated cabin air. Separating these functions recovers the heat of condensation, which results in a higher cycle efficiency. It also eliminates condenser freezing problems because the condensing heat exchanger is operated above freezing conditions.

The air-conditioning packs are located in unpressurized areas of the aircraft to minimize structural requirements of the ram air circuit that provides the necessary heat sink for the air-conditioning cycle. This location also provides protection against cabin depressurization in the event of a bleed or ram air duct rupture. The most common areas for the air-conditioning packs are the underwing/wheel well area and the tail cone area aft of the rear pressure bulkhead. Other areas include the areas adjacent to the nose wheel and overwing fairing. The temperature control components and recirculating fans are located throughout the distribution system in the pressurized compartments. The electronic pack and zone temperature controllers are located in the E/E bay. The air-conditioning control panel is located in the flight deck. A schematic diagram of a typical air-conditioning system is shown in Figure 8.

Cabin Pressure Control

Cabin pressure is controlled by modulating the airflow discharged from the pressurized cabin through one or more cabin outflow valves. The cabin pressure control includes the outflow valves, controller, selector panel, and redundant positive pressure relief valves. Provisions for negative pressure relief are incorporated in the relief valves and/or included in the aircraft structure (door). The system controls the cabin ascent and descent rates to acceptable comfort levels, and maintains cabin pressure altitude in accordance with cabin-to-ambient differential pressure schedules. Modern controls usually set landing field altitude if not available from the flight management system (FMS), and monitor aircraft flight via the FMS and the air data computer (ADC) to minimize the cabin pressure altitude and rate of change.

The cabin pressure modulating valves and safety valves (positive pressure relief valves) are located either on the aircraft skin in the case of large commercial aircraft, or on the fuselage pressure bulkhead in the case of commuter, business and military aircraft. Locating the outflow valves on the aircraft skin precludes the handling of large airflows in the unpressurized tailcone or nose areas and provides some thrust recovery; however, these double gate valves are more complex than the butterfly valves or poppet-type valves used for bulkhead installations. The safety valves are poppet-type valves for either installation. Most commercial aircraft have electronic controllers located in the E/E bay. The cabin pressure selector panel is located in the flight deck.

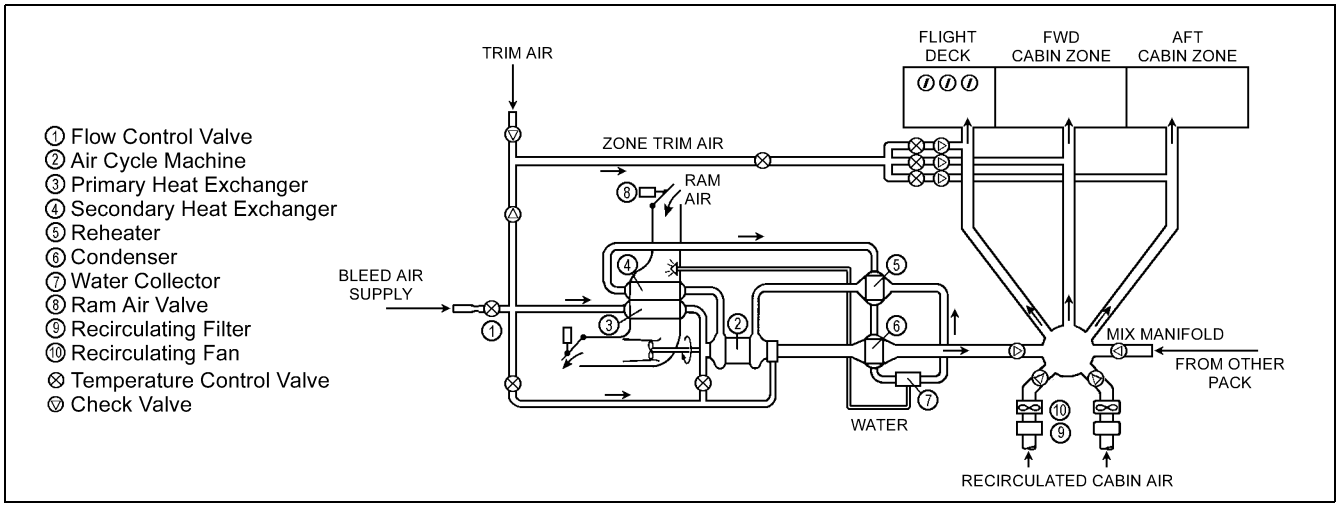

Fig. 8 Typical Aircraft Air-Conditioning Schematic

TYPICAL FLIGHT

A typical flight scenario from London's Heathrow Airport to Los Angeles International Airport would be as follows:

While the aircraft is at the gate, the ECS can be powered by bleed air supplied by the auxiliary power unit (APU), bleed air from a ground cart, or bleed air from the main engines after engine start. The APU or ground-cart bleed air is ducted directly to the bleed air manifold upstream of the air-conditioning packs. Engine bleed air is preconditioned by the engine bleed air system prior to being ducted to the air-conditioning packs. The air-conditioning packs are normally switched to operation using engine bleed air after the engines are started.

Taxiing from the gate at Heathrow, the outside air temperature is 15°C with an atmospheric pressure of 101 kPa. The aircraft engines are at low thrust, pushing the aircraft slowly along the taxiway.

Engine Bleed Air Control

As outside air enters the compressor stages of the engine, it is compressed to 220 kPa and a temperature of 165°C. Some of this air is then extracted from the engine core through one of two bleed port openings in the side of the engine. Which bleed port extracts the air depends on the positioning of valves that control the ports. One bleed port is at the engine's fifteenth compressor stage, commonly called high stage. The second is at the eighth compressor stage, commonly called low stage or intermediate stage. The exact stage varies depending on engine type. The high stage is the highest air pressure available from the engine compressor. At low engine power, the high stage is the only source of air at sufficient pressure to meet the needs of the bleed system. The bleed system is totally automatic, except for a shutoff selection available to the pilots on the overhead panel in the flight deck.

As the aircraft turns onto the runway, the pilots advance the engine thrust to takeoff power. The engine's high stage compresses the air to 650°C and 3.0 MPa. This energy level exceeds the requirements for the air-conditioning packs and other pneumatic services—approximately 50% of the total energy available at the high stage port cannot be used. However, the bleed system automatically switches to the low-stage port, which conserves energy.

Because the engine must cope with widely varying conditions from ground level to flight at an altitude of up to 13 000 m, during all seasons and throughout the world, the air at the high or low stage of the engine compressor will seldom exactly match the needs of the pneumatic systems. Excess energy must be discarded as waste heat. The bleed system constantly monitors engine conditions and selects the least wasteful port. Even so, bleed temperatures often exceed safe levels at which fuel will not auto-ignite. The precooler automatically discharges excess energy to the atmosphere to ensure that the temperature of the pneumatic manifold is well below that which could ignite fuel. The precooler is particularly important in the event of a fuel leak.

The aircraft climbs to a cruise altitude of 12 000 m where the outside air temperature is –57°C at an atmospheric pressure of 20 kPa, and the partial pressure of oxygen in 3.5 kPa. Until the start of descent to Los Angeles, the low compressor stage is able to compress the low-pressure cold outside air to a pressure of more than 200 kPa and temperature above 200°C. This conditioning of the air is all accomplished through the heat of compression—fuel is added only after the air has passed through the compressor stages of the engine core.

Figure 9 shows the temperature of the air being extracted from the engine compressor to the bleed system from the time of departure at London to the time of arrival at Los Angeles. The temperature of the air supplied to the bleed system far exceeds that required to destroy any microorganisms present in the outside air during any point of the trip. At cruising altitudes, outside air contains very few biological particles (a few dark fungal spores per cubic metre of air), although there are higher concentrations at lower altitudes. Because of the high air temperatures from the engine compressor, the air supplied to the air-conditioning packs is sterile.

Air leaving the bleed system while in cruise enters the pneumatic manifold at a temperature of 200°C and a pressure of 200 kPa. The air then passes through an ozone converter on its way to the air-conditioning packs located under the wing at the center of the aircraft.

Ozone Protection

While flying at 12 000 m, several ozone plumes are encountered. Some have ozone concentrations as high as 0.8 parts per million (ppm) or 0.62 ppm sea level equivalent (SLE). This assumes a worst case flight during the month of April, when ozone concentrations are highest. If this concentration of ozone were introduced into the cabin, passengers and crew could experience some chest pain, coughing, shortness of breath, fatigue, headache, nasal congestion, and eye irritation.

Atmospheric ozone dissociation occurs when the ozone goes through the compressor stages of the engine, the ozone catalytic converter (which is on aircraft with a route structure that can encounter high ozone concentrations), and the air-conditioning

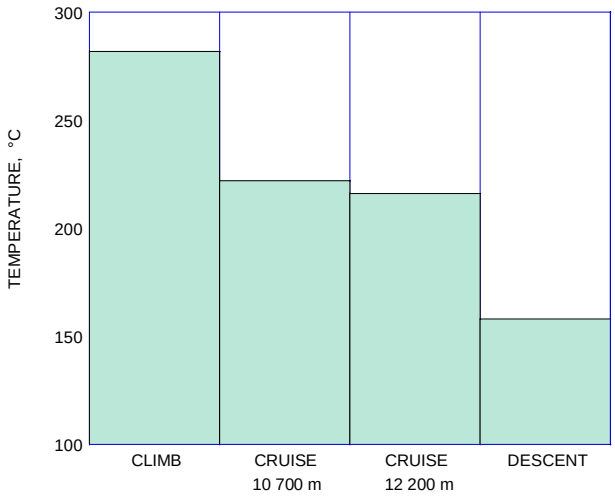

Fig. 9 Typical Air Temperature Supplied to Bleed System During Flight (Adapted from Hunt et al. 1995)

packs. The ozone further dissociates when contacting airplane ducts, interior surfaces, and the airplane recirculation system. The ozone converter dissociates ozone to oxygen molecules by the catalyzing action of a noble catalyst such as palladium. A new converter dissociates approximately 95% of the ozone entering the converter to oxygen. It has a useful life of about 12,000 flight hours.

As the air leaves the ozone converter, it is still at 200°C and a pressure of 200 kPa. Assuming a worst case when the converter is approaching the end of its useful life with an ozone conversion efficiency of 60%, the ozone concentration leaving the converter is about 0.25 ppm SLE. This air goes through the air-conditioning packs and enters the cabin. The ozone concentration in the cabin is about 0.09 ppm. As mentioned in the section on Regulations, the FAA sets a three-hour time-weighted average ozone concentration limit in the cabin of 0.1 ppm and a peak ozone concentration limit of 0.25 ppm.

Air Conditioning and Temperature Control

The air next enters the air-conditioning packs. The air-conditioning pack provides essentially dry, sterile, and dust free conditioned air to the airplane cabin at the proper temperature, flow rate, and pressure to satisfy pressurization and temperature control requirements. For most aircraft, this is approximately 2.5 L/s per passenger. To ensure redundancy, two air-conditioning packs (two are typical, some aircraft have more) provide a total of about 5 L/s of conditioned air per passenger. An equal quantity of filtered, recirculated air is mixed with the air from the air-conditioning packs for a total of approximately 10 L/s per passenger. This quantity of supply air results in a complete cabin air exchange about every 2.5 min, or about 25 air changes per hour. The high air exchange rate is necessary to control temperature gradients, prevent stagnant cold areas, maintain air quality, and dissipate smoke and odors in the cabin. Temperature control is the predominant driver of outside airflow requirements.

The automatic control for the air-conditioning packs constantly monitors airplane flight parameters, the flight crew's selection for the temperature zones, the cabin zone temperature, and the mixed distribution air temperature. The control automatically adjusts the various valves for a comfortable environment under normal conditions. The pilot's controls are located on the overhead panel in the flight deck along with the bleed system controls. Normally, pilots are required only to periodically monitor the compartment temperatures from the overhead panel. Temperatures can be adjusted based on flight attendant reports of passengers being too hot or too cold. Various selections are available to the pilots to accommodate abnormal operational situations.

Air Recirculation

The air has now been cooled and leaves the air-conditioning packs. It leaves the packs at 15°C and 80 kPa. The relative humidity is less than 5% and ozone concentration is less than 0.25 ppm. The carbon dioxide concentration remains unchanged from that of the outside air at about 350 ppm. As this air enters a mixing chamber, it is combined with an equal quantity of filtered recirculated air.

The recirculated air entering the mix manifold is essentially sterile. Over 99.9% of the bacteria and viruses produced by the passengers are removed by HEPA filters, which are used on most modern aircraft. The filters cannot be bypassed and become more efficient with increased service life. They do, however, require replacement at periodic maintenance intervals. Gases, which are not removed by the filters, are diluted to low levels with outside air at a high exchange rate of about 12.5 times per hour.

Air Distribution

The air flows from the mix manifold into duct risers dedicated to each seating zone. The risers direct the air from below the floor to the overhead cabin ventilation system. Trim air (hot bleed air from the pneumatic manifold) is added in the risers to increase the air temperature, if needed. The supply air temperature per seating zone can vary due to differences in seating densities between seating zones.

The overhead air distribution network runs the length of the cabin. The air is dust free and sterile with a relative humidity of 10% to 20%. The temperature is 18 to 29°C, depending upon the seating zone the air is being supplied to, and the carbon dioxide concentration is about 1050 ppm. The carbon dioxide is generated by passenger respiration.

Due to the large quantity of air entering the relatively small volume of the cabin, as compared to a building, control of the airflow patterns is required to give comfort without draftiness. Air enters the passenger cabin from overhead distribution outlets that run the length of the cabin. These outlets create circular airflow patterns in the cabin (Figure 5). Air leaves the outlets at a velocity of more than 2.5 m/s, becomes entrained with cabin air, and maintains sufficient momentum to sweep the cabin walls and floor and to wash out any cold pockets of air in the cabin. The air direction is oriented to avoid exposed portions of a seated passenger, such as the arms, hand, face, neck, and legs; yet it is of sufficient velocity to avoid the sensation of stagnant air. This requires seated passenger impingement velocities between 0.1 and 0.35 m/s.

The air volume circulates in the cabin while continuously mixing with cabin air for 2 to 3 min before it enters the return air grilles that are located in the sidewalls near the floor and run the length of the cabin along both sides. While this air is in the cabin, about 0.33% of the oxygen is consumed by human metabolism. The oxygen is replaced by an equal quantity of carbon dioxide from passenger respiration. In addition, the return air entrains microorganisms or other contaminants from passengers or the cabin itself. Approximately one-half of the return air is exhausted overboard and the other half recirculated to sterile conditions through HEPA filters.

In the aft section, exhaust air is extracted by the cabin pressure outflow valve and exhausted overboard. In the forward section, it is continuously extracted from below the floor by recirculation fans filtered, and then mixed with the outside air being supplied by the air-conditioning packs.

The cabin ventilation is balanced so that air supplied at one seat row leaves at approximately the same seat row. This minimizes airflow in the fore and aft directions, to minimize the spread of passenger-generated contaminants.

Cabin Pressure Control

The cabin pressure control continuously monitors ground and flight modes, altitude, climb, cruise or descent modes, as well as the airplane's holding patterns at various altitudes. It uses this information to position the cabin pressure outflow valve to maintain cabin pressure as close to sea level as practical, without exceeding a cabin-to-outside pressure differential of 60 kPa. At a 12 000 m cruise altitude, the cabin pressure is equivalent to 2100 m or a pressure of 79 kPa. In addition, the outflow valve repositions itself to allow more or less air to escape as the airplane changes altitude. The resulting cabin altitude is consistent with airplane altitude within the constraints of keeping pressure changes comfortable for passengers. Normal pressure change rates are 1.8 kPa per minute ascending and 1.1 kPa per minute descending.

The cabin pressure control system panel is located in the pilot's overhead panel near the other air-conditioning controls. Normally, the cabin pressure control system is totally automatic, requiring no attention from the pilots.

AIR QUALITY

Aircraft cabin air quality is a complex function of many variables including ambient air quality, the design of the cabin volume, the design of the ventilation and pressurization systems, the way the systems are operated and maintained, the presence of sources of contaminants, and the strength of such sources. The following factors can individually or collectively affect aircraft cabin air quality.

Airflow

The total volume of air is exchanged approximately every 2.5 to 3 min in a wide-body aircraft, and every 2 to 3 min on a standard-body aircraft. The airflow per unit length of the airplane is the same for all sections. However, economy class has a lower airflow per passenger because of its greater seating density as compared to first class and business class. A high air exchange rate and sufficient quantity of outside air is supplied to each cabin zone to maintain air quality, control temperature gradients, prevent stagnant cold areas, and dissipate smoke and odors in the cabin.

The flight deck is provided with a higher airflow per person than the cabin in order to maintain a positive pressure in the cockpit (1) to prevent smoke ingress from adjacent areas (abnormal condition), (2) to provide cooling for electrical equipment, (3) to account for increased solar loads and night heat loss through the airplane skin and windows, and (4) to minimize temperature gradients.

Typical commercial transport aircraft provide approximately 50% conditioned (outside) and 50% filtered recirculated air to the passenger cabin on a continuous basis. Increasing the quantity of outside air beyond 50% to the cabin would lower the cabin CO_2 concentration slightly, but it would also increase the potential cabin ozone concentration and lower the cabin relative humidity.

The recirculated air is cleaned by drawing it through HEPA filters; the filters cannot be bypassed. The air distribution system is designed to provide approximately 5 L/s outside air and 5 L/s filtered, recirculated air per passenger. A fully-loaded, all-tourist-class passenger aircraft, which has the maximum seating density throughout the airplane, provides an outside airflow per passenger of 3.1 L/s (standard-body) to 3.8 L/s (wide-body).

The outside air quantity supplied on some aircraft models can be lowered by shutting off one air-conditioning pack. The flight crew has control of these packs to provide flexibility in case of a system failure or for special use of the aircraft. Packs should be in full operation whenever passengers are on board.

Environmental Tobacco Smoke (ETS)

Currently, there are no governmental, occupational, or ambient standards for environmental tobacco smoke (ETS). However, in 1986, the National Academy of Sciences recommended banning smoking on U.S. domestic flights to eliminate the possibility of fires caused by cigarettes, to lessen irritation and discomfort to passengers and crew, and to reduce potential health hazards.

On flights where smoking is allowed, ETS in the cabin is controlled indirectly by controlling the concentration of carbon monoxide (CO) and respirable suspended particulates (RSP). CO and RSP are tracer constituents of ETS and several standards do list acceptable maximum levels for these constituents. (Table 1 and Table 2 in Chapter 9 of the 1997 *ASHRAE Handbook—Fundamentals* summarize these standards.) This method of control does not consider other constituents present in ETS.

Measured CO levels in the smoking section(s) of aircraft during peak smoking are within acceptable limits. RSP concentrations in the smoking sections can exceed recommended levels during peak smoking, which is also true of most heavy smoking areas (e.g. restaurants, bowling alleys, etc.). Of 92 airplanes tested in a DOT sponsored study, average RSP values of 40 $\mu g/m^3$ and 175 $\mu g/m^3$ were measured in the nonsmoking and smoking sections, respectively.

Ozone

Ozone is present in the atmosphere as a consequence of the photochemical conversion of oxygen by solar ultraviolet radiation. Ozone levels vary with season, altitude, latitude, and weather systems. A marked and progressive increase in ozone concentration occurs in the flight altitude of commercial aircraft. The mean ambient ozone concentration increases with increasing latitude, is maximal during the spring (fall season for southern latitudes), and often varies when weather causes high ozone plumes to descend.

Residual cabin ozone concentration is a function of the ambient concentration, the design of the air distribution system and how it is operated and maintained, and whether or not catalytic ozone converters are installed.

Cabin ozone limits are set by FAR 121.578 and FAR 25.832. The use of catalytic ozone converters is generally required on airplanes flying mission profiles where the cabin ozone levels are predicted to exceed these FAR limits (refer to the FAA Code of Federal Regulations for other compliance methods).

Microbial Aerosols

Biologically derived particles that become airborne include viruses, bacteria, actinomycetes, fungal spores and hyphae, arthropod fragments and droppings, and animal and human dander. Only one study has documented the occurrence of an outbreak of infectious disease related to airplane use. In 1977, because of an engine malfunction, an airliner with 54 persons onboard was delayed on the ground for 3 h, during which the airplane ventilation system was reportedly turned off. Within 3 days of the incident, 72% of the passengers became ill with influenza. One passenger (the index case) was ill while the airplane was delayed.

With the ventilation system shut off, no fresh air was introduced into the cabin to displace microbial aerosols and CO_2 or to control cabin temperatures. It is believed that had the ventilation system been operating during the delay, the possibility of other passengers becoming ill would have been minimal.

The airplane ventilation system should never be shut off when passengers are on board; an exception to this recommendation is during no-pack takeoffs when the air packs (but not the recirculation fans) are shut off for the short time only on takeoff.

To remove particulates and biological particles from the recirculated air, filter assemblies that contain a HEPA filter that has a minimum efficiency of 94 to 99.97% DOP as measured by MIL-STD-282 should be used. A HEPA filter is rated using 0.3 μm size particles. A filter's efficiency increases over time as particulates become trapped by the filter. Due to the overlap of capture mechanisms in a filter, the efficiency also increases for particles smaller

and larger than the most penetrating particle size (MPPS). For an airplane filter, the MPPS is about 0.1 to 0.2 μm.

The efficiency of the filter to remove 0.003 μm particles from the air is in excess of 99.9+%. Most bacteria (99%) are larger than 1 μm. Viruses are approximately 0.003 to 0.05 μm in size. Test results in a DOT study conducted on 92 randomly selected flights showed that bacteria and fungi levels measured in the airplane cabin are similar to or lower than those found in the home. These low microbial contaminant levels are due to the large quantity of outside airflow and high filtration of the recirculation system.

Volatile Organic Compounds

Volatile organic compounds (VOCs) can be emitted by material used in furnishings, pesticides, disinfectants, cleaning fluids, and food and beverages. In-flight air quality testing on revenue flights sponsored by The Boeing Company and the Air Transport Association of America (ATAA 1994) detected trace quantities of VOCs, which were considered well below levels that could result in adverse health effects.

Carbon Dioxide

Carbon dioxide is the product of normal human metabolism, which is the predominant source in aircraft cabins. The CO_2 concentration in the cabin varies with outside air rate, the number of people present, and their individual rates of CO_2 production that vary with activity and (to a smaller degree) with diet and health. CO_2 has been widely used as an indicator of indoor air quality, typically serving the function of a surrogate. Per a DOT-sponsored study, measured cabin CO_2 values of 92 randomly selected smoking and nonsmoking flights average 1500 ppm.

The Environmental Exposure Limit adopted by the American Conference of Governmental Industrial Hygienists (ACGIH) is 5000 ppm as the time-weighted average (TWA) limit for CO_2; this value corresponds to a fresh air ventilation rate of 1.1 L/s per person. The TWA is the concentration, for a normal 8 h workday and a 40 hour workweek, to which nearly all workers can be repeatedly exposed, day after day, without adverse effects. As mentioned in the Regulations section under Ventilation, an FAA amendment also limits CO_2 to 5000 ppm (0.5%). Aircraft cabin CO_2 concentrations are below this limit.

ASHRAE *Standard* 62, which does not apply to aircraft per se, states, "Comfort (odor) criteria are likely to be satisfied if the ventilation rate is set so that 1000 ppm CO_2 is not exceeded." It further states, "This level is not considered a health risk but is a surrogate for human comfort (odor)." An interpretation of this standard noted that 1000 ppm CO_2 is not a requirement of the standard, but it can be considered a target concentration level.

Humidity

The relative humidity in airplanes tested in a DOT-sponsored study ranged from approximately 5% to 35% with an average of 15% to 20%. The humidity is made up mainly of moisture from passengers and will increase with more passengers and decrease with increased outside airflow. A major benefit of filtered, recirculated air supplied to the passenger cabin is an increase in cabin humidity compared to airplanes with only outside supply air.

After three or four hours of exposure to relative humidity in the 5 to 10% range, some passengers may experience such discomfort as dryness of the eyes, nose, and throat. However, no serious adverse health effects of low relative humidity on the flying population have been documented.

Cabin Pressure/Oxygen

At a normal airplane cruise altitude, aircraft cabins are pressurized to a maximum cabin altitude of 2400 m (to compress the ambient air to a form that is physiologically acceptable). A DOT-sponsored National Academy of Sciences study concluded that current pressurization criteria and regulations are generally adequate to protect the traveling public. The Academy also noted that the normal maximum rates of change of cabin pressure (approximately 150 m/min in increasing altitude and 90 m/min in decreasing altitude) are such that they do not pose a problem for the typical passenger.

However, pressurization of the cabin to equivalent altitudes of up to 2400 m, as well as changes in the normal rates of pressure during climb and descent, may create discomfort for some people such as those suffering from upper respiratory or sinus infections, obstructive pulmonary diseases, anemias, or certain cardiovascular conditions. In those cases, supplemental oxygen may be recommended. Children and infants sometimes experience discomfort or pain because of pressure changes during climb and descent. Injury to the middle ear has occurred to susceptible people, but is rare.

Some articles and reports state that substandard conditions exist in airplane cabins due to a lack of oxygen. Some reports suggest that this condition is exacerbated by reduced fresh air ventilation rates or through the use of recirculated air. These arguments imply that the oxygen content of cabin air is depleted through the consumption by occupants. Humans at rest breathe at a rate of approximately 150 mL/s while consuming oxygen at a rate of 7 mL/s. The percent oxygen makeup of the supply air remains at approximately 21% at cruise altitude. A person receiving 5 L/s of outside air and 5 L/s of recirculation air would therefore receive approximately 2.1 L/s of oxygen. Consequently, the content of oxygen in cabin air is little affected by breathing as it is replaced in sufficient quantities compared to the human consumption rate.

Although the percentage of oxygen in cabin air remains virtually unchanged (21%) at all normal flight altitudes, the partial pressure of oxygen decreases with increasing altitude, which decreases the amount of oxygen held by the blood's hemoglobin. The increase in cabin altitude may cause low grade hypoxia (reduced tissue oxygen levels) to some people. Low grade hypoxia in combination with other stresses is the main cause of passenger fainting and fatigue. However, the National Academy of Sciences concluded that pressurization of the cabin to an equivalent altitude of 1500 to 2400 m is physiologically safe—no supplemental oxygen is needed to maintain sufficient arterial oxygen saturation.

SHIPS

BASIC CRITERIA 10.1
MERCHANT SHIPS 10.1
Design Criteria 10.1
Equipment Selection 10.2
Typical Systems 10.3
Air Distribution Methods 10.5
Control 10.5
Regulatory Agencies 10.6
NAVAL SURFACE SHIPS 10.6
Design Criteria 10.6
Equipment Selection 10.6

THIS chapter covers air conditioning for oceangoing surface vessels, including luxury liners, tramp steamers, and naval vessels. Although the general principles of air conditioning that apply to land installations also apply to marine installations, some types are not suitable for ships due to their inability to meet shock and vibration requirements. The chapter focuses on load calculations and air distribution for these ships.

BASIC CRITERIA

Air conditioning in ships provides an environment in which personnel can live and work without heat stress. It also increases crew efficiency, improves the reliability of electronic and similar critical equipment, and prevents rapid deterioration of special weapons equipment aboard naval ships.

The following factors should be considered in the design of air conditioning for shipboard use:

1. It should function properly under conditions of roll and pitch.
2. The construction materials should withstand the corrosive effects of salt air and seawater.
3. It should be designed for uninterrupted operation during the voyage and continuous year-round operation. Because ships en route cannot be easily serviced, some standby capacity, spare parts for all essential items, and extra refrigerant charges should be carried.
4. It should have no objectionable noise or vibration, and must meet the noise criteria required by shipbuilding specifications.
5. It should meet the special requirements for operation given in Section 4 of ASHRAE *Standard* 26.
6. The equipment should occupy a minimum of space commensurate with its cost and reliability. Its mass should be kept to a minimum.
7. Because a ship may pass through one or more complete cycles of seasons on a single voyage and may experience a change from winter to summer operation in a matter of hours, the system should be flexible enough to compensate for climatic changes with minimal attention of the ship's operating personnel.
8. Infiltration through weather doors is generally disregarded. However, specifications for merchant ships occasionally require an assumed infiltration load for heating steering gear rooms and the pilothouse.
9. Sun load must be considered on all exposed surfaces above the waterline. If a compartment has more than one exposed surface, the surface with the greatest sun load is used, and the other exposed boundary is calculated at outside ambient temperature.
10. Cooling load inside design conditions are given as a dry-bulb temperature with a maximum relative humidity. For merchant ships, the cooling coil leaving air temperature is assumed to be 9°C dry bulb. For naval ships, it is assumed to be 10.8°C dry bulb. For both naval and merchant ships, the wet bulb is consistent with 95% rh. This off-coil air temperature is changed only when humidity control is required in the cooling season.
11. When calculating winter heating loads, heat transmission through boundaries of machinery spaces in either direction is not considered.

Calculations for Merchant Ship Heating, Ventilation, and Air Conditioning Design, a bulletin available from the Society of Naval Architects and Marine Engineers (SNAME), gives sample calculation methods and estimated values.

MERCHANT SHIPS

DESIGN CRITERIA

Outdoor Ambient Temperature

The service and type of vessel determines the proper outdoor design temperature. Some luxury liners make frequent off-season cruises where more severe heating and cooling loads may be encountered. The selection of the ambient design should be based on the temperatures prevalent during the voyage. In general, for the cooling cycle, outdoor design conditions for North Atlantic runs are 35°C dry bulb and 25.5°C wet bulb; for semitropical runs, 35°C dry bulb and 26.5°C wet bulb; and for tropical runs, 35°C dry bulb and 28°C wet bulb. For the heating cycle, −18°C is usually selected as the design temperature, unless the vessel will always operate in higher temperature climates. The design temperatures for seawater are 29°C in summer and −2°C in winter.

Indoor Temperature

Effective temperatures (ETs) from 21.5 to 23°C are generally selected as inside design conditions for commercial oceangoing surface ships.

Inside design temperature ranges from 24.5 to 27°C dry bulb and approximately 50% rh for summer and from 18 to 24°C dry bulb for winter.

Comfortable room conditions during intermediate outside ambient conditions should be considered in the design. Quality systems are designed to (1) provide optimum comfort when outdoor ambient conditions of 18 to 24°C dry bulb and 90 to 100% rh exist, and (2) ensure that proper humidity and temperature are maintained during periods when sensible loads are light.

Ventilation Requirements

Ventilation must meet the requirements given in ASHRAE *Standard* 62, except when special consideration is required for ships.

The preparation of this chapter is assigned to TC 9.3, Transportation Air Conditioning.

Air-Conditioned Spaces. In public spaces (e.g., mess rooms, dining rooms, and lounges), 10 to 15 L/s of outdoor air per person or 3 air changes per hour (ACH) are required. In all other spaces, at least 8 L/s of outside air per person or 2 ACH must be provided. However, the maximum outside air for any air-conditioned space is 25 L/s per person.

Ventilated Spaces. The fresh air to be supplied to a space is determined by the required rate of change or the limiting temperature rise. The minimum quantity of air to a space is 15 L/s per occupant or 18 L/s per terminal. In addition to these requirements, exhaust requirements must be balanced.

Load Determination. The cooling load estimate for air conditioning considers factors discussed in Chapter 28 of the 1997 *ASHRAE Handbook—Fundamentals*, including the following:

- Solar radiation
- Heat transmission through hull, decks, and bulkheads
- Heat (latent and sensible) dissipation from occupants
- Heat gain due to lights
- Heat (latent and sensible) gain due to ventilation air
- Heat gain due to motors or other electrical equipment
- Heat gain from piping, machinery, and equipment

The cooling effect of adjacent spaces is not considered unless temperatures are maintained with refrigeration or air-conditioning equipment. The latent heat from the scullery, galley, laundry, washrooms, and similar ventilated spaces is assumed to be fully exhausted overboard.

The heating load estimate for air conditioning should consist of the following:

- Heat losses through decks and bulkheads
- Ventilation air
- Infiltration (when specified)

No allowances are made for heat gain from warmer adjacent spaces.

Heat Transmission Coefficients

The overall heat transmission coefficient U for the composite structures common to shipboard construction do not lend themselves to theoretical derivation; they are most commonly obtained from full-scale panel tests. SNAME *Bulletin* 4-7 gives a method for determining these coefficients when tested data are unavailable.

Heat Dissipation from People

The rate at which heat and moisture dissipate from people depends on their activity levels and the ambient dry-bulb temperature. Values that can be used at 27°C room dry bulb are listed in Table 1.

Heat Gain from Sources Within a Space

Information regarding the heat gain from motors, appliances, lights, and other equipment should be obtained from the manufacturers. Data in Chapter 28 of the 1997 *ASHRAE Handbook—Fundamentals* may be used when manufacturers' data are unavailable.

Table 1 Heat Gain from Occupants

Activity at 27°C	Heat Rate, W		
	Sensible	Latent	Total
Dancing	72	177	249
Eating (mess rooms and dining rooms)	64	97	161
Waiters	88	205	293
Moderate activity (lounge, ship's office, chart rooms)	59	73	132
Light activity (staterooms, crew's berthing)	57	60	117
Workshops	73	149	222

EQUIPMENT SELECTION

The principal equipment required for an air-conditioning system can be divided into four categories:

1. Central station air-handling, consisting of fans, filters, central heating and cooling coils, and sound treatment
2. Distribution network, including air ductwork, water piping, and steam piping
3. Required terminal treatment, consisting of heating and cooling coils, terminal mixing units, and diffusing outlets
4. Refrigeration equipment

When selecting air-conditioning equipment, the following factors should be considered:

- Installed initial cost
- Space available in fan rooms, passageways, machinery rooms, and staterooms
- Operation cost, including maintenance
- Noise levels
- Mass

High-velocity air distribution offers many advantages. The use of unitary (factory-assembled) central air-handling equipment and prefabricated piping, clamps, and fittings facilitates installation for both new construction and conversions. Substantial space-saving is possible as compared to the conventional low-velocity sheet metal ducts. Maintenance is also reduced.

Fans must be selected for stable performance over their full range of operation and should have adequate isolation to prevent transmission of vibration to the deck. Because fan rooms are often located adjacent to or near living quarters, effective sound treatment is essential.

In general, equipment used for ships is considerably more rugged than equipment for land applications, and it must withstand the corrosive environment of the salt air and sea. Materials such as stainless steel, nickel-copper, copper-nickel, bronze alloys, and hot-dipped galvanized steel are used extensively. Sections 6 through 10 of ASHRAE *Standard* 26 list equipment requirements.

Fans

The U.S. Maritime Administration (USMA) specifies a family of standard vaneaxial, tubeaxial, and centrifugal fans. Selection curves found on the standard drawings are used in selecting fans (*Standard Plans* S38-1-101, S38-1-102, S38-1-103). Belt-driven centrifugal fans must conform to these requirements, except for speed and drive.

Cooling Coils

Cooling coils are based on an inlet water temperature of 5.5°C with a temperature rise of about 5.5 K, and must meet the following requirements:

- Maximum face velocity of 2.5 m/s
- At least six rows of tubes and 25% more rows than required by the manufacturer's published ratings
- Construction and materials as specified in USMA (1965)

Heating Coils

Heating coils must meet the following requirements:

- Maximum face velocity of 5 m/s
- Supply preheaters with a final design temperature between 13 and 16°C with outside air at −18°C
- Preheaters for air-conditioning systems suit design requirements but have a discharge temperature not less than 7°C with 100% outside air at −18°C
- Tempering heaters for supply systems have a final design temperature between 10 and 21°C, with outside air at −18°C

- Pressure drop for preheater and reheater in series, with full fan volume, does not exceed 125 Pa
- Capacity of steam heaters is based on a steam pressure of 240 kPa (gage), less an allowed 35 kPa line pressure drop and the design pressure drop through the control valve

Filters

Filters must meet the following requirements:

- All supply systems fitted with cooling and/or heating coils have manual roll, renewable marine-type air filters
- Maximum face velocity of 2.5 m/s
- Weather protection
- Located so that they are not bypassed when the fan room door is left open
- Clean, medium rolls are either fully enclosed or arranged so that the outside surface of the clean roll becomes the air-entering side as the medium passes through the airstream
- Dirty medium is wound with the dirty side inward

Medium rolls are 20 m long and are readily available as standard factory-stocked items in nominal widths of 0.6, 0.9, 1.2, or 1.5 m. A permanently installed, dry-type filter gage, graduated to read from 0 to 250 kPa, is installed on each air filter unit.

Air-Mixing Boxes

If available, air-mixing boxes should fit between the deck beams. Other requirements include

- Volume regulation over the complete mixing range within +5% of the design volume, with static pressure in the hot and cold ducts equal to at least the fan design static pressure
- Leakage rate of the hot and cold air valve(s) less than 2% when closed
- Calculations for space air quantities allow for leakage through the hot air damper

Box sizes are based on manufacturer's data, as modified by the above requirements.

Air Diffusers

Air diffusers ventilate the space without creating drafts. In addition, diffusers must meet the following requirements:

- Diffusers serving air-conditioned spaces should be a high-induction type and constructed so that moisture will not form on the cones when a temperature difference of 17 K is used with the space dew point at least 5 K above that corresponding to summer inside design conditions. Compliance with this requirement should be demonstrated in a mock-up test, unless previously tested and approved.
- Volume handled by each diffuser should not, in general, exceed 240 L/s.
- Diffusers used in supply ventilation are of the same design, except have adjustable blast skirts.
- Manufacturer's published data are used in selecting diffusers.

Air-Conditioning Compressors

Compressors should be the same types used for ship's service and cargo refrigeration, except for the number of cylinders or the speed (see Chapter 30, Marine Refrigeration, in the 1998 *ASHRAE Handbook—Refrigeration*).

TYPICAL SYSTEMS

Comfort air-conditioning systems installed on merchant ships are classified as those serving (1) passenger staterooms, (2) crew's quarters and similar small spaces, and (3) public spaces.

Single-Zone Central Air Conditioning

Public spaces are treated as one zone and are effectively handled by single-zone central air conditioning. Exceptionally large spaces may require two systems. Generally, either built-up or factory-assembled fan-coil central station air conditioning is selected for large public spaces. A schematic of a typical air conditioning system, also known as the **Type A** system, is shown in Figure 1. Under certain conditions, it is desirable to avoid the use of return ducts and to use all outdoor air, which requires more refrigeration. Outdoor air and return air are both filtered before being preheated, cooled, and reheated as required at the central station unit. A room thermostat maintains the desired temperature by modulating the valve regulating the flow of steam to the reheat coil. Humidity control is often provided. During mild weather, the dampers frequently are opened to admit 100% outdoor air automatically.

Multizone Central Air Conditioning

Multizone central air conditioning, also known as the **Type C** system, is usually confined to the crew's and officers' quarters (Figure 2). Spaces are divided into zones in accordance with similarity of loads and exposures. Each zone has a reheat coil to supply air at a temperature adequate for all the spaces served. These coils, usually steam-heated, are controlled thermostatically. Manual control of the air volume is the only means for occupant control of conditions. Filters, cooling coils, and dampers are essentially the same as for Type D systems.

Each internal sensible heat load component, particularly solar and lights, varies greatly. The thermostatic control methods cannot

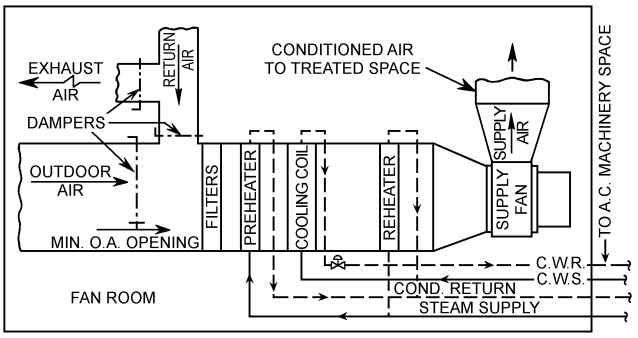

Fig. 1 Single-Zone Central (Type A) System

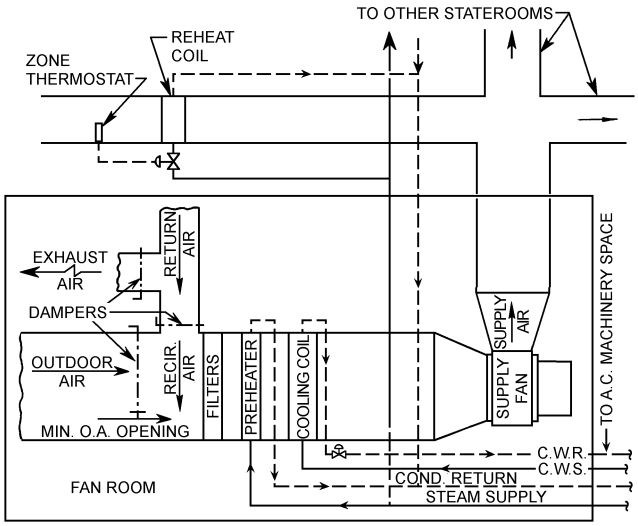

Fig. 2 Multizone Central (Type C) System

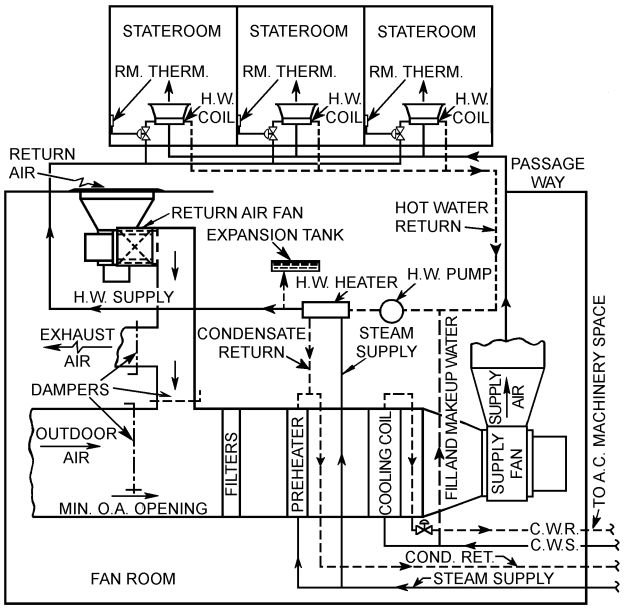

Fig. 3 Terminal Reheat (Type D) System

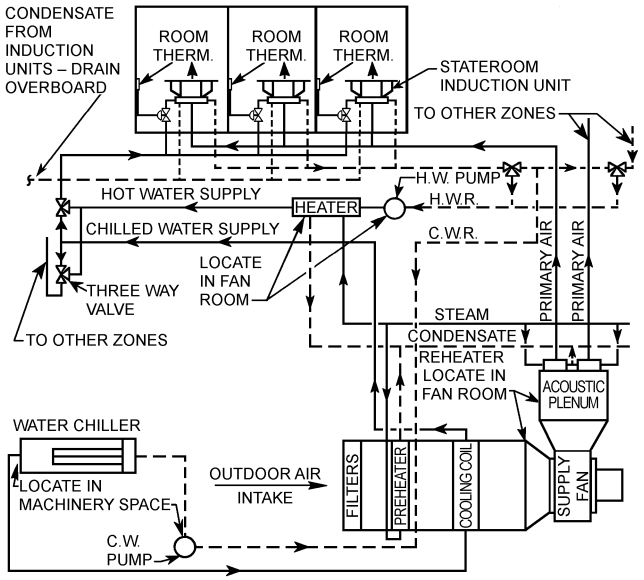

Fig. 4 Air-Water Induction (Type E) System

compensate for these large variations; therefore, this system cannot always satisfy individual space requirements. Volume control is conducive to noise, drafts, and odors.

Terminal Reheat Air Conditioning

Terminal reheat, or **Type D** air conditioning, is generally used for passengers' staterooms, officers' and crew's quarters, and miscellaneous small spaces (Figure 3). Conditioned air is supplied to each space in accordance with its maximum design cooling load requirements. The room dry-bulb temperature is controlled by a reheater. A room thermostat automatically controls the volume of hot water passing through the reheat coil in each space. A mixture of outdoor and recirculated air flows through the ductwork to the conditioned spaces. A minimum of outdoor air mixed with return or recirculated air in a central station system is filtered, dehumidified, and cooled by the chilled water cooling coils, and then distributed by the supply fan through conventional ductwork to the spaces.

Dampers control the volume of outdoor air. No recirculated air is permitted for operating rooms and hospital spaces. When heating is required, the conditioned air is preheated at the control station to a predetermined temperature, and the reheat coils provide additional heating to maintain rooms at the desired temperature.

Air-Water Induction Air Conditioning

A second type of system for passenger staterooms and other small spaces is the air-water induction system, designated as **Type E** air conditioning. This system is normally used for the same spaces as Type D, except where the sensible heat factor is low, such as in mess rooms. In this type of air conditioning, a central station dehumidifies and cools the primary outdoor air only (Figure 4).

The primary air is distributed to induction units located in each of the spaces to be conditioned. Nozzles in the induction units, through which the primary air passes, induce a fixed ratio of room (secondary) air to flow through a water coil and mix with the primary air. The mixture of treated air is then discharged to the room through the supply grille. The room air is either heated or cooled by the water coil. Water flow to the coil (chilled or hot) can be controlled either manually or automatically to maintain the desired room conditions.

This system requires no return or recirculated air ducts because only a fixed amount of outdoor (primary) air needs to be conditioned by the central station equipment. This relatively small amount of conditioned air must be cooled to a sufficiently low dew point to take care of the entire latent load (outdoor air plus room air). It is distributed at high velocity and pressure and thus requires relatively little space for air distribution ducts. However, this saving of space is offset by the additional space required for water piping, secondary water pumps, induction cabinets in staterooms, and drain piping.

Space design temperature is maintained during intermediate conditions (i.e., the outdoor temperature is above the changeover point and chilled water is at the induction units), with primary air heated at the central station unit according to a predetermined temperature schedule. Unit capacity in spaces requiring cooling must be sufficient to satisfy the room sensible heat load plus the load of the primary air.

When outdoor temperature is below the changeover point, the chiller is secured, and space design temperature is maintained by circulating hot water to the induction units. Preheated primary air provides cooling for spaces that have a cooling load. Unit capacity in spaces requiring heating must be sufficient to satisfy the room heat load plus the load of the primary air. Detailed analysis is required to determine the changeover point and temperature schedules for water and air.

High-Velocity Dual-Duct System

High-velocity dual-duct air conditioning, also known as the **Type G** system, is normally used for the same kinds of spaces as Types D and E. In Type G air conditioning, all air is filtered, cooled, and dehumidified in the central units (Figure 5). Blow-through coil arrangements are essential to ensure efficient design. A high-pressure fan circulates air at high velocity approaching 30 m/s, through two ducts or pipes, one carrying cold air and the other warm air. A steam reheater in the central unit heats the air as required.

In each space served, the warm and cold air flow to an air-mixing unit that has a control valve to proportion hot and cold air to obtain the desired temperature. Within the capacity limits of the equipment, any temperature can quickly be obtained and maintained, regardless of load variations in adjacent spaces. The air-mixing unit also incorporates self-contained regulators that maintain a constant volume of total air delivery to the various spaces, regardless of adjustments in the air supplied to rooms down the line.

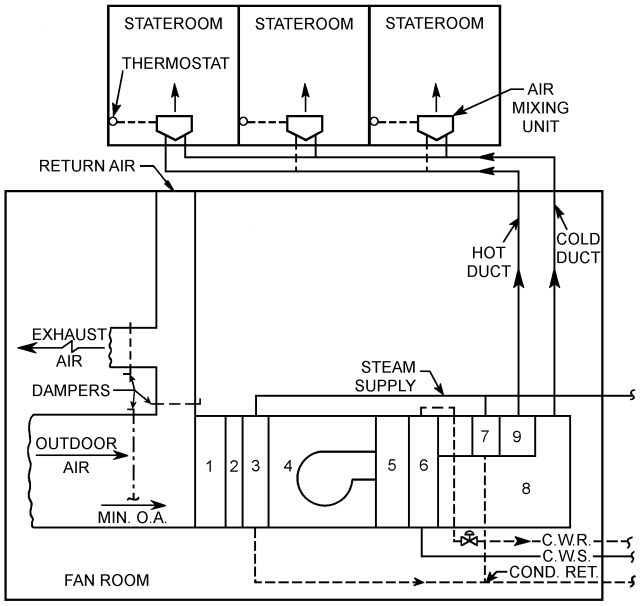

Fig. 5 Dual-Duct (Type G) System

The following are some advantages of this system:

- All conditioning equipment is centrally located, simplifying maintenance and operation
- The system can heat and cool adjacent spaces simultaneously without cycle changeover and with a minimum of automatic controls
- Because only air is distributed from fan rooms, no water or steam piping, electrical equipment, or wiring are in the conditioned spaces
- With all conditioning equipment centrally located, direct-expansion cooling using halocarbon refrigerants is possible, eliminating all intermediary water-chilling equipment

AIR DISTRIBUTION METHODS

Good air distribution in staterooms and public spaces is difficult to achieve due to low ceiling heights and compact space arrangements. The design should consider room dimensions, ceiling height, volume of air handled, air temperature difference between supply and room air, location of berths, and allowable noise. For major installations, mock-up tests are often used to establish the exacting design criteria required for satisfactory performance.

Air usually returns from individual small spaces either by a sight-tight louver mounted in the door or by an undercut in the door leading to the passageway. An undercut door can only be used with small air quantities of 35 L/s or less. Louvers are most commonly sized for a velocity of 2 m/s based on net area.

Ductwork

Ductwork on merchant ships is constructed of steel. Ducts, other than those requiring heavier construction because of susceptibility to damage or corrosion, are usually made with riveted seams sealed with hot solder or fire-resistant duct sealer, welded seams, or hooked seams and laps. They are fabricated of hot-dipped, galvanized, copper-bearing sheet steel, suitably stiffened externally. The minimum thickness of material is determined by the diameter of round ducts or by the largest dimension of rectangular ducts, as listed in Table 2.

The increased application of high-velocity, high-pressure systems has resulted in a greater use of prefabricated round pipe and fittings, including spiral formed sheet metal ducts. It is important that the field fabrication of ducts and fittings ensure that all are airtight.

Table 2 Minimum Thickness of Steel Ducts

All vertical exposed ducts	16 USSG	1.52 mm
Horizontal or concealed vertical ducts less than 150 mm	24 USSG	0.62 mm
Horizontal or concealed vertical ducts 160 to 300 mm	22 USSG	0.76 mm
Horizontal or concealed vertical ducts ducts 310 to 460 mm	20 USSG	0.91 mm
Horizontal or concealed vertical ducts 470 to 760 mm	18 USSG	1.21 mm
Horizontal or concealed vertical ducts over 760 mm	16 USSG	1.52 mm

The use of factory-fabricated fittings, clamps, and joints effectively minimizes air leakage for these high-pressure ducts.

In addition to the space advantage, small ductwork saves mass, another important consideration for this application.

CONTROL

The conditioning load, even on a single voyage, varies over a wide range in a short period. Not only must the refrigeration plant meet these variations in load, but the controls must readily adjust the system to sudden climatic changes. Accordingly, it is general practice to equip the plant with automatic controls. Since comfort is a matter of individual taste, adjustable room thermostats are placed in living spaces.

Manual volume control has also been used to regulate temperatures in cabins and staterooms. For low-velocity air distribution, however, manual volume control tends to disturb the air balance of the remainder of the spaces served. Manual controls are also applied on high-velocity single-duct systems if a constant volume regulator is installed in the terminal box.

Design conditions in staterooms and public spaces can be controlled by one or a combination of the following:

Volume Control. (Used in Type C systems.) This is the least expensive and simplest control. Its disadvantages are an inability to meet simultaneous heating and cooling demands in adjacent spaces, unsatisfactory air distribution, objectionable noise, and inadequate ventilation because of reduction in air delivery.

Reheater Control. Zone reheaters of Type C systems are controlled by regulating the amount of steam to the zone coils by one of two methods. The first method uses a room thermostat in a *representative* space with other spaces in the zone using manual dampers. Spaces served by this type of control do not always develop the desired comfort conditions. Master-submaster control, used in the second method, adjusts the reheater discharge temperature according to a predetermined schedule so that full heat is applied at the design outside heating temperature and less heat is applied as the temperature rises. This control does not adjust to meet variations in individual room loads; however, it is superior to the first method because it is more dependable.

Preheater Control. A duct thermostat, which modulates steam through the valve, controls the preheaters. To prevent bucking, the set point usually is a few degrees below the design cooling off-coil setting.

Coil Control. Except for Type A air conditioning with humidity control and Type E air conditioning primary air coils, cooling coils (water) are controlled by a dew-point thermostat to give a constant off-coil temperature during the entire cooling cycle. No control is provided for coils of Type E air conditioning because they are in series with the flow-through induction units, and maximum dehumidification must be accomplished by the primary coil to maintain dry-coil operation in the room units.

Damper Control. Outdoor, return, and exhaust dampers are either manually (as a group) or automatically controlled. In automatic control, one of two methods is used: (1) controlling the

damper settings by thermostats exposed to weather air, or (2) using a duct thermostat that restricts the outdoor airflow only when the design temperature leaving the cooling coil cannot be achieved with full flow through the coil.

REGULATORY AGENCIES

Merchant vessels that operate under the United States flag come under the jurisdiction of the Coast Guard. Accordingly, the installation and components must conform to the Marine Engineering Rules and Marine Standards of the Coast Guard. Equipment design and installation must also comply with the requirements of both the U.S. Public Health Service and the U.S. Department of Agriculture. Principally, this involves rat-proofing.

Comfort air-conditioning installations do not primarily come under the American Bureau of Shipping. However, equipment should be manufactured, wherever possible, to comply with the American Bureau of Shipping Rules and Regulations. This is important when the vessels are equipped for carrying cargo refrigeration, because the air-conditioning compressors may serve as standby units in the event of a cargo compressor failure. This compliance eliminates the necessity of a separate spare cargo compressor.

NAVAL SURFACE SHIPS

DESIGN CRITERIA

Outdoor Ambient Temperature

Design conditions for naval vessels have been established as a compromise, considering the large cooling plants required for internal heat loads generated by machinery, weapons, electronics, and personnel. Temperatures of 32°C dry bulb and 27°C wet bulb are used as design requirements for worldwide applications, together with 29.5°C seawater temperatures. Heating season temperatures are assumed to be –12°C for outdoor air and –2°C for seawater.

Indoor Temperature

Naval ships are generally designed for space temperatures of 26.5°C dry bulb with a maximum of 55% rh for most areas requiring air conditioning. The *Air Conditioning, Ventilation and Heating Design Criteria Manual for Surface Ships of the United States Navy* (USN 1969) gives design conditions established for specific areas. *Standard Specification for Cargo Ship Construction* (USMA 1965) gives temperatures for ventilated spaces.

Ventilation Requirements

Ventilation must meet the requirements given in ASHRAE *Standard* 62, except when special consideration is required for ships.

Air-Conditioned Spaces. Naval ship design requires that air-conditioning systems serving living and berthing areas on surface ships replenish air in accordance with damage control classifications, as specified in USN (1969):

1. Class Z systems: 2.4 L/s per person.
2. Class W systems for troop berthing areas: 2.4 L/s per person.
3. All other Class W systems: 4.7 L/s per person. The flow rate is increased only to meet either a 35 L/s minimum branch requirement or to balance exhaust requirements. Outdoor air should be kept at a minimum to prevent the air-conditioning plant from becoming excessively large.

Load Determination

The cooling load estimate consists of coefficients from *Design Data Sheet* DDS511-2 of USN *General Specifications for Building Navel Ships* or USN (1969) and includes allowances for the following:

- Solar radiation
- Heat transmission through hull, decks, and bulkheads
- Heat (latent and sensible) dissipation of occupants
- Heat gain due to lights
- Heat (latent and sensible) gain due to ventilation air
- Heat gain due to motors or other electrical equipment
- Heat gain from piping, machinery, and equipment

Loads should be derived from requirements indicated in USN (1969). The heating load estimate for air conditioning should consist of the following:

- Heat losses through hull, decks, and bulkheads
- Ventilation air
- Infiltration (when specified)

Some electronic spaces listed in USN (1969) require adding 15% to the calculated cooling load for future growth and using one-third of the cooling season equipment heat dissipation (less the 15% added for growth) as heat gain in the heating season.

Heat Transmission Coefficients. The overall heat transmission coefficient U between the conditioned space and the adjacent boundary should be estimated from *Design Data Sheet* DDS511-2. Where new materials or constructions are used, new coefficients may be used from SNAME or calculated using methods found in DDS511-2 and SNAME.

Heat Dissipation from People. USN (1969) gives heat dissipation values for people in various activities and room conditions.

Heat Gain from Sources Within the Space. USN (1969) gives heat gain from lights and motors driving ventilation equipment. Heat gain and use factors for other motors and electrical and electronic equipment may be obtained from the manufacturer or from Chapter 28 of the 1997 *ASHRAE Handbook—Fundamentals*.

EQUIPMENT SELECTION

The equipment described for merchant ships also applies for U.S. naval vessels, except as follows:

Fans

A family of standard fans is used by the navy, including vaneaxial, tubeaxial, and centrifugal fans. Selection curves used for system design are found on NAVSEA *Standard Drawings* 810-921984, 810-925368, and 803-5001058. Manufacturers are required to furnish fans dimensionally identical to the standard plan and within 5% of the delivery. No belt-driven fans are included in the fan standards.

Cooling Coils

The navy uses eight standard sizes of direct-expansion and chilled water cooling coils. All coils have eight rows in the direction of airflow, with a range in face area of 0.06 to 0.93 m^2.

The coils are selected for a face velocity of 2.5 m/s maximum; however, sizes 54 DW to 58 DW may have a face velocity up to 3.2 m/s if the bottom of the duct on the discharge is sloped up at 15° for a distance equal to the height of the coil.

Chilled water coils are most commonly used and are selected based on 7.2°C inlet water with approximately a 3.7 K rise in water temperature through the coil. This is equivalent to 65 mL/s per kilowatt of cooling.

Construction and materials are specified in MIL-C-2939.

Heating Coils

The standard naval steam and electric duct heaters have specifications as follows:

Steam Duct Heaters

- Maximum face velocity is 9.1 m/s.
- Preheater leaving air temperature is 5.5 to 10°C.

- Steam heaters are served from a 350 kPa (gage) steam system

Electric Duct Heaters

- Maximum face velocity is 7.1 m/s.
- Temperature rise through the heater is per MIL-H-22594A, but is in no case more than 27 K.
- Power supply for the smallest heaters is 120 V, 3 phase, 60 Hz. All remaining power supplies are 440 V, 3 phase, 60 Hz.
- Pressure drop through the heater must not exceed 85 Pa at 5 m/s. Manufacturers' tested data should be used in system design

Filters

Characteristics of the seven standard filter sizes the navy uses are as follows:

- Filters are available in steel or aluminum
- Filter face velocity is between 1.9 and 4.6 m/s.
- A filter-cleaning station on board ship includes facilities to wash, oil, and drain filters

Air Diffusers

Although it also uses standard diffusers for air-conditioning, the navy generally uses a commercial type similar to those used for merchant ships.

Air-Conditioning Compressors

The navy uses reciprocal compressors up to approximately 530 kW. For larger capacities, open, direct-drive centrifugal compressors are used. Seawater is used for condenser cooling at the rate of 90 mL/s per kilowatt for reciprocal compressors and 72 mL/s per kilowatt for centrifugal compressors.

Table 3 Minimum Thickness of Materials for Ducts

Sheet for Fabricated Ductwork				
	Nonwatertight		Watertight	
Diameter or Longer Side	Galvanized Steel	Aluminum	Galvanized Steel	Aluminum
Up to 150	0.46	0.64	1.90	2.69
160 to 300	0.76	1.02	2.54	3.56
310 to 460	0.91	1.27	3.00	4.06
470 to 760	1.22	1.52	3.00	4.06
Above 760	1.52	2.24	3.00	4.06

Welded or Seamless Tubing		
Tubing Size	Nonwatertight Aluminum	Watertight Aluminum
50 to 150	0.89	2.69
160 to 300	1.27	3.56

Spirally Wound Duct (Nonwatertight)		
Diameter	Steel	Aluminum
Up to 200	0.46	0.64
Over 200	0.76	0.81

Note: All dimensions in millimetres.

Typical Systems

On naval ships, zone reheat is used for most applications. Some ships with sufficient electric power have used low-velocity terminal reheat systems with electric heaters in the space. Some newer ships have used a fan coil unit with fan, chilled water cooling coil, and electric heating coil in spaces with low to medium sensible heat per unit area of space requirements. The unit is supplemented by conventional systems serving spaces with high sensible or latent loads.

Air Distribution Methods

Methods used on naval ships are similar to those discussed in the section on Merchant Ships. The minimum thickness of materials for ducts is listed in Table 3.

Control

The navy's principal air-conditioning control uses a two-position dual thermostat that controls a cooling coil and an electric or steam reheater. This thermostat can be set for summer operation and does not require resetting for winter operation.

Steam preheaters use a regulating valve with (1) a weather bulb controlling approximately 25% of the valve's capacity to prevent freeze-up, and (2) a line bulb in the duct downstream of the heater to control the temperature between 5.5 and 10°C.

Other controls are used to suit special needs. For example, pneumatic/electric controls can be used when close tolerances in temperature and humidity control are required, as in operating rooms. Thyristor controls are sometimes used on electric reheaters in ventilation systems.

CHAPTER 11

INDUSTRIAL AIR CONDITIONING

GENERAL REQUIREMENTS 11.1
Process and Product Requirements 11.1
Employee Requirements 11.4
Design Considerations 11.5
Load Calculations 11.6
SYSTEM AND EQUIPMENT SELECTION 11.6
Heating Systems 11.6
Cooling Systems 11.7
Air Filtration Systems 11.8
Exhaust Systems 11.9
Operation and Maintenance of Components 11.9

INDUSTRIAL plants, warehouses, laboratories, nuclear power plants and facilities, and data processing rooms are designed for specific processes and environmental conditions that include proper temperature, humidity, air motion, air quality, and cleanliness. Airborne contaminants generated must be collected and treated before being discharged from the building or returned to the area.

Many industrial buildings require large quantities of energy, both in manufacturing and in the maintenance of building environmental conditions. Energy can be saved by the proper use of insulation, ventilation, and solar energy and by the recovery of waste heat and cooling.

For worker efficiency, the environment should be comfortable, minimize fatigue, facilitate communication, and not be harmful to health. Equipment should (1) control temperature and humidity or provide spot cooling to prevent heat stress, (2) have low noise levels, and (3) control health-threatening fumes.

GENERAL REQUIREMENTS

Typical temperatures, relative humidities, and specific filtration requirements for the storage, manufacture, and processing of various commodities are listed in Table 1. Requirements for a specific application may differ from those in the table. Improvements in processes and increased knowledge may cause further variation; thus, systems should be flexible to meet future requirements.

Inside temperature, humidity, filtration levels, and allowable variations should be established by agreement with the owner. A compromise between the requirements for product or process conditions and those for comfort may optimize quality and production costs.

A work environment that allows a worker to perform assigned duties without fatigue caused by temperatures that are too high or too low and without exposure to harmful airborne contaminants results in better, continued performance. It may also improve worker morale and reduce absenteeism.

PROCESS AND PRODUCT REQUIREMENTS

A process or product may require control of one or more of the following: (1) moisture regain; (2) rates of chemical reactions; (3) rates of biochemical reactions; (4) rate of crystallization; (5) product accuracy and uniformity; (6) corrosion, rust, and abrasion; (7) static electricity; (8) air cleanliness; and (9) product formability. Discussion of each of these factors follows.

Moisture Regain

In the manufacture or processing of hygroscopic materials such as textiles, paper, wood, leather, and tobacco, the air temperature and relative humidity have a marked influence on the production rate and on product mass, strength, appearance, and quality.

Moisture in vegetable or animal materials (and some minerals) reaches equilibrium with the moisture of the surrounding air by **regain**. Regain is defined as the percentage of absorbed moisture in a material compared to its bone-dry mass. If a material sample with a mass of 110 g has a mass of 100 g after a thorough drying under standard conditions of 104 to 110°C, the mass of absorbed moisture is 10 g—10% of the sample's bone-dry mass. The regain, therefore, is 10%.

Table 2 lists typical values of regain for materials at 24°C in equilibrium at various relative humidities. Temperature change affects the rate of absorption or drying, which generally varies with the nature of the material, its thickness, and its density. Sudden temperature changes cause a slight regain change, even with fixed relative humidity; but the effect of temperature on regain is small compared to the effect of relative humidity.

Hygroscopic Materials. In absorbing moisture from the air, hygroscopic materials deliver sensible heat to the air in an amount equal to that of the latent heat of the absorbed moisture. Moisture gains or losses by materials in processes are usually quite small, but if they are significant, the amount of heat liberated should be included in the load estimate. Actual values of regain should be obtained for a particular application. Manufacturing economy requires regain to be maintained at a level suitable for rapid and satisfactory manipulation. Uniform humidity allows high-speed machinery to operate efficiently.

Conditioning and Drying. Materials may be exposed to the required humidity during manufacturing or processing, or they may be treated separately after conditioning and drying. Conditioning removes or adds hygroscopic moisture. Drying removes both hygroscopic moisture and free moisture in excess of that in equilibrium. Free moisture may be removed by evaporation, physically blowing it off, or other means.

Drying and conditioning may be combined to remove moisture and accurately regulate final moisture content in, for example, tobacco and some textile products. Conditioning or drying is frequently a continuous process in which the material is conveyed through a tunnel and subjected to controlled atmospheric conditions. Chapter 22 of the 2000 *ASHRAE Handbook—Systems and Equipment* describes dehumidification and pressure-drying equipment.

Rates of Chemical Reactions

Some processes require temperature and humidity control to regulate chemical reactions. For example, in rayon manufacture, pulp sheets are conditioned, cut to size, and passed through a mercerizing process. The temperature directly controls the rate of the reaction, while the relative humidity maintains a solution of constant strength and a constant rate of surface evaporation.

The oxidizing process in drying varnish depends on temperature. Desirable temperatures vary with the type of varnish. High relative humidity retards surface oxidation and allows internal gases to escape as chemical oxidizers cure the varnish from within. Thus, a bubble-free surface is maintained with a homogeneous film throughout.

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

Table 1 Temperatures and Humidities for Industrial Air Conditioning

Process	Dry Bulb, °C	rh, %
ABRASIVE		
Manufacture	26	50
CERAMICS		
Refractory	43 to 66	50 to 90
Molding room	27	60 to 70
Clay storage	16 to 27	35 to 65
Decalcomania production	24 to 27	48
Decorating room	24 to 27	48

Use high-efficiency filtration in decorating room. To minimize the danger of silicosis in other areas, a dust-collecting system or medium-efficiency particulate air filtration may be required.

DISTILLING		
General manufacturing	16 to 24	45 to 60
Aging	18 to 22	50 to 60

Low humidity and dust control are important where grains are ground. Use high-efficiency filtration for all areas to prevent mold spore and bacteria growth. Use ultrahigh-efficiency filtration where bulk flash pasteurization is performed.

ELECTRICAL PRODUCTS		
Electronics and X-ray		
Coil and transformer winding	22	15
Semiconductor assembly	20	40 to 50
Electrical instruments		
Manufacture and laboratory	21	50 to 55
Thermostat assembly and calibration	24	50 to 55
Humidistat assembly and calibration	24	50 to 55
Small mechanisms		
Close tolerance assembly	22*	40 to 45
Meter assembly and test	24	60 to 63
Switchgear		
Fuse and cutout assembly	23	50
Capacitor winding	23	50
Paper storage	23	50
Conductor wrapping with yarn	24	65 to 70
Lightning arrester assembly	20	20 to 40
Thermal circuit breakers assembly and test	24	30 to 60
High-voltage transformer repair	26	5
Water wheel generators		
Thrust runner lapping	21	30 to 50
Rectifiers		
Processing selenium and copper oxide plates	23	30 to 40

*Temperature to be held constant.

Dust control is essential in these processes. Minimum control requires medium-efficiency filters. Degree of filtration depends on the type of function in the area. Smaller tolerances and miniature components suggest high-efficiency particulate air (HEPA) filters.

FLOOR COVERING		
Linoleum		
Mechanical oxidizing of linseed oil*	32 to 38	
Printing	27	
Stoving process	70 to 120	

*Precise temperature control required.

Medium-efficiency particulate air filtration is recommended for the stoving process.

Process	Dry Bulb, °C	rh, %
FOUNDRIES*		
Core making	16 to 21	
Mold making		
Bench work	16 to 21	
Floor work	13 to 18	
Pouring	4	
Shakeout	4 to 10	
Cleaning room	13 to 18	

*Winter dressing room temperatures. Spot coolers are sometimes used in larger installations.

In mold making, provide exhaust hoods at transfer points with wet-collector dust removal system. Use 280 to 380 L/s per hood.

In shakeout room, provide exhaust hoods with wet-collector dust removal system. Exhaust 190 to 240 L/s in grate area. Room ventilators are generally not effective.

In cleaning room, provide exhaust hoods for grinders and cleaning equipment with dry cyclones or bag-type collectors. In core making, oven and adjacent cooling areas require fume exhaust hoods. Pouring rooms require two-speed powered roof ventilators. Design for minimum of 10 L/s per square metre of floor area at low speed. Shielding is required to control radiation from hot surfaces. Proper introduction of air minimizes preheat requirements.

FUR		
Drying	43	
Shock treatment	−8 to −7	
Storage	4 to 10	55 to 65

Shock treatment or eradication of any insect infestations requires lowering the temperature to −8 to −7°C for 3 to 4 days, then raising it to 16 to 21°C for 2 days, then lowering it again for 2 days and raising it to the storage temperature.

Furs remain pliable, oxidation is reduced, and color and luster are preserved when stored at 4 to 10°C.

Humidity control is required to prevent mold growth (which is prevalent with humidities above 80%) and hair splitting (which is common with humidities lower than 55%).

GUM		
Manufacturing	25	33
Rolling	20	63
Stripping	22	53
Breaking	23	47
Wrapping	23	58

LEATHER		
Drying	20 to 52	75
Storage, winter room temperature	10 to 16	40 to 60

After leather is moistened in preparation for rolling and stretching, it is placed in an atmosphere of room temperature and 95% relative humidity.

Leather is usually stored in warehouses without temperature and humidity control. However, it is necessary to keep humidity sufficiently low to prevent mildew. Medium-efficiency particulate air filtration is recommended for fine finish.

LENSES (OPTICAL)		
Fusing	24	45
Grinding	27	80

Table 1 Temperatures and Humidities for Industrial Air Conditioning (*Concluded*)

Process	Dry Bulb, °C	rh, %
MATCHES		
Manufacture	22 to 23	50
Drying	21 to 24	60
Storage	16 to 17	50

Water evaporates with the setting of the glue. The amount of water evaporated is 8 to 9 kg per million matches. The match machine turns out about 750 000 matches per hour.

PAINT APPLICATION		
Lacquers: Baking	150 to 180	
Oil paints: Paint spraying	16 to 32	80

The required air filtration efficiency depends on the painting process. On fine finishes, such as car bodies, high-efficiency particulate air filters are required for the outdoor air supply. Other products may require only low- or medium-efficiency filters.

Makeup air must be preheated. Spray booths must have 0.5 m/s face velocity if spraying is performed by humans; lower air quantities can be used if robots perform spraying. Ovens must have air exhausted to maintain fumes below explosive concentration. Equipment must be explosion-proof. Exhaust must be cleaned by filtration and solvents reclaimed or scrubbed.

PHOTO STUDIO		
Dressing room	22 to 23	40 to 50
Studio (camera room)	22 to 23	40 to 50
Film darkroom	21 to 22	45 to 55
Print darkroom	21 to 22	45 to 55
Drying room	32 to 38	35 to 45
Finishing room	22 to 24	40 to 55
Storage room (b/w film and paper)	22 to 24	40 to 60
Storage room (color film and paper)	4 to 10	40 to 50
Motion picture studio	22	40 to 55

The above data pertain to average conditions. In some color processes, elevated temperatures as high as 40°C are used, and a higher room temperature is required.

Conversely, ideal storage conditions for color materials necessitate refrigerated or deep-freeze temperatures to ensure quality and color balance when long storage times are anticipated.

Heat liberated during printing, enlarging, and drying processes is removed through an independent exhaust system, which also serves the lamp houses and dryer hoods. All areas except finished film storage require a minimum of medium-efficiency particulate air filters.

Process	Dry Bulb, °C	rh, %
PLASTICS		
Manufacturing areas		
Thermosetting molding compounds	27	25 to 30
Cellophane wrapping	24 to 27	45 to 65

In manufacturing areas where plastic is exposed in the liquid state or molded, high-efficiency particulate air filters may be required. Dust collection and fume control are essential.

PLYWOOD		
Hot pressing (resin)	32	60
Cold pressing	32	15 to 25
RUBBER-DIPPED GOODS		
Manufacture	32	
Cementing	27	25 to 30*
Dipping surgical articles	24 to 27	25 to 30*
Storage prior to manufacture	16 to 24	40 to 50*
Testing laboratory	23	50*

*Dew point of air must be below evaporation temperature of solvent.

Solvents used in manufacturing processes are often explosive and toxic, requiring positive ventilation. Volume manufacturers usually install a solvent-recovery system for area exhaust systems.

TEA		
Packaging	18	65

Ideal moisture content is 5 to 6% for quality and mass. Low-limit moisture content for quality is 4%.

TOBACCO		
Cigar and cigarette making	21 to 24	55 to 65*
Softening	32	85 to 88
Stemming and stripping	24 to 29	70 to 75
Packing and shipping	23 to 24	65
Filler tobacco casing and conditioning	24	75
Filter tobacco storage and preparation	25	70
Wrapper tobacco storage and conditioning	24	75

*Relative humidity fairly constant with range as set by cigarette machine.
Before stripping, tobacco undergoes a softening operation.

Rates of Biochemical Reactions

Fermentation requires temperature and humidity control to regulate the rate of biochemical reactions.

Rate of Crystallization

The cooling rate determines the size of crystals formed from a saturated solution. Both temperature and relative humidity affect the cooling rate and change the solution density by evaporation.

In the coating pans for pills, a heavy sugar solution is added to the tumbling mass. As the water evaporates, sugar crystals cover each pill. Blowing the proper quantity of air at the correct dry- and wet-bulb temperatures forms a smooth opaque coating. If cooling and drying are too slow, the coating is rough, translucent, and unsatisfactory in appearance; if cooling and drying are too fast, the coating chips through to the interior.

Product Accuracy and Uniformity

In the manufacture of precision instruments, tools, and lenses, air temperature and cleanliness affect the quality of work. If manufacturing tolerances are within 5μm, close temperature control prevents expansion and contraction of the material. Constant temperature is more important than the temperature level; thus conditions are usually selected for personnel comfort and to prevent a film of moisture on the surface. High- or ultrahigh-efficiency particulate air filtration may be required.

Corrosion, Rust, and Abrasion

In the manufacture of metal articles, the temperature and relative humidity are kept sufficiently low to prevent hands from sweating, thus protecting the finished article from fingerprints, tarnish, and/or etching. The salt and acid in body perspiration can cause corrosion and rust within a few hours. The manufacture of polished surfaces usually requires medium- to high-efficiency particulate air filtering to prevent surface abrasion. This is also true for steel-belted radial tire manufacturing.

Static Electricity

In processing light materials such as textile fibers and paper, and where explosive atmospheres or materials are present, humidity can be used to reduce static electricity, which is often detrimental to

Table 2 Regain of Hygroscopic Materials[a]

Classification	Material	Description	Relative Humidity 10	20	30	40	50	60	70	80	90
Natural textile fibers	Cotton	Sea island—roving	2.5	3.7	4.6	5.5	6.6	7.9	9.5	11.5	14.1

[a]Moisture content expressed in percent of dry mass of the substance at various relative humidities, temperature 24°C.

processing and extremely dangerous in explosive atmospheres. Static electricity charges are minimized when the air has a relative humidity of 35% or higher. The power driving the processing machines is converted into heat that raises the temperature of the machines above that of the adjacent air, where humidity is normally measured. Room relative humidity may need to be 65% or higher to maintain the high humidity required in the machines.

Air Cleanliness

Each application must be evaluated to determine the filtration needed to counter the adverse effects on the product or process of (1) minute dust particles, (2) airborne bacteria, and (3) other air contaminants such as smoke, radioactive particles, spores, and pollen. These effects include chemically altering production material, spoiling perishable goods, and clogging small openings in precision machinery. See Chapter 24 of the 2000 *ASHRAE Handbook—Systems and Equipment*.

Product Formability

The manufacture of pharmaceutical tablets requires close control of humidity for optimum tablet formation.

EMPLOYEE REQUIREMENTS

Space conditions required by health and safety standards to avoid excess exposure to high temperatures and airborne contaminants are often established by the American Conference of Governmental Industrial Hygienists (ACGIH). In the United States, the National Institute of Occupational Safety and Health (NIOSH) does research and recommends guidelines for workspace environmental control. The Occupational Safety and Health Administration (OSHA) sets standards from these environmental control guidelines and enforces them through compliance inspection at industrial facilities. Enforcement may be delegated to a corresponding state agency.

Standards for safe levels of contaminants in the work environment or in air exhausted from facilities do not cover all contaminants encountered. Minimum safety standards and facility design criteria are available from various U.S. Department of Health, Education, and Welfare (DHEW) agencies such as the National Cancer Institute, the National Institutes of Health, and the Public Health Service (Centers for Disease Control and Prevention). For radioactive substances, standards established by the U.S. Nuclear Regulatory Commission (NRC) should be followed.

Thermal Control Levels

In industrial plants that need no specific control for products or processes, conditions range from 20 to 38°C and 25 to 60% rh. For a more detailed analysis, the work rate, air velocity, quantity of rest, and effects of radiant heat must be considered (see Chapter 8 of the 1997 *ASHRAE Handbook—Fundamentals*). To avoid stress to workers exposed to high work rates and hot temperatures, the ACGIH established guidelines to evaluate high-temperature air velocity and humidity levels in terms of heat stress (Dukes-Dobos and Henschel 1971).

If a comfortable environment is of concern rather than the avoidance of heat stress, the thermal control range becomes more specific (McNall et al. 1967). In still air, nearly sedentary workers (120 W metabolism) prefer 22 to 24°C dry-bulb temperature with 20 to 60% rh, and they can detect a 1 K change per hour. Workers at a high rate

of activity (300 W metabolism) prefer 17 to 19°C dry bulb with 20 to 50% rh, but they are less sensitive to temperature change (ASHRAE *Standard* 55). Workers at a high activity level can also be cooled by increasing the air velocity (ASHRAE *Standard* 55).

Contaminant Control Levels

Toxic materials are present in many industrial plants and laboratories. In such plants, the air-conditioning and ventilation systems must minimize human exposure to toxic materials. When these materials become airborne, their range expands greatly, thus exposing more people. Chapter 12 of the 1997 *ASHRAE Handbook—Fundamentals*, current OSHA regulations, and ACGIH (1998) give guides to evaluating the health impact of contaminants.

In addition to being a health concern, gaseous flammable substances must also be kept below explosive concentrations. Acceptable concentration limits are 20 to 25% of the lower explosive limit of the substance. Chapter 12 of the 1997 *ASHRAE Handbook—Fundamentals* includes information on flammable limits and means of control.

Instruments are available to measure concentrations of common gases and vapors. For less common gases or vapors, the air is sampled by drawing it through an impinger bottle or by inertial impaction-type air samplers, which support biological growth on a nutrient gel for subsequent identification after incubation.

Gases and vapors are found near acid baths and tanks holding process chemicals. Machine processes, plating operations, spraying, mixing, and abrasive cleaning operations generate dusts, fumes, and mists. Many laboratory procedures, including grinding, blending, homogenizing, sonication, weighing, dumping of animal bedding, and animal inoculation or intubation, generate aerosols.

DESIGN CONSIDERATIONS

To select equipment, the required environmental conditions, both for the product and personnel comfort, must be known. Consultation with the owner establishes design criteria such as temperature and humidity levels, energy availability and opportunities to recover it, cleanliness, process exhaust details, location and size of heat-producing equipment, lighting levels, frequency of equipment use, load factors, frequency of truck or car loadings, and sound levels. Consideration must be given to separating dirty processes from manufacturing areas that require relatively clean air. If uncontrolled by physical barriers, hard-to-control contaminants—such as mists from presses and machining, or fumes and gases from welding—can migrate to areas of final assembly, metal cleaning, or printing and can cause serious problems.

Because of changing mean radiant temperature, insulation should be evaluated for initial and operating cost, saving of heating and cooling, elimination of condensation (on roofs in particular), and maintenance of comfort. When high levels of moisture are required within buildings, the structure and air-conditioning system must prevent condensation damage to the structure and ensure a quality product. Condensation can be prevented by (1) proper selection of insulation type and thickness, (2) proper placing of vapor retarders, and (3) proper selection and assembly of construction components to avoid thermal short circuits. Chapters 22 and 23 of the 1997 *ASHRAE Handbook—Fundamentals* have further details.

Personnel engaged in some industrial processes may be subject to a wide range of activity levels for which a broad range of indoor temperature and humidity levels are desirable. Chapter 8 of the 1997 *ASHRAE Handbook—Fundamentals* addresses recommended indoor conditions at various activity levels.

If layout and construction drawings are not available, a complete survey of existing premises and a checklist for proposed facilities is necessary (Table 3).

New industrial buildings are commonly single-story with flat roofs and ample height to distribute utilities without interfering with process operation. Fluorescent fixtures are commonly mounted at heights up to 3.5 m, high-output fluorescent fixtures up to 6 m, and high-pressure sodium or metal halide fixtures above 6 m.

Lighting design considers light quality, degree of diffusion and direction, room size, mounting height, and economics. Illumination levels should conform to the recommended levels of the Illuminating Engineering Society of North America (IESNA 1993). Air-conditioning systems can be located in the top of the building. However, the designs require coordination because air-handling equipment and ductwork compete for space with sprinkler systems, piping, structural elements, cranes, material-handling systems, electric wiring, and lights.

Operations within the building must also be considered. Production materials may be moved through outside doors and large amounts of outdoor air be allowed to enter. Some operations require close control of temperature, humidity, and contaminants.

Table 3 Facilities Checklist

Construction

1. Single or multistory
2. Type and location of doors, windows, crack lengths
3. Structural design live loads
4. Floor construction
5. Exposed wall materials
6. Roof materials and color
7. Insulation type and thicknesses
8. Location of existing exhaust equipment
9. Building orientation

Use of Building

1. Product needs
2. Surface cleanliness; acceptable airborne contamination level
3. Process equipment: type, location, and exhaust requirements
4. Personnel needs, temperature levels, required activity levels, and special workplace requirements
5. Floor area occupied by machines and materials
6. Clearance above floor required for material-handling equipment, piping, lights, or air distribution systems
7. Unusual occurrences and their frequency, such as large cold or hot masses of material moved inside
8. Frequency and length of time doors open for loading or unloading
9. Lighting, location, type, and capacity
10. Acoustical levels
11. Machinery loads, such as electric motors (size, diversity), large latent loads, or radiant loads from furnaces and ovens
12. Potential for temperature stratification

Design Conditions

1. Design temperatures—indoor and outdoor dry and wet bulb
2. Altitude
3. Wind velocity
4. Makeup air required
5. Indoor temperature and allowable variance
6. Indoor relative humidity and allowable variance
7. Indoor air quality definition and allowable variance
8. Outdoor temperature occurrence frequencies
9. Operational periods: one, two, or three
10. Waste heat availability and energy conservation
11. Pressurization required
12. Mass loads from the energy release of productive materials

Code and Insurance Requirements

1. State and local code requirements for ventilation rates, etc.
2. Occupational health and safety requirements
3. Insuring agency requirements

Utilities Available and Required

1. Gas, oil, compressed air (pressure), electricity (characteristics), steam (pressure), water (pressure), wastewater, interior and site drainage
2. Rate structures for each utility
3. Potable water

A time schedule of operation helps in estimating the heating and cooling load.

LOAD CALCULATIONS

Table 1 and specific product chapters discuss product requirements. Chapter 28 of the 1997 *ASHRAE Handbook—Fundamentals* covers load calculations for heating and cooling.

Solar and Transmission

The solar load on the roof is generally the largest perimeter load and is usually a significant part of the overall load. Roofs should be light colored to minimize solar heat gain. Wall loads are often insignificant, and most new plants have no windows in the manufacturing area, so a solar load through glass is not present. Large windows in old plants may be closed in.

Internal Heat Generation

The process, product, facility utilities, and employees generate internal heat. People, power or process loads, and lights are internal sensible loads. Of these, production machinery often creates the largest sensible load. The design should consider anticipated brake power rather than connected motor loads. The lighting load is generally significant. Heat gain from people is usually negligible in process areas.

Heat from operating equipment is difficult to estimate. Approximate values can be determined by studying the load readings of the electrical substations that serve the area.

In most industrial facilities, the latent heat load is minimal, with people and outdoor air being the major contributors. In these areas, the sensible heat factor approaches 1.0. Some processes, such as papermaking, release large amounts of moisture. This moisture and its condensation on cold surfaces must be managed.

Stratification Effect

The cooling load may be dramatically reduced in a work space that takes advantage of temperature stratification, which establishes a stagnant blanket of air directly under the roof by keeping air circulation to a minimum. The convective component of high energy sources such as the roof, upper walls, and high-level lights has little impact on the cooling load in the lower occupied zones. A portion of the heat generated by high-energy sources (such as process equipment) in the occupied zone is not part of the cooling load. Due to radiation and a buoyancy effect, 20-60% of the energy rises to the upper strata. The amount that rises depends on the building construction, air movement, and temperatures of the source, other surfaces, and air.

Supply- and return-air ducts should be as low as possible to avoid mixing the warm boundary layers. The location of supply-air diffusers generally establishes the boundary of the warmer stratified air. For areas with supply air quantities greater than 10 L/s per square metre, the return air temperature is approximately that of the air entrained by the supply airstream and only slightly higher than that at the end of the throw. With lower air quantities, the return air is much warmer than the supply air at the end of the throw. The amount depends on the placement of return inlets relative to internal heat sources. The average temperature of the space is higher, thus reducing the effect of outside conditions on heat gain. Spaces with a high area-to-employee ratio adapt well to low quantities of supply air and to spot cooling. For design specifics, refer to Chapter 28, the section on General Comfort and Dilution Ventilation.

Makeup Air

Makeup air that has been filtered, heated, cooled, humidified, and/or dehumidified is introduced to replace exhaust air, provide ventilation, and pressurize the building. For exhaust systems to function, air must enter the building by infiltration or the air-conditioning equipment. The space air-conditioning system must be large enough to heat or cool the outside air required to replace the exhaust. Cooling or heat recovery from exhaust air to makeup air can substantially reduce the outdoor air load.

Exhaust from air-conditioned buildings should be kept to a minimum by proper hooding or by relocating exhausted processes to areas not requiring air conditioning. Frequently, excess makeup air is provided to pressurize the building slightly, thus reducing infiltration, flue downdrafts, and ineffective exhaust under certain wind conditions. Makeup air and exhaust systems can be interlocked so that outdoor makeup air can be reduced as needed, or makeup air units may be changed from outdoor air heating to recirculated air heating when process exhaust is off.

In some facilities, outdoor air is required for ventilation because of the function of the space. Recirculation of air is avoided to reduce concentrations of health-threatening fumes, airborne bacteria, and radioactive substances. Ventilation rates for human occupancy should be determined from ASHRAE *Standard* 62 and applicable codes.

Outdoor air dampers of industrial air-conditioning units should handle 100% supply air, so modulating the dampers satisfies the room temperature under certain weather conditions. For 100% outside air, a modulating exhaust damper or fan must be used. The infiltration of outdoor air often creates considerable load in industrial buildings due to poorly sealed walls and roofs. Infiltration should be minimized to conserve energy.

Fan Heat

The heat from air-conditioning return-air fans or supply fans goes into the refrigeration load. This energy is not part of the room sensible heat with the exception of supply fans downstream of the conditioning apparatus.

SYSTEM AND EQUIPMENT SELECTION

Industrial air-conditioning equipment includes heating and cooling sources, air-handling and air-conditioning apparatus, filters, and an air distribution system. To provide low life-cycle cost, components should be selected and the system designed for long life with low maintenance and operating costs.

Systems may consist of (1) heating only in cool climates, where ventilation air provides comfort for workers; (2) air washer systems, where high humidities are desired and where the climate requires cooling; or (3) heating and mechanical cooling, where temperature and/or humidity control are required by the process and where the activity level is too high to be satisfied by other means of cooling. All systems include air filtration appropriate to the contaminant control required.

A careful evaluation will determine the zones that require control, especially in large, high-bay areas where the occupied zone is a small portion of the space volume. ASHRAE *Standard* 55 defines the occupied zone as 80 to 1830 mm high and more than 600 mm from the walls.

Air-Handling Units

Air-handling units heat, cool, humidify, and dehumidify air that is distributed to a workspace. They can supply all or any portion of outdoor air so that in-plant contaminants do not become too concentrated. Units may be factory assembled or field constructed.

HEATING SYSTEMS

Floor Heating

Floor heating is often desirable in industrial buildings, particularly in large high-bay buildings, garages, and assembly areas where workers must be near the floor, or where large or fluctuating outdoor air loads make maintenance of ambient temperature difficult.

As an auxiliary to the main heating system, floors may be tempered to 18 or 21°C by embedded hydronic systems, electrical resistance cables, or warm-air ducts. The heating elements may be buried deep (150 to 450 mm) in the floor to permit slab warm-up at off-peak times, thus using the floor mass for heat storage to save energy during periods of high use.

Floor heating may be the primary or sole heating means, but floor temperatures above 29°C are uncomfortable, so such use is limited to small, well-insulated spaces.

Unit Heaters

Gas, oil, electricity, hot water, or steam unit heaters with propeller fans or blowers are used for spot heating areas or are arranged in multiples for heating an entire building. Temperatures can be varied by individual thermostatic control. Unit heaters are located so that the discharge (or throw) will reach the floor and flow adjacent to and parallel with the outside wall. They are spaced so that the discharge of one heater is just short of the next heater, thus producing a ring of warm air moving peripherally around the building. In industrial buildings with heat-producing processes, much heat stratifies in high-bay areas. In large buildings, additional heaters should be placed in the interior so that their discharge reaches the floor to reduce stratification. Downblow unit heaters in high bays and large areas may have a revolving discharge.

Gas- and oil-fired unit heaters should not be used where corrosive vapors are present. Unit heaters function well with regular maintenance and periodic cleaning in dusty or dirty conditions. Propeller fans generally require less maintenance than centrifugal fans. Centrifugal fans or blowers usually are required if heat is to be distributed to several areas. Gas- and oil-fired unit heaters require proper venting.

Ducted Heaters

Ducted heaters include large direct- or indirect-fired heaters, door heaters, and heating and ventilating units. They generally have centrifugal fans.

Code changes and improved burners have led to increased use of direct-fired gas heaters (the gas burns in the air supplied to the space) for makeup air heating. With correct interlock safety precautions for supply air and exhaust, no harmful effect from direct firing occurs. The high efficiency, high turndown ratio, and simplicity of maintenance make these units suitable for makeup air heating.

For industrial applications of ducted heaters, the following is a list of problems commonly encountered and their solutions:

- **Steam coil freeze-up.** Use steam-distributing-type (sometimes called nonfreeze) coils, face-and-bypass control with the steam valve wide open for entering air below 2°C, and a thermostat in the exit to stop the airflow when it falls below 5°C. Ensure free condensate drainage.
- **Hot water coil freeze-up.** Ensure adequate circulation through drainable coil at all times; a thermostat in the air and in the water leaving the coil opens the water valve wide and stops the airflow under freezing conditions.
- **Temperature override.** Because of wiping action on coil with face-and-bypass control, zoning control is poor. Locate face damper carefully and use room thermostat to reset the discharge air temperature controller.
- **Bearing failure.** Follow bearing manufacturer's recommendations for application and lubrication.
- **Insufficient air quantity.** Require capacity data based on testing; keep forward-curved blade fans clean or use backward-inclined blade fans; inspect and clean coils; install low- to medium-efficiency particulate air filters and change when required.

Door Heating

Unit heaters and makeup air heaters commonly temper outdoor air that enters the building at open doors. These door heaters may have directional outlets to offset the incoming draft or may resemble a vestibule where air is recirculated.

Unit heaters successfully heat air at small doors open for short periods. They temper the incoming outdoor air through mixing and quickly bring the space to the desired temperature after the door is closed. The makeup air heater should be applied as a door heater in buildings where the doors are large (those that allow railroad cars or large trucks to enter) and open for long periods. Unit heaters are also needed in facilities with a sizable negative pressure or that are not tightly constructed. These units help pressurize the door area, mix the incoming cold air and temper it, and bring the area quickly back to the normal temperature after the door is closed.

Often, door heater nozzles direct heated air at the top or down the sides of a door. Doors that create large, cold drafts when open can best be handled by introducing air in a trench at the bottom of the door. When not tempering cold drafts through open doors, some door heaters direct heated air to nearby spots. When the door is closed, they can switch to a lower output temperature.

The door heating units that resemble a vestibule operate with air flowing down across the opening and recirculating from the bottom, which helps reduce cold drafts across the floor. This type of unit is effective on doors routinely open and no higher than 3 m.

Infrared

High-intensity infrared heaters (gas, oil, or electric) transmit heat energy directly to warm the occupants, floor, machines, or other building contents, without appreciably warming the air. Some air heating occurs by convection from objects warmed by the infrared. These units are classed as near- or far-infrared heaters, depending on the closeness of the wavelengths to visible light. Near-infrared heaters emit a substantial amount of visible light.

Both vented and unvented gas-fired infrared heaters are available as individual radiant panels, or as a continuous radiant pipe with burners 3 to 9 m apart and an exhaust vent fan at the end of the pipe. Unvented heaters require exhaust ventilation to remove flue products from the building, or moisture will condense on the roof and walls. Insulation reduces the exhaust required. Additional information on both electric and gas infrared is given in Chapter 15 of the 2000 *ASHRAE Handbook—Systems and Equipment.*

Infrared heaters are used in the following areas:

1. High-bay buildings, where the heaters are usually mounted 3 to 9 m above the floor, along outside walls, and tilted to direct maximum radiation to the floor. If the building is poorly insulated, the controlling thermostat should be shielded to avoid influence from the radiant effect of the heaters and the cold walls.
2. Semiopen and outdoor areas, where people can comfortably be heated directly and objects can be heated to avoid condensation.
3. Loading docks, where snow and ice can be controlled by strategic placement of near-infrared heaters.

COOLING SYSTEMS

Common cooling systems include refrigeration equipment, evaporative coolers, and high-velocity ventilating air.

For manufacturing operations, particularly heavy industry where mechanical cooling cannot be economically justified, evaporative cooling systems often provide good working conditions. If the operation requires heavy physical work, spot cooling by ventilation, evaporative cooling, or refrigerated air can be used. To minimize summer discomfort, high outdoor air ventilation rates may be adequate in some hot process areas. In all these operations, a mechanical air supply with good distribution is needed.

Refrigerated Cooling Systems

The refrigeration cooling source may be located in a central equipment area, or smaller packaged cooling systems may be placed near or combined with each air-handling unit. Central mechanical equipment uses positive-displacement, centrifugal, or absorption refrigeration to chill water. Pumped through unit cooling coils, the chilled water absorbs heat, then returns to the cooling equipment.

Central system condenser water rejects heat through a cooling tower. The heat may be transferred to other sections of the building where heating or reheating is required, and the cooling unit becomes a heat recovery heat pump. Refrigerated heat recovery is particularly advantageous in buildings with a simultaneous need for heating exterior sections and cooling interior sections.

When interior spaces are cooled with a combination of outdoor air and chilled water obtained from reciprocating or centrifugal chillers with heat recovery condensers, hot water at temperatures up to 45°C is readily available. Large quantities of air at room temperature, which must be exhausted because of contaminants, can first be passed through a chilled water coil to recover heat. Heating or reheating obtained by refrigerated heat recovery occurs at a COP approaching 4, regardless of outdoor temperature, and can save considerable energy.

Mechanical cooling equipment should be selected in multiple units. This enables the equipment to match its response to fluctuations in the load and allows maintenance during nonpeak operation. Small packaged refrigeration equipment commonly uses positive-displacement (reciprocating or screw) compressors with air-cooled condensers. These units usually provide up to 700 kW of cooling. Because equipment is often on the roof, the condensing temperature may be affected by warm ambient air, which is often 5 to 10 K higher than the design outdoor air temperature. In this type of system, the cooling coil may receive refrigerant directly.

ASHRAE *Standard* 15 limits the type and quantity of refrigerant in direct air-to-refrigerant exchangers. Fins on the air side improve heat transfer, but they increase the pressure drop through the coil, particularly as they get dirty.

Evaporative Cooling Systems

Evaporative cooling systems may be evaporative coolers or air washers. Evaporative coolers have water sprayed directly on a wetted surface through which air moves. An air washer recirculates water, and the air flows through a heavily misted area. Water atomized in the airstream evaporates, and the water cools the air. Refrigerated water simultaneously cools and dehumidifies the air.

Evaporative cooling offers energy conservation opportunities, particularly in intermediate seasons. In many industrial facilities, evaporative cooling controls both temperature and humidity. In these systems, the sprayed water is normally refrigerated, and a reheat coil is often used. Temperature and humidity of the exit airstream may be controlled by varying the temperature of the chilled water and the reheat coil and by varying the quantity of air passing through the reheat coil with a dewpoint thermostat.

Care must be taken that accumulation of dust or lint does not clog the nozzles or evaporating pads of the evaporative cooling systems. It may be necessary to filter the air before the evaporative cooler. Fan heat, air leakage through closed dampers, and the entrainment of room air into the supply airstream all affect design. Chemical treatment of the water may be necessary to prevent mineral buildup or biological growth on the pads or in the pans.

AIR FILTRATION SYSTEMS

Air filtration systems remove contaminants from air supplied to, or exhausted from, building spaces. Supply air filtration (most frequently on the intake side of the air-conditioning apparatus) removes particulate contamination that may foul heat transfer surfaces, contaminate products, or present a health hazard to people, animals, or plants. Gaseous contaminants must sometimes be removed to prevent exposing personnel to health-threatening fumes or odors. The supply airstream may consist of air recirculated from building spaces and/or outdoor air for ventilation or exhaust air makeup. Return air with a significant potential for carrying contaminants should be recirculated only if it can be filtered enough to minimize personnel exposure. If monitoring and contaminant control cannot be ensured, the return air should be exhausted.

The supply air filtration system usually includes a collection medium or filter, a medium-retaining device or filter frame, and a filter house or plenum. The filter medium is the most important component of the system; a mat of randomly distributed small-diameter fibers is commonly used.

Depending on fiber material, size, density, and arrangement, fibrous filters have a wide range of performance. Low-density filter media with relatively large-diameter fibers remove large particles, such as lint. These roughing filters collect a large percentage by mass of the particulates, but are ineffective in reducing the total particle concentration. The fibers are sometimes coated with an adhesive to reduce particle reentrainment.

Small-fiber, high-density filter media effectively collect essentially all particulates. Ultrahigh-efficiency particulate air filters reduce total particle concentration by more than 99.9%. As filter efficiency increases, so does the resistance to airflow, with typical pressure drops ranging from 12 to 250 Pa. Conversely, dust-holding capacity decreases with increasing filter efficiency, and fibrous filters should not be used for dust loading greater than 4 mg/m^3 of air. For more discussion of particulate filtration systems, refer to Chapter 24 of the 2000 *ASHRAE Handbook—Systems and Equipment*.

Exhaust Air Filtration Systems

Exhaust air systems are either (1) general systems that remove air from large spaces or (2) local systems that capture aerosols, heat, or gases at specific locations within a room and transport them so they can be collected (filtered), inactivated, or safely discharged to the atmosphere. The air in a general system usually requires minimal treatment before discharging to the atmosphere. The air in local exhaust systems can sometimes be safely dispersed into the atmosphere, but sometimes contaminants must be removed so that the emitted air meets air quality standards. Chapters 28 and 29 have more information on industrial ventilation and exhaust systems.

Many types of contamination collection or inactivation systems are applied in exhaust air emission control. Fabric bag filters, glass-fiber filters, venturi scrubbers, and electrostatic precipitators all collect particulates. Packed bed or sieve towers can absorb toxic gases. Activated carbon columns or beds, often with oxidizing agents, are frequently used to absorb toxic or odorous organics and radioactive gases.

Outdoor air intakes should be carefully located to avoid recirculation of contaminated exhaust air. Because wind direction, building shape, and the location of the effluent source strongly influence concentration patterns, exact patterns are not predictable.

Air patterns resulting from wind flow over buildings are discussed in Chapter 15 of the 1997 *ASHRAE Handbook—Fundamentals*. The leading edge of a roof interrupts smooth airflow, resulting in reduced air pressure at the roof and on the lee side. To prevent fume damage to the roof and roof-mounted equipment, and to keep fumes from the building air intakes, fumes must be discharged through either (1) vertical stacks terminating above the turbulent air boundary or (2) short stacks with a velocity high enough to project the effluent through the boundary into the undisturbed air passing over the building. A high vertical stack is the safest and simplest solution to fume dispersal.

Contaminant Control

In addition to maintaining thermal conditions, air-conditioning systems should control contaminant levels to provide (1) a safe and

healthy environment, (2) good housekeeping, and (3) quality control for the processes. Contaminants may be gases, fumes, mists, or airborne particulate matter. They may be produced by a process within the building or contained in the outside air.

Contamination can be controlled by (1) preventing the release of aerosols or gases into the room environment and (2) diluting room air contaminants. If the process cannot be enclosed, it is best to capture aerosols or gases near their source of generation with local exhaust systems that include an enclosure or hood, ductwork, a fan, a motor, and an exhaust stack.

Dilution controls contamination in many applications but may not provide uniform safety for personnel within a space (West 1977). High local concentrations of contaminants can exist within a room, even though the overall dilution rate is quite high. Further, if tempering of outdoor air is required, high energy costs can result from the increased airflow required for dilution.

EXHAUST SYSTEMS

An exhaust system draws the contaminant away from its source and removes it from the space. An exhaust hood that surrounds the point of generation contains the contaminant as much as is practical. The contaminants are transported through ductwork from the space, cleaned as required, and exhausted to the atmosphere. The suction air quantity in the hood is established by the velocities required to contain the contaminant. Chapter 29 has more information on local exhaust systems.

Design values for average and minimum face velocities are a function of the characteristics of the most dangerous material that the hood is expected to handle. Minimum values may be prescribed in codes for exhaust systems. Contaminants with greater mass may require higher face velocities for their control.

Properly sized ductwork keeps the contaminant flowing. This requires very high velocities for heavy materials. The selection of materials and the construction of exhaust ductwork and fans depend on the nature of the contaminant, the ambient temperature, the lengths and arrangement of duct runs, the method of hood fan operation, and the flame and smoke spread rating.

Exhaust systems remove chemical gases, vapors, or smokes from acids, alkalis, solvents, and oils. Care must be taken to minimize the following:

1. **Corrosion**, which is the destruction of metal by chemical or electrochemical action; commonly used reagents in laboratories are hydrochloric, sulfuric, and nitric acids, singly or in combination, and ammonium hydroxide. Common organic chemicals include acetone, benzene, ether, petroleum, chloroform, carbon tetrachloride, and acetic acid.
2. **Dissolution**, which is a dissolving action. Coatings and plastics are subject to this action, particularly by solvent and oil fumes.
3. **Melting**, which can occur in certain plastics and coatings at elevated hood operating temperatures.

Low temperatures that cause condensation in ferrous metal ducts increase chemical destruction. Ductwork is less subject to attack when the runs are short and direct to the terminal discharge point. The longer the runs, the longer the period of exposure to fumes and the greater the degree of condensation. Horizontal runs allow moisture to remain longer than it can on vertical surfaces. Intermittent fan operation can contribute to longer periods of wetness (because of condensation) than continuous operation. High loading of condensables in exhaust systems should be avoided by installing condensers or scrubbers as close to the source as possible.

OPERATION AND MAINTENANCE OF COMPONENTS

All designs should allow ample room to clean, service, and replace any component quickly so that design conditions are affected as little as possible. Maintenance of refrigeration and heat-rejection equipment is essential for proper performance without energy waste.

For system dependability, water treatment is essential. Air washers and cooling towers should not be operated unless the water is properly treated.

Maintenance of heating and cooling systems includes changing or cleaning system filters on a regular basis. Industrial applications are usually dirty, so proper selection of filters, careful installation to avoid bypassing, and prudent changing of filters to prevent overloading and blowout are required. Dirt that lodges in ductwork and on forward-curved fan blades reduces air-handling capacity appreciably.

Fan and motor bearings require lubrication, and fan belts need periodic inspection. Infrared and panel systems usually require less maintenance than equipment with filters and fans, although gas-fired units with many burners require more attention than electric heaters.

The direct-fired makeup heater has a relatively simple burner that requires less maintenance than a comparable indirect-fired heater. The indirect oil-fired heater requires more maintenance than a comparable indirect gas-fired heater. With either type, the many safety devices and controls require periodic maintenance to ensure constant operation without nuisance cutout. Direct- and indirect-fired heaters should be inspected at least once per year.

Steam and hot water heaters have fewer maintenance requirements than comparable equipment having gas and oil burners. When used for makeup air in below-freezing conditions, however, the heaters must be correctly applied and controlled to prevent frozen coils.

THIS chapter deals with the ventilation requirements for cooling, contaminant control, and emergency smoke and temperature control for road tunnels, rapid transit tunnels and stations, enclosed parking structures, bus garages, and bus terminals. Also included are the design approach and type of equipment applied to these ventilation systems.

ROAD TUNNELS

A road tunnel is defined as any enclosed facility through which an operating roadway carrying motor vehicles passes. Road tunnels may be of the underwater, mountain, or urban type. Tunnels may also be created by development of air-right structures over a roadway and overbuilds of the roadway.

All road tunnels require ventilation to remove the contaminants produced by vehicle engines during normal operation. Ventilation may be provided by natural means, by the traffic-induced piston effect, or by mechanical equipment. The method selected should be the most economical in terms of construction and operating costs. Natural and traffic-induced ventilation is adequate for relatively short tunnels and tunnels with low traffic volume (or density). Long and heavily traveled tunnels should have mechanical ventilation.

The exhaust gas constituent of greatest concern from spark-ignition engines is carbon monoxide (CO), because of its asphyxiate nature. From compression-ignition (diesel) engines the predominant contaminant is nitrogen dioxide (NO_2). Tests and operating experience indicate that when the level of carbon monoxide is properly diluted, the other dangerous and objectionable exhaust by-products are also diluted to acceptable levels. An exception to this condition is the large amount of unburned hydrocarbons from vehicles with diesel engines. When the diesel-engine vehicle portion of the traffic mix exceeds 15%, visibility in the tunnel can become a serious concern. The section on Bus Terminals includes further information on diesel engine contaminants and their dilution.

VENTILATION

Three types of mechanical ventilation are considered for road tunnels. **Normal ventilation** is used during normal traffic operations to maintain acceptable levels of contaminants in the tunnel.

Emergency ventilation is used during a fire emergency to remove and control smoke and hot gases. The primary objective of emergency ventilation is to provide an environment sufficiently clear of smoke and hot gases and at a sufficiently low temperature to permit safe evacuation of motorists, and to allow relatively safe access for firefighters.

Temporary ventilation (usually removed after construction is complete) is needed by workers during construction of the facility or while working in the finished tunnel. These ventilation requirements, which are not covered in this chapter, are specified by state or local mining laws, industrial codes, or in the standards set by the U.S. Occupational Safety and Health Administration (OSHA).

VENTILATION SYSTEMS

Any ventilation must dilute contaminants during normal tunnel operations and control smoke during emergency operations. Factors that determine the system selected include tunnel length, cross section, and grade; surrounding environment; traffic volume; and construction cost.

Natural Ventilation

Naturally-ventilated tunnels rely primarily on atmospheric conditions to maintain airflow and a satisfactory environment in the tunnel. The piston effect of traffic provides additional airflow when the traffic is moving. The chief factor affecting the tunnel environment is the pressure differential that is created by differences in elevation, ambient temperature, or wind between the tunnels two portals. Unfortunately, none of these factors can be relied on for continued, consistent results. A change in wind direction or speed can negate all these natural effects, including the piston effect. The pressure must be large enough to overcome the tunnel resistance, which is influenced by tunnel length, cross-sectional geometry, wall roughness, number of vehicles in the tunnel, and air density.

Air can flow through a naturally ventilated tunnel from portal-to-portal (Figure 1A) or portal-to-shaft (Figure 1B). Portal-to-portal flow functions best with unidirectional traffic, which produces a consistent, positive airflow. The air speed in the roadway area is relatively uniform, and the contaminant concentration increases to a maximum at the exit portal. Under adverse atmospheric conditions, the air speed decreases and the contaminant concentration increases, as shown by the dashed line on Figure 1A. The introduction of

The preparation of this chapter is assigned to TC 5.9, Enclosed Vehicular Facilities.

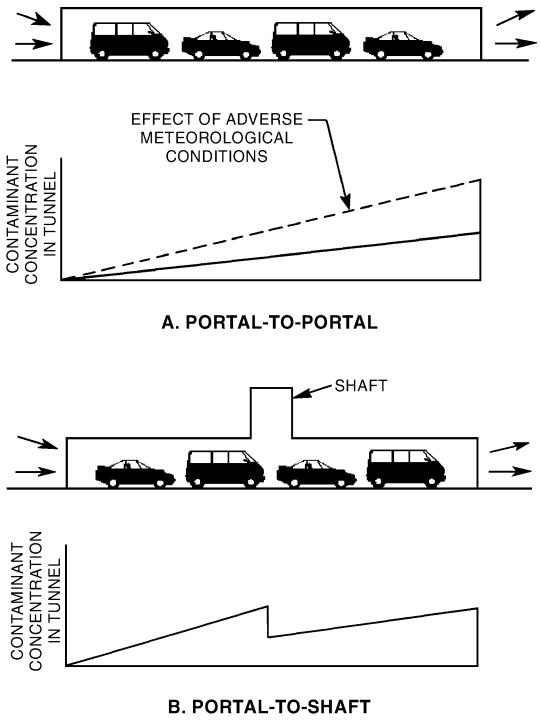

Fig. 1 Natural Ventilation

bidirectional traffic into such a tunnel will further reduce the tunnel airflow and increases the contaminant concentration.

The naturally ventilated tunnel with an intermediate shaft (Figure 1B) is best suited for bidirectional traffic. However, airflow through such a shafted tunnel is also at the mercy of the elements. The benefit of the stack effect of the shaft depends on air and rock temperatures, wind, and shaft height. The addition of more than one shaft to a naturally ventilated tunnel may be more of a disadvantage than an advantage because a pocket of contaminated air can be trapped between the shafts.

Naturally ventilated urban tunnels over 240 m long require emergency mechanical ventilation to extract smoke and hot gases generated during a fire. This emergency system may also be used to remove stagnate contaminants during adverse atmospheric conditions. Because of the uncertainties of natural ventilation, especially the effect of adverse meteorological and operating conditions, reliance on natural ventilation for tunnels over 240 m long should be thoroughly evaluated. This is particularly important for a tunnel with an anticipated heavy or congested traffic flow. If the natural ventilation is inadequate, the installation of a mechanical system with fans should be considered for normal operations.

Smoke from a fire in a tunnel with only natural ventilation moves up the grade driven primarily by the buoyant effect of the hot smoke and gases. The steeper the grade the faster the smoke will move thus restricting the ability of motorists trapped between the incident and the portal at the higher elevation to evacuate the tunnel safely. As shown in Table 1, MHD/FHWA (1995) demonstrates how smoke moves in a naturally ventilated tunnel with a 3.2% grade.

Mechanical Ventilation

A tunnel that is sufficiently long, has heavy traffic flow, or experiences adverse atmospheric conditions requires mechanical ventilation with fans. Mechanical ventilation layouts in road tunnels include longitudinal ventilation, semitransverse ventilation, and full transverse ventilation.

Longitudinal Ventilation. This type of ventilation introduces or removes air from the tunnel at a limited number of points, thus creating a longitudinal flow of air along the roadway. Ventilation is either by injection, by jet fans, or by a combination of injection or extraction at intermediate points in the tunnel.

Table 1 Smoke Movement During Natural Ventilation Tests
(Memorial Tunnel Fire Ventilation Test Program)

Test No.	Fire Heat Release Rate, MW		Smoke Layer Begins Descent, min	Smoke Fills Tunnel Roadway, min	Peak Smoke Velocity, m/s
	Nominal	Peak			
501	20	29	3+	5	6.1
502	50	57	1+	3	8.1

Note: Tunnel grade is 3.2%.

Injection longitudinal ventilation is frequently used in rail tunnels and is also found in road tunnels. Air injected at one end of the tunnel mixes with air brought in by the piston effect of the incoming traffic (Figure 2A). This type of ventilation is most effective where traffic is unidirectional. The air speed remains uniform throughout the tunnel, and the concentration of contaminants increases from zero at the entrance to a maximum at the exit. Adverse external atmospheric conditions can reduce the effectiveness of this system. The contaminant level at the exit portal increases as the airflow decreases or the tunnel length increases.

Injection longitudinal ventilation with the supply at a limited number of locations in the tunnel is economical because it requires the least number of fans, places the least operating burden on these fans, and requires no distribution air ducts. As the length of the tunnel increases, however, disadvantages such as excessive air velocities in the roadway and smoke being drawn the entire length of the roadway during an emergency become apparent. Uniform air distribution would alleviate these problems, however the system then becomes a semitransverse ventilation system.

A longitudinal system with a fan shaft (Figure 2B) is similar to the naturally ventilated system with a shaft, except that it provides a positive stack effect. Bidirectional traffic in a tunnel ventilated in this manner causes a peak contaminant concentration at the shaft location. For unidirectional tunnels, the contaminant levels become unbalanced.

Another form of longitudinal system has two shafts near the center of the tunnel: one for exhaust and one for supply (Figure 2C). This arrangement reduces contaminant concentration in the second half of the tunnel. A portion of the air flowing in the roadway is replaced in the interaction at the shafts. Adverse wind conditions can reduce the airflow, causing the contaminant concentration to rise in the second half of the tunnel, and short-circuit the flow from fan to exhaust.

Jet fan longitudinal ventilation has been installed in a number of tunnels worldwide. Longitudinal ventilation is achieved with specially designed axial fans (jet fans) mounted at the tunnel ceiling (Figure 2D). Such a system eliminates the space needed to house ventilation fans in a separate structure or ventilation building; however, it may require a tunnel of greater height or width to accommodate jet fans so that they are out of the tunnel's **dynamic clearance envelope**. This envelope, formed by the vertical and horizontal planes surrounding the roadway pavement in a tunnel, define the maximum limits of predicted vertical and lateral movement of vehicles traveling on the road at design speed. As the length of the tunnel increases, however, the disadvantages of longitudinal systems, such as excessive air speed in the roadway and smoke being drawn the entire length of the roadway during an emergency, become apparent.

The longitudinal form of ventilation is the most effective method of smoke control in a highway tunnel with unidirectional traffic. A ventilation system must generate sufficient longitudinal air velocity to prevent the backlayering of smoke. Backlayering is the movement of smoke and hot gases contrary to the direction of the ventilation airflow in the tunnel roadway. The air velocity necessary to prevent backlayering of smoke over the stalled

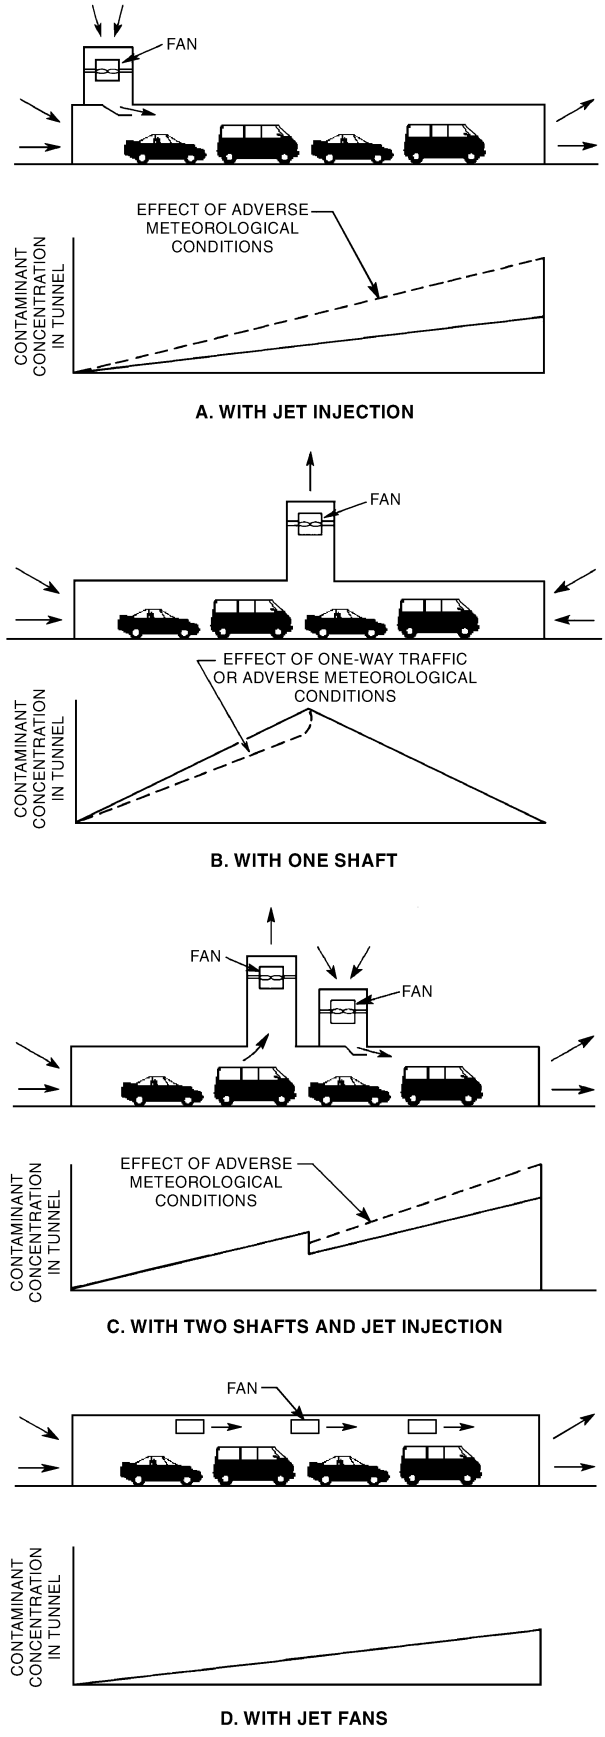

Fig. 2 Longitudinal Ventilation

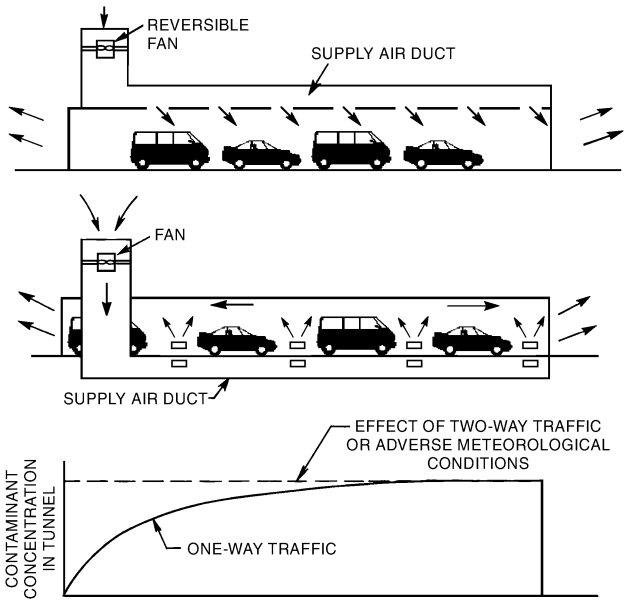
motor vehicles is the minimum velocity needed for smoke control in a longitudinal ventilation system and is known as the critical velocity.

Semitransverse Ventilation. Semitransverse ventilation can be configured as either a supply system or an exhaust system. This type of ventilation incorporates the distribution of (supply system) or collection of (exhaust) air uniformly throughout the length of a road tunnel. Semitransverse ventilation is normally used in tunnels up to about 2000 m; beyond that length the tunnel air speed near the portals become excessive.

Supply semitransverse ventilation applied to a tunnel with bidirectional traffic produces a uniform level of contaminants throughout the tunnel because the air and the vehicle exhaust gases enter the roadway area at the same uniform rate. In a tunnel with unidirectional traffic, additional airflow is generated in the roadway by the movement of the vehicles, thus reducing the contaminant level in portions of the tunnel, as shown in Figure 3A.

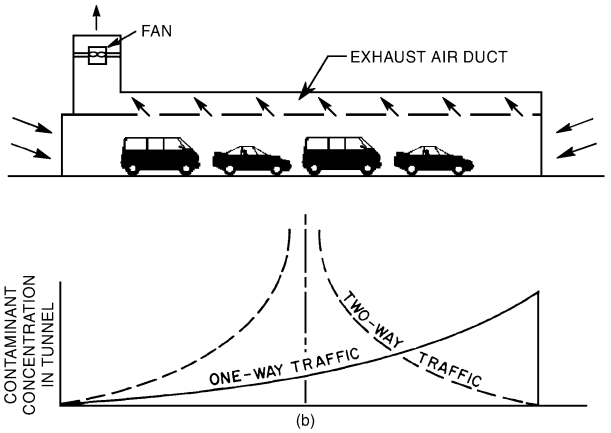
Because the tunnel airflow is fan-generated, this type of ventilation is not adversely affected by atmospheric conditions. The air flows the length of the tunnel in a duct fitted with supply outlets spaced at predetermined distances. Fresh air is best introduced at vehicle exhaust pipe level to dilute the exhaust gases immediately. An adequate pressure differential between the duct and the roadway must be generated and maintained to counteract piston effect and adverse atmospheric winds.

If a fire occurs in the tunnel, the supply air initially dilutes the smoke. Supply semitransverse ventilation should be operated in a reversed mode for the emergency so that fresh air enters the tunnel through the portals to create a respirable environment for fire-fighting efforts and emergency egress. Therefore, the ventilation configuration for a supply semitransverse system should preferably have a ceiling supply and reversible fans so that smoke can be drawn up to the ceiling in an emergency.



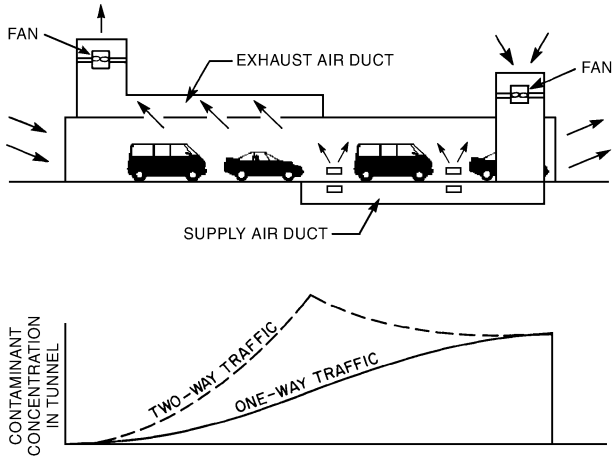
Exhaust semitransverse ventilation (Figure 3B) installed in a unidirectional tunnel produces a maximum contaminant concentration at the exit portal. In a bidirectional tunnel, the maximum level of contaminants is located near the center of the tunnel. A combination supply and exhaust system (Figure 3C) should be applied only in a unidirectional tunnel where air entering with the traffic stream is exhausted in the first half, and air supplied in the second half is exhausted through the exit portal.

In a fire emergency both the exhaust semitransverse ventilation system and the reversed semitransverse supply system create a longitudinal air velocity in the tunnel roadway, which extracts smoke and hot gases at uniform intervals.



Full Transverse Ventilation. Full transverse ventilation is used in extremely long tunnels and in tunnels with heavy traffic volume. Full transverse ventilation includes both a supply duct and an exhaust duct to achieve uniform distribution of supply air and uniform collection of vitiated air (Figure 4) throughout the tunnel length. With this arrangement, pressure along the roadway is uniform and there is no longitudinal airflow except that generated by the traffic piston effect, which tends to reduce contaminant levels. An adequate pressure differential between the ducts and the roadway is required to assure proper air distribution under all ventilation conditions.

During a fire emergency the exhaust system should be operated at the highest available capacity while the supply is operated at a somewhat lower capacity. This operation allows smoke that has stratified towards the ceiling to remain at that higher elevation and to be extracted by the exhaust without mixing. This then maintains a respirable environment at the roadway and allows fresh air to enter through the portals and create a respirable environment for fire fighting and emergency egress.



In longer tunnels a means should be provided to control the individual sections or zones so that the section with traffic trapped behind a fire is provided with maximum supply and no exhaust and

Fig. 3 Semitransverse Ventilation

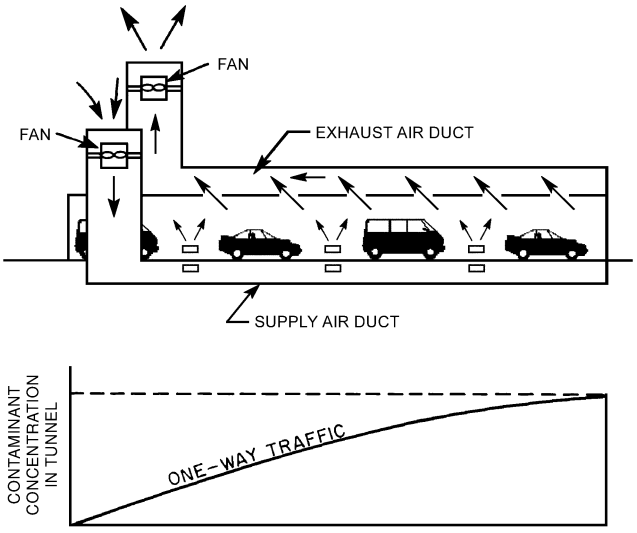

Fig. 4 Full Transverse Ventilation

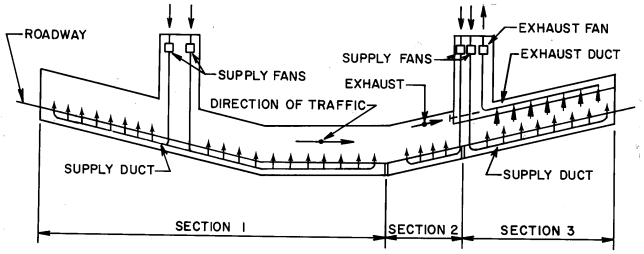

Fig. 5 Combined Ventilation System

the section on the other side of the fire where traffic has driven away is provided with maximum exhaust and minimum or no supply.

Full-scale tests conducted by Fieldner et al. (1921) showed that for rapid dilution of exhaust gases, supply air inlets should be at exhaust pipe level, and exhaust outlets should be in the ceiling. The air distribution can be one or two sided.

Other Ventilation Systems

There are many variations and combinations of the systems described previously. Most of the hybrid systems are configured to solve a particular problem faced in the development and planning of the specific tunnel, such as excessive air contaminants exiting at the portal(s). Figure 5 shows a hybrid system developed for a tunnel with a nearly zero level of acceptable contaminant discharge at one portal.

Ventilation System Enhancements

A few enhancements are available for the systems described previously. The two major enhancements are single point extraction and oversized exhaust ports.

Single point extraction is an enhancement to a transverse system that adds large openings to the extraction (exhaust) duct. These openings include devices that can be operated during a fire emergency to extract a large volume of smoke as close to the fire source as possible. Tests conducted as a part of the Memorial Tunnel Fire Ventilation Test Program (MHD/FHWA 1995) concluded that this concept is effective in reducing the temperature and smoke in the tunnel. The size of opening tested ranged from 9.3 to 28 m^2.

Oversized exhaust ports are simply an expansion of the standard exhaust port installed in the exhaust duct of a transverse or semitransverse ventilation system. Two methods are used to create

such a configuration. One is to install on each port expansion a damper with a fusible link; the other uses a material that when heated to a specific temperature melts and opens the airway. Several tests of such meltable material were conducted as part of the Memorial Tunnel Fire Ventilation Test Program but with limited success.

NORMAL VENTILATION AIR QUANTITIES

Contaminant Emission Rates

The vehicle emissions of carbon monoxide (CO), oxides of nitrogen (NO_x), and hydrocarbons for any given calendar year can be predicted in the United States by using the model developed and maintained by the EPA (1992).

All suggested ventilation rates given in this chapter are derived using uncontrolled emission rates, but the results can be corrected as indicated to reflect the impact of emission control devices.

Allowable Carbon Monoxide

In 1975, the EPA issued a supplement to its *Guidelines for Review of Environmental Statements for Highway Projects* that evolved into a design approach based on keeping a CO concentration of 143 mg/m^3 (125 ppm) or below for a maximum of one hour exposure time for tunnels located at or below an altitude of 1000 m. In 1988, the EPA revised its recommendations for maximum CO levels in tunnels located at or below an altitude of 1500 m to the following:

- Maximum 137 mg/m^3 (120 ppm) for 15 min exposure time
- Maximum 74 mg/m^3 (65 ppm) for 30 min exposure time
- Maximum 52 mg/m^3 (45 ppm) for 45 min exposure time
- Maximum 40 mg/m^3 (35 ppm) for 60 min exposure time

These guidelines do not apply to tunnels in operation prior to the adoption date. Outdoor air standards and regulations such as those from the Occupational Safety and Health Standards (OSHA) and the American Conference of Governmental Industrial Hygienists (ACGIH) are discussed in the section on Bus Terminals.

At higher elevations the CO emission of vehicles is greatly increased, and human tolerance to CO exposure is reduced. For tunnels above 1500 m, the engineer should consult with medical authorities to establish a proper design value for CO concentrations. Unless specified otherwise, the material in this chapter refers to tunnels at or below an altitude of 1500 m.

Computer Programs Available

SES. The Subway Environment Simulation (SES) computer program can be used to examine longitudinal airflow in a road tunnel (DOT 1997). The SES is a one dimensional network model is the predominant worldwide tool used to evaluate longitudinal airflow in tunnels.

TUNVEN. This program solves the coupled one-dimensional steady-state tunnel aerodynamic and advection equations. It can predict quasi-steady-state longitudinal air velocities and the concentrations of CO, oxides of nitrogen (NO_x), and total hydrocarbons along a highway tunnel for a wide range of tunnel designs, traffic loads, and external ambient conditions. The program can model all common ventilation system: natural, longitudinal, semitransverse, and transverse. The program is available from NTIS (1980).

EMERGENCY VENTILATION AIR QUANTITIES

The ventilation system must have the capacity to protect the traveling public during the most adverse and dangerous conditions, as well as during normal conditions. Establishing air requirements is difficult because many uncontrollable variables, such as the many possible vehicle combinations and traffic situations, could occur during the lifetime of the facility. Longitudinal flow and extraction and dilution are two primary methods of controlling smoke from fire in a tunnel.

Table 2 Typical Fire Size Data for Road Vehicles

Cause of Fire	Equivalent Size of Gasoline Pool, m^2	Fire Heat Release Rate, MW	Smoke Generation Rate, m^3/s	Maximum Temp.,[a] °C
Passenger car	2.0	≈5	20	400
Bus/Truck	8.0	≈20	60	700
Gasoline tanker	30–100	≈100	100–200	1000

Source: PIARC (1995).
[a]Temperature 10 m downwind of fire with the minimum air velocity necessary to prevent back-layering.

Table 3 Maximum Temperature Experienced at Ventilation Fans (Memorial Tunnel Fire Ventilation Test Program)

Nominal FHRR, MW	Temperature at Central Fans[a], °C	Temperature at Jet Fan[b], °C
100	163	680
50	124	370
20	107	230

[a]Central fans were located about 200 m from fire site.
[b]Jet fans were located 52 m downstream of fire site.

Fire Size. The design fire size selected has a significant effect on the magnitude of the critical air velocity necessary to prevent backlayering. The data in Table 2 provide a guideline to the typical fire size for a selection of road vehicles. The method for calculating the required critical velocity is shown below.

Temperature. A fire in a tunnel significantly increases the air temperature in the tunnel roadway or duct. This means that the structure and equipment are exposed to the high gas and smoke temperature. The temperatures shown in Table 3 provide guidance in selecting the design temperature for structures and equipment.

Critical Velocity. The simultaneous solution of Equations (1) and (2), by iteration, determines critical velocity (Kennedy et al. 1996), which is the minimum steady-state velocity of the ventilation air moving toward the fire that is needed to prevent backlayering:

$$V_C = K_1 K_g \left(\frac{gHq}{\rho c_p A T_f} \right)^{1/3} \quad (1)$$

$$T_f = \left(\frac{q}{\rho c_p A V_C} \right)^{1/3} + T \quad (2)$$

where

A = area perpendicular to the flow, m^2
c_p = specific heat of air, kJ/(kg·K)
g = acceleration caused by gravity, m/s^2
H = height of duct or tunnel at the fire site, m
K_1 = 0.606
K_g = grade factor (see Figure 6).
q = heat that fire adds directly to air at the fire site, kW
T = temperature of approach air, K
T_f = average temperature of fire site gases, K
V_C = critical velocity, m/s
ρ = average density of approach (upstream) air, kg/m^3

Memorial Tunnel Fire Ventilation Test Program. This full-scale test program was conducted to evaluate the effectiveness of various tunnel ventilation systems and ventilation airflow rates to control smoke from a fire (MHS/FHWA 1995). The results are useful in the development of emergency tunnel ventilation design and emergency operational procedures.

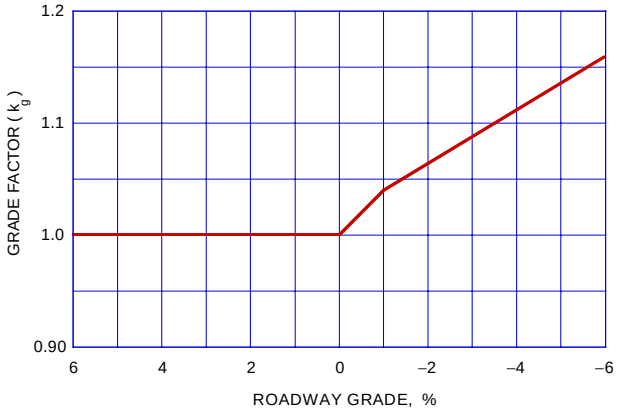

Fig. 6 Roadway Grade Factor

Computer Programs Available

SES. This program contains a fire model that can be used to determine how much longitudinal airflow is required to overcome backlayering and control smoke movement in a tunnel.

CFD. Computational fluid dynamics software has become the design tool of choice of engineers from different disciplines to obtain an optimum design due to the high cost, complexity, and limited information obtained from experimental methods. CFD can analyze different tunnel configurations without having to perform actual tests.

PRESSURE EVALUATION

Air pressure losses in the tunnel ducts must be evaluated to compute fan pressure and drive requirements. Fan selection should be based on total pressure across the fans, not on static pressure only.

Fan total pressure (FTP) is defined by ASHRAE *Standard* 51/AMCA *Standard* 210 as the algebraic difference between the total pressures at the fan discharge (TP_2) and at the fan inlet (TP_1), as shown in Figure 7. The fan velocity pressure (FVP) is defined as the pressure (VP_2) corresponding to the bulk air velocity and air density at the fan discharge.

$$FVP = VP_2 \tag{3}$$

The fan static pressure (FSP) equals the difference between the fan total pressure and the fan velocity pressure.

$$FSP = FTP - FVP \tag{4}$$

The total pressure at the fan discharge (TP_2) must equal the total pressure losses ($\Delta TP_{2\text{-}3}$) in the discharge duct and the exit velocity pressure (VP_3).

$$TP_2 = \Delta TP_{2\text{-}3} + VP_3 \tag{5}$$

Likewise, the total pressure at the fan inlet (TP_1) must equal the total pressure losses in the inlet duct and the inlet pressure.

$$TP_1 = TP_0 + \Delta TP_{0\text{-}1} \tag{6}$$

Straight Ducts

Straight ducts in tunnel ventilation systems can be classified as (1) those that transport air and (2) those that uniformly distribute (supply) or uniformly collect (exhaust) air. Several methods have been developed to predict pressure losses in a duct of constant cross-sectional area that uniformly distributes or collects air. The most widely used method was developed for the Holland Tunnel in New York (Singstad 1929). The following relationships based on the Singstad's work, give pressure losses at any point in the duct.

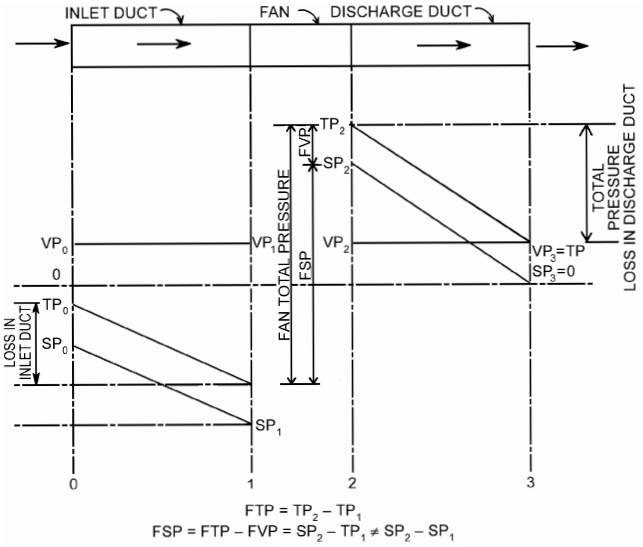

Fig. 7 Fan Total Pressure

Total pressure for a **supply duct**,

$$p_T = p_1 + \frac{\rho_a V_0^2}{2\rho_w}\left[\frac{aLZ^3}{3H} - (1-K)\frac{Z^2}{2}\right] \tag{7}$$

Static pressure loss for an **exhaust duct**,

$$p_s = p_1 + \frac{\rho_a V_0^2}{2\rho_w}\left[\frac{aLZ^3}{(3+c)H} - \frac{3Z^2}{(2+c)}\right] \tag{8}$$

where

p_T = total pressure loss at any point in duct, kPa
p_s = static pressure loss at any point in duct, kPa
p_1 = pressure at last outlet, kPa
ρ_a = density of air, kg/m^3
ρ_w = density of water, kg/m^3
V_0 = velocity of air entering duct, m/s
a = constant related to coefficient of friction for concrete = 0.0035
L = total length of duct, m
Z = $(L - X)/L$
X = distance from duct entrance to any location, m
H = hydraulic radius, m
K = constant accounting for turbulence = 0.615
c = constant relating to turbulence of exhaust port = 0.25

The geometry of the exhaust air slot connection to the main duct is a concern in the derivation of the exhaust duct equation. The derivation is based on a 45° angle between the slot discharge and the main airstream axes. Variations in this angle can greatly affect the energy losses at the convergence from each exhaust slot, with total pressure losses for a 90° connection increasing by 50 to 100% over the 45° values (Haerter 1963).

For **distribution ducts** with sections that differ along their length, these equations may also be solved sequentially for each constant area section, with transition losses considered at each change in section area. For a **transport duct** having constant cross-sectional area and constant velocity, the pressure losses are due to friction alone and can be computed using the standard expressions for losses in ducts and fittings (see Chapter 32 of the 1997 *ASHRAE Handbook—Fundamentals*).

CARBON MONOXIDE ANALYZERS AND RECORDERS

The air quality in a tunnel should be monitored continuously at several key points. Carbon monoxide is the contaminant usually selected as the prime indicator of tunnel air quality. CO-analyzing instruments base their measurements on one of three processes: catalytic oxidation, infrared absorption, or electrochemical oxidation.

The **catalytic oxidation (metal oxide) instrument**, the most widely used in road tunnels, offers reliability and stability at a moderate initial cost. Maintenance requirements are low, and the instruments can be calibrated and serviced by maintenance personnel after only brief instruction.

The **infrared analyzer** has the advantage of sensitivity and response but the disadvantage of high initial cost. A precise and complex instrument, it requires a highly trained technician for maintenance and servicing.

The **electrochemical analyzer** is precise, compact, and light. The units are of moderate cost; but have a limited life, usually not exceeding two years, thus requiring periodic replacement.

No matter which type of CO analyzer is selected, each air sampling point must be located where significant readings can be obtained. For example, the area near the entrance of a unidirectional tunnel usually has very low CO concentrations, and sampling points there yield little information for ventilation control. The length of piping between the sampling point and the CO analyzer should be as short as possible to maintain a reasonable air sample transport time.

Where intermittent analyzers are used, provisions should be made to prevent the loss of more than one sampling point during an air pump outage. Each analyzer should be provided with a strip chart recorder to keep a permanent record of tunnel air conditions. Usually, recorders are mounted on the central control board.

Haze or smoke detectors have been used on a limited scale, but most of these instruments are optical devices and require frequent or constant cleaning with a compressed air jet. If traffic is predominantly diesel powered, smoke haze and oxides of nitrogen require monitoring in addition to CO.

CONTROLS

To reduce the number of operating personnel at a tunnel, all ventilating equipment should be controlled at a central location. At many older tunnel facilities, fan operation is manually controlled by an operator at the central control board. Many new tunnels, however, have partial or total automatic control for fan operation.

CO Analyzer Control

In this system, adjustable contacts in CO analyzers turn on additional fans or increase fan speeds as CO readings increase. The reverse occurs as CO levels decrease. The system requires fairly complex wiring because fan operation must normally respond to the single highest level being recorded at several analyzers. A manual override and delay devices are required to prevent the ventilation system from responding to short-lived high or low levels.

Time Clock Control

This automatic fan control is best suited for installations that experience heavy rush-hour traffic. A time clock is set to increase the ventilation level in preset increments before the anticipated traffic increase. The system is simple and easily revised to suit changing traffic patterns. Because it anticipates an increased air requirement, the ventilation system can be made to respond slowly and thus avoid expensive demand charges by the power company. As with the CO system, a manual override is needed to cope with unanticipated conditions.

Traffic-Actuated Control

Several automatic fan controls based on recorded traffic flow have been devised. Most of them require the installation of computers and other electronic equipment needing maintenance expertise.

Local Fan Control

In addition to a central control board, each fan should have local control in sight of the unit. It should be interlocked to permit positive isolation of the fan from remote or automatic operation during maintenance and servicing.

TOLLBOOTHS

Toll plazas for vehicular tunnels, bridges, and toll roads generally include a series of individual tollbooths. An overhead weather canopy and a utility tunnel located below the roadway surface are frequently provided. The canopy facilitates the installation of roadway signs and lighting. The utility tunnel is used for installation of electrical and mechanical systems; also it provides access to each tollbooth. An administration building is usually situated nearby.

Toll collectors and supervisors are exposed to adverse environmental conditions similar to those in bus terminals and underground parking garages. The normal highway automotive emission levels are increased considerably by vehicles decelerating, idling, and accelerating at the toll facility. The presence of the increased levels of CO, NO_x, diesel and gasoline fumes, and other automotive emissions has a potential detrimental effect on health.

The toll collectors can not rely on physical barriers to isolate them totally from the automotive emissions because toll windows are necessary for collecting tolls. The frequent opening and closing of the window makes the heating and cooling loads of each booth fluctuate independently. The heat loss or gain is extremely high as all four sides (and frequently the ceiling) of the relatively small tollbooth are exposed to the outdoor ambient temperature.

Workplace air quality standards are mandated by local, state, and federal agencies. The adverse ambient conditions to which the toll collecting personnel are exposed and the need to maintain an acceptable environment inside the tollbooths require a careful evaluation of air distribution when designing the HVAC system.

AIR QUALITY CRITERIA

ACGIH (1998) recommends a threshold limit of 29 mg/m^3 (25 ppm) of CO for an 8 hour exposure. The OSHA standard for repeated (day after day) 8 hour exposure to CO in the ambient air is 40 mg/m^3 (35 ppm). The deceleration, idling, and acceleration of varying number of vehicles make it difficult to estimate the CO levels in the vicinity of the toll collecting facilities. However, the resultant CO levels must be estimated using computer programs now available.

Longitudinal tunnel ventilation systems that use jet fans or Saccardo nozzles are being used increasingly for vehicular tunnels with unidirectional traffic flow. These longitudinal ventilation systems discharge air contaminants from the tunnel towards the exit portal. The resultant CO levels in the vicinity of the tunnel toll collecting facilities may be higher than other toll facilities.

Any contaminants that enter booths would remain in the ventilation air if recirculation is used. The ventilation system should be designed to distribute 100% outside air to each booth in order to prevent the intrusion of air contaminants.

DESIGN CONSIDERATIONS

The ventilation system for toll plazas should pressurize the booths to keep out contaminants exhausted by vehicular traffic. The opening of the window during toll collection varies with booth design and individual toll collector habits. The amount of ventilation air required for pressurization also varies.

A variable air volume (VAV) system that varies the air supply rate based on the pressure differential between the booth and outdoor or toll window position is achievable with controls now available. A constant volume maximum-minimum arrangement may also be used at booths with a VAV central unit.

Because open window area varies with individual toll collectors and booth architecture, a design window opening that is based on an estimated average opening may be used for determining the air supply rate. The minimum air supply when the booth window is closed should be based on the amount of air required to meet the heating/cooling requirement and to prevent infiltration of air contaminants through door and window cracks. Where the minimum air supply exceeds the air exfiltration rate, provisions to relieve the excess air should be made to prevent overpressurization.

The space between the booth roof and the overhead canopy may be used for installation of individual HVAC units, fan coil units, or VAV boxes. Air ducts and piping may be installed on top of the plaza canopy or in the utility tunnel.

The amount of ventilation air is high compared to the size of the booth. The resultant rate of air change is extremely high. Supply air outlets should be sized and arranged to deliver air at low velocity. Air reheating should be considered where the supply air temperature is considered too low.

In summer, the ideal air supply is from the booth ceiling to allow the cold air to descend through the booth. In winter, the ideal air supply is from the bottom of the booth or at floor level. Distribution that is ideal for both cooling and heating is not always possible. When air is supplied from the ceiling, other means of providing heat at the floor level, such as electric forced air heaters, electric radiant heating, or heating coils in the floor should be considered.

The supply air intake should be located such that the air drawn into the system is as free as practicable of vehicle exhaust fumes. The prevailing wind should be considered when locating the intake, and it should be placed as far off the side of the roadway as is practicable to ensure better quality ventilation air.

EQUIPMENT SELECTION

Two types of HVAC systems for toll plazas are commonly used: individual HVAC units and central HVAC systems. Individual HVAC units allow each toll collector the freedom of choosing either heating, cooling, or ventilation mode. Maintenance of individual units can be performed without affecting other lanes. In contrast, a central HVAC system should have redundancy to avoid a shut down of the system for the entire toll plaza during maintenance.

The design emphasis on booth pressurization requires the use of 100% outside air. Where a VAV system is used to reduce the operating cost, the varying supply rate of 100% outside air requires a complex temperature control that is normally not available for individual HVAC units. The individual HVAC units should be considered only where the toll plaza is small or tollbooths are so dispersed that a central HVAC system is not economically justifiable.

Where hot water, chilled water, or secondary water service are available from an adjacent administration building, individual fan coils for each booth and a central air handler for supplying ventilation air may be economical. When operating hours for booths and the administration building are significantly different, separate heating and cooling for the toll collecting facility should be considered. The selection of a central air distribution system should be based on the number of maximum open traffic lanes during peak hours and minimum open traffic lanes during moderate traffic.

The HVAC for toll plazas is generally required to operate continuously. A minimum amount of air may be supplied to tollbooths that are not occupied to prevent infiltration of exhaust fumes into tollbooths. Otherwise consideration should be given to remotely flushing the closed booths with ventilation air prior to occupancy.

PARKING GARAGES

Automobile parking garages are either fully enclosed or partially open. Fully enclosed parking areas are usually underground and require mechanical ventilation. Partially open parking levels are generally above-grade structural decks having open sides (except for barricades), with a complete deck above. Natural ventilation, mechanical ventilation, or a combination of both can be used for partially open garages.

The operation of automobiles presents two concerns. The most serious is the emission of carbon monoxide, with its known risks. The second concern is the presence of oil and gasoline fumes, which may cause nausea and headaches as well as present a fire hazard. Additional concerns regarding oxides of nitrogen and smoke haze from diesel engines may also require consideration. However, the ventilation required to dilute carbon monoxide to acceptable levels also controls the other contaminants satisfactorily, provided the percentage of diesel vehicles does not exceed 20%.

For many years, the model codes and ASHRAE *Standard* 62 and its predecessor standards have recommended a flat exhaust rate of either 0.0075 $m^3/(s \cdot m^2)$ or 6 air changes per hour (ACH) for enclosed parking garages. But because vehicle emissions have been reduced over the years, ASHRAE sponsored a study to determine ventilation rates required to control contaminant levels in enclosed parking facilities (Krarti et al. 1998). The results of that study, which are summarized here, found that in some cases much less ventilation than 0.0075 $m^3/(s \cdot m^2)$ is satisfactory. However, local codes may still require 0.0075 $m^3/(s \cdot m^2)$ or 6 ACH, so the engineer may be required to request a variation or waiver from the authorities having jurisdiction to implement the recommendations given here.

VENTILATION REQUIREMENTS

The design ventilation rate required for an enclosed parking facility depends on four factors:

- Contaminant level acceptable in the parking facility
- Number of cars in operation during peak conditions
- Length of travel and operation time of cars in the parking garage
- Emission rate of a typical car under various conditions

Contaminant Level Criteria

ACGIH (1998) recommends a threshold limit of CO of 29 mg/m^3 (25 ppm) for an 8-hour exposure, and the EPA has determined that at or near sea level, exposure to a CO concentration of 40 mg/m^3 (35 ppm) for up to 1 hour is acceptable. For installations above 1000 m, more stringent limits would be required. European countries maintain an average of 40 mg/m^3 (35 ppm) and a maximum level of 230 mg/m^3 (200 ppm).

Opinions of the various agencies and countries differ on acceptable CO levels. A reasonable solution at this time would be a ventilation rate designed to maintain a CO level of 40 mg/m^3 (35 ppm) for 1 hour exposure with a maximum of 135 mg/m^3 (120 ppm) or 29 mg/m^3 (25 ppm) for an 8 hour exposure. Because the time involved in parking or driving out of the garage is in the order of minutes, the 40 mg/m^3 (35 ppm) level should be an acceptable level of exposure.

Table 4 Average Entrance and Exit Times for Vehicles

Level	Average Entrance Time, s	Average Exit Time, s
1	35	45
3[a]	40	50
5	70	100

Source: Stankunas et al. (1980).
[a]Average pass-through time = 30 s.

Table 5 Predicted CO Emissions in Parking Garages

	Hot Emission, (Stabilized), g/min		Cold Emission, g/min	
Season	**1991**	**1996**	**1991**	**1996**
Summer (32ºC)	2.54	1.89	4.27	3.66
Winter (0ºC)	3.61	3.38	20.74	18.96

Results from EPA Mobile 3, version NYC-2.2; sea level location.
Note: Assumed vehicle speed is 8 km/h.

Number of Cars in Operation

The number of cars operating at any one time depends on the type of facility served by the parking garage. For a distributed, continuous use such as an apartment house or shopping area, the variation is generally from 3 to 5% of the total vehicle capacity. It could reach 15 to 20% for peak use, such as in a sports stadium or short-haul airport.

Length of Time of Operation

The length of time that a car remains in operation in a parking garage is a function of the size and layout of the garage and the number of cars attempting to enter or exit at a given time. This time could vary from 60 to 600 s, but on the average it usually ranges from 60 to 180 s. Table 4 lists approximate data for vehicle movements. These data should be adjusted to suit the specific physical configuration of the facility.

Car Emission Rate

The operation of a car engine in a parking garage differs considerably from normal vehicle operation, including normal operation in a road tunnel. On entry the car travels slowly. As the car proceeds from the garage, the engine is cold and operates with a rich fuel mixture and in low gear. Emissions for a cold start are considerably higher, so the distinction between hot and cold emission plays a critical role in determining the ventilation rate. Motor vehicle emission factors for hot and cold start operation are presented in Table 5. An accurate analysis requires correlation of CO readings with the survey data on car movements (Hama et al. 1974). These data should be adjusted to suit the specific physical configuration of the facility and design year.

Design Method

To determine the design flow rate required to ventilate an enclosed parking garage, the following procedure can be followed:

Step 1. Collect the following data:

- Number of cars in operation during hour of peak use (N)
- Average CO emission rate for typical car (E), g/h
- Average length of operation and travel time for typical car (θ), s
- CO concentration acceptable in garage (CO_{max}), ppm
- Total floor area of parking area (A_f), m^2

Step 2. (a) Determine peak generation rate (G) in $g/h \cdot m^2$, for parking garage per unit floor area using Equation (9):

$$G = NE/A_f \tag{9}$$

(b) Normalize value of generation rate using reference value $G_0 = 26.7\ g/h \cdot m^2$. This reference value is based on an actual enclosed parking facility (Krarti et al. 1998):

$$f = 100\,G/G_0 \tag{10}$$

Step 3. Determine the minimum required ventilation rate per unit floor area (Q) using Figure 8 or the correlation presented by Equation (11) depending on the maximum level of CO concentration CO_{max}:

$$Q = Cf\theta \tag{11}$$

where

$C = 1.204 \times 10^{-6}\ (m^3/s)/(m^2 \cdot s)$ for $CO_{max} = 15$ ppm
$= 0.692 \times 10^{-6}\ (m^3/s)/(m^2 \cdot s)$ for $CO_{max} = 25$ ppm
$= 0.238 \times 10^{-6}\ (m^3/s)/(m^2 \cdot s)$ for $CO_{max} = 35$ ppm

Example 1. Consider a two level enclosed parking garage with a total capacity of 450 cars, a total floor area of 9000 m^2, and an average height of 2.7 m. The total length of time for a typical car operation is 2 min (120 s). Determine the required ventilation rate for the enclosed parking garage in $(m^3/s)/m^2$ and in ACH so that the CO level never exceeds 25 ppm. Assume that the number of cars in operation during peak use is 40% of the total vehicle capacity.

Step 1. Garage data:

$N = 450 \times 0.4 = 180$ cars;
$E = 11.66$ g/min = 700 g/h (average of all values of the emission rate for a winter day obtained from Table 5)
$CO_{max} = 25$ ppm, $\theta = 120$ s.

Step 2. Calculate CO generation rate:

$$G = (180 \times 700\ g/h)/9000\ m^2 = 14.0\ g/(h \cdot m^2)$$

$$f = 100 \times 14.0/26.7 = 52$$

Step 3. Determine the ventilation requirement:

Using Figure 8 or the correlation of Equation (11) for CO_{max} = 25 ppm

$$Q = 0.692 \times 10^{-6} \times 52 \times 120\ s = 0.0043\ m^3/(s \cdot m^2)$$

Or, in air changes per hour:

$$ACH = (0.0043\ (m^3/s)/m^2 \times 3600\ s/h)/2.7\ m = 5.7$$

Notes:

1. If the emission was $E = 6.6$ g/min (due, for instance, to better emission standards or better maintained cars), the required minimum ventilation rate would be 3.3 ACH ($0.0025\ m^3/(s \cdot m^2)$).
2. Once the calculations are made and a decision is reached to use CO demand ventilation control, increasing the airflow by a safety margin does not increase operating cost as the larger fans work for shorter periods to sweep the garage and maintain satisfactory conditions.

CO Demand Ventilation Control

The ventilation system, whether mechanical, natural, or both, should meet applicable codes and maintain an acceptable contaminant level. To conserve energy, fans should be controlled by a CO monitor to vary the amount of air supplied, if permitted by local codes. For example, ventilation could consist of multiple fans with single- or variable-speed motors or variable-pitch blades. In multilevel parking garages or single-level structures of extensive area, independent fan systems, each under individual control are preferred. Figure 9 shows the maximum CO level in a tested garage (Krarti et al. 1998) for three car movement profiles (as illustrated in Figure 10) and the following ventilation control strategies:

- Constant volume (CV) where ventilation is on during the entire occupancy period
- On-Off control, with fans stopped and started based on input from CO sensors
- Variable air volume (VAV) control, with fan speeds adjusted depending on the CO level in the garage, based on input from CO sensors

Figure 9 also indicates typical fan energy saving achieved by the On-Off and VAV systems relative to the fan energy used by the constant-volume systems. As illustrated in the figure, a significant saving in fan energy can be obtained when a CO-based demand ventilation control strategy is used to operate the ventilation system

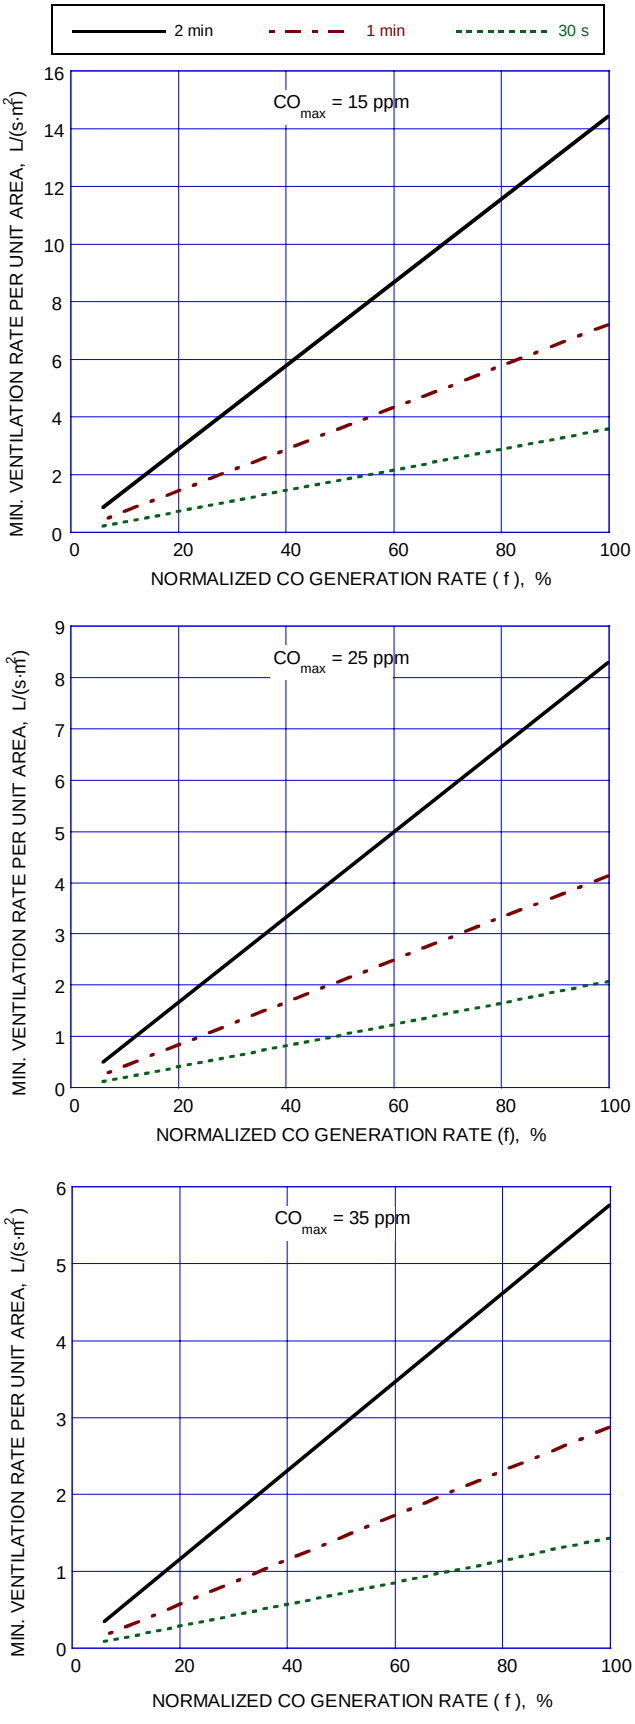

Fig. 8 Ventilation Requirement for Enclosed Parking Garage

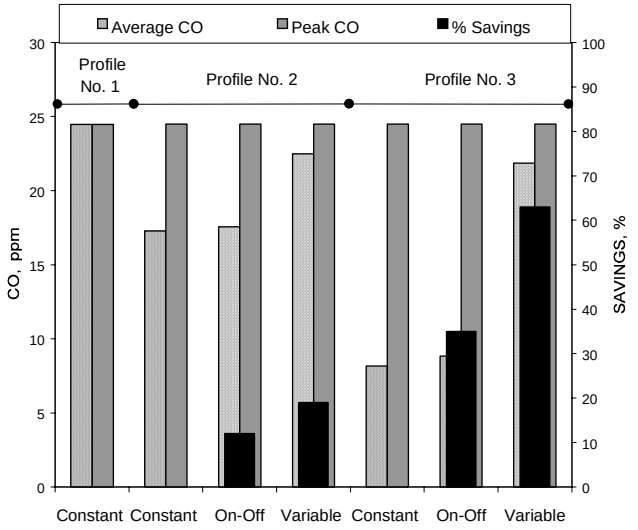

Fig. 9 Typical Energy Savings and Maximum CO Level Obtained for Demand CO-Ventilation Controls

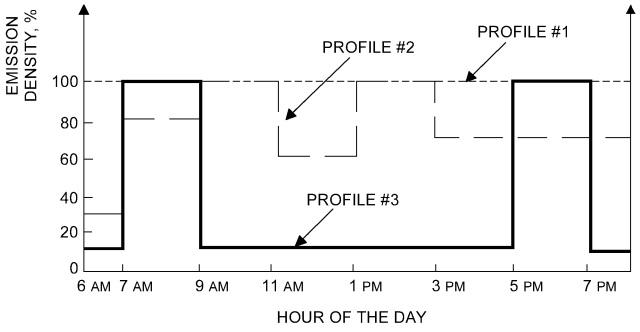

Fig. 10 Three Car Movement Profiles

while maintaining CO levels below 29 mg/m^3 or 25 ppm. Also, wear and tear and maintenance on the mechanical and electrical equipment is reduced.

In cold climates, the additional cost of heating the makeup air is also reduced. Even if only outside air openings are used or infiltration is permitted, energy is lost to the cold incoming air as energy stored in the mass of the structure helps maintain the garage temperature at an acceptable level.

Ventilation System Configuration

Systems can be classified as supply-only, exhaust-only, or combined. Regardless of which design is chosen, the following should be considered:

- Contaminant level of outside air drawn in for ventilation
- Avoiding short circuiting of supply air
- Avoiding long flow fields that permit the contaminant levels to build up above an acceptable level at the end of the flow field
- Providing short flow fields in areas of high contaminant emission, thereby limiting the extent of mixing
- Providing an efficient, adequate flow throughout the parking structure
- Stratification of engine exhaust gases

Other Considerations

Access tunnels or long, fully enclosed ramps should be designed the same way as road tunnels. When natural ventilation is used, the wall opening free area should be as large as possible. A portion of

the free area should be at floor level. For parking levels with large interior floor areas, a central emergency smoke exhaust system should be considered for smoke removal or fume removal during calm weather.

Noise

In general, parking garage ventilation systems move large quantities of air through large openings without extensive ductwork. These conditions, in addition to the highly reverberant nature of the space, contribute to high noise levels. For this reason, sound attenuation should be considered. This is a safety concern as well, since high noise levels may mask the sound of an approaching car.

Ambient Standards and Contaminant Control

The air exhausted from the garage should meet state and local air pollution control requirements.

BUS GARAGES

Bus garages generally include a maintenance and repair area, a service lane where buses are fueled and cleaned, a storage area where buses are parked, and support areas such as offices, a stock room, a lunch room, and locker rooms. The location and layout of these spaces can depend on such factors as climate, bus fleet size, and type of fuel used by the buses. Servicing and storage functions may be located outdoors in temperate regions, but are often found indoors in colder climates. While large fleets cannot always be stored indoors, maintenance areas may double as storage space for small fleets. Local building and/or fire codes may prohibit the dispensing of certain types of fuel indoors.

In general, for areas where buses are maintained or serviced, ventilation should be accomplished using 100% outside air with no recirculation. Therefore, the use of heat recovery devices should be considered in colder climates. Tailpipe emissions should be exhausted directly in maintenance and repair areas. Offices and similar support areas should be kept under positive pressure to prevent the infiltration of vehicle emissions.

MAINTENANCE AND REPAIR AREAS

ASHRAE *Standard* 62 and most model codes require a minimum outdoor air ventilation rate of 0.0075 m^3/s per square metre of floor area in vehicle repair garages, with no recirculation recommended. However, because the interior ceiling height may vary greatly from garage to garage, the designer should consider making a volumetric analysis of contaminant generation and air exchange rates. The section on Bus Terminals has information on diesel engine emissions and the ventilation rates necessary to control their concentrations in areas where buses are operated.

Maintenance and repair areas often include below-grade inspection and repair pits for working underneath buses. Because the vapors produced by conventional bus fuels are heavier than air, they tend to settle in these pit areas, so a separate exhaust system should be provided to prevent their accumulation. NFPA *Standard* 88B recommends a minimum of 12 air changes per hour in pit areas and the location of exhaust registers near the pit floor.

Fixed repair stations, such as inspection and repair pits or hydraulic lifts, should include a direct exhaust for tailpipe emissions. Such systems have a flexible hose and coupling that is attached to the bus tailpipe; emissions are discharged to the outdoors through an exhaust fan. The system may be of the overhead reel type, overhead tube type, or underfloor duct type, depending on the location of the tailpipe. For heavy diesel engines, a minimum exhaust rate of 0.28 m^3/s per station is recommended to capture emissions without creating excessive back pressure in the vehicle. Fans, ductwork, and hoses should be able to receive vehicle exhaust at temperatures exceeding 260°C without degradation.

Garages often include areas for battery charging, a process that can produce potentially explosive concentrations of corrosive, toxic gases. There are no published code requirements for the ventilation of battery-charging areas, but DuCharme (1991) has suggested using a combination of floor and ceiling exhaust registers to remove gaseous by-products. Recommended exhaust rates are 0.011 m^3/s per square metre of room area at floor level to remove acid vapors and 0.0038 m^3/s per square metre of room area at ceiling level to remove hydrogen gases. Supply air volume should be 10 to 20% less than exhaust air volume and directed to provide 0.5 m/s terminal velocity at floor level. If the battery-charging space is located in the general maintenance area rather than in a dedicated room, an exhaust hood should be provided to capture gaseous by-products. Chapter 29 contains specific information on exhaust hood design. Makeup air should be provided to replace that removed by the exhaust hood.

Garages may also contain spray booths or rooms for painting buses. Most model codes reference NFPA *Standard* 33 for spray booth requirements, and that document should be consulted when designing heating and ventilating systems for such areas.

SERVICING AREAS

For indoor service lanes, ASHRAE *Standard* 62 and several model codes specify a minimum of 0.0075 $m^3/(s \cdot m^2)$ of ventilation air, while NFPA *Standard* 30A requires only 0.005 $m^3/(s \cdot m^2)$. The designer should determine which minimum requirement is applicable for the project location; additional ventilation may be necessary due to the nature of servicing operations. Buses often queue up in the service lane with their engines running during the service cycle. Depending on the length of the queue and the time to service each bus, the contaminant levels may exceed maximum allowable concentrations. A volumetric analysis examining contaminant generation should thus be considered.

Because of the increased potential for concentrations of flammable or combustible vapor, service lane HVAC systems should not be interconnected with systems serving other parts of the garage. Service lane systems should be interlocked with the dispensing equipment to prevent operation of the latter if the former is shut off or fails. Exhaust inlets should be located at ceiling level and between 75 and 300 mm above the finished floor, with supply and exhaust diffusers/registers arranged to provide air movement across all planes of the dispensing area.

Another feature common to modern service lanes is the cyclone cleaning system, which is used to vacuum out the interior of a bus. These devices have a dynamic connection to the front door(s) of the bus, through which a large-volume fan vacuums dirt and debris from inside the bus. A large cyclone assembly then removes the dirt and debris from the airstream and deposits it into a large hopper for disposal. Because of the large volume of air involved, the designer should consider the discharge and makeup air systems required to complete the cycle. Recirculation or energy recovery should be considered, especially in the winter months. To aid in contaminant and heat removal during the summer months, some systems currently in use discharge the cyclone air to the outdoors and provide untempered makeup air through relief hoods above the service lane.

STORAGE AREAS

Where buses are stored indoors, the minimum ventilation standard of 0.0075 $m^3/(s \cdot m^2)$ should be provided, subject to volumetric considerations. The designer should also consider the increased contaminant levels present during peak traffic periods. An example is the morning pull-out, when the majority of the bus fleet is dispatched for rush-hour commute. It is common practice to start and idle a large number of buses during this period to warm up the engines and check for defects. As a result, the concentration of emissions in the storage area rises, and additional ventilation may be required to maintain contaminant levels in acceptable limits. The

use of supplemental purge fans is a common solution to this problem. These fans can be (1) interlocked with a timing device to operate during peak traffic periods, (2) started manually on an as-needed basis, or (3) connected to an air quality monitoring system that activates them when contaminant levels exceed some preset limit.

DESIGN CONSIDERATIONS AND EQUIPMENT SELECTION

Most model codes require that open flame heating equipment such as unit heaters be located at least 2400 mm above the finished floor or, where located in active trafficways, 600 mm above the tallest vehicle. Fuel-burning equipment located outside of the garage area, such as boilers in a mechanical room, should be installed with the combustion chamber at least 450 mm above the floor. Combustion air should be taken from outside the building. Exhaust fans should be of the nonsparking type, with the motor located outside the airstream.

Infrared heating systems and air curtains are often considered for repair garages because of the size of the building and the high amount of infiltration through the large overhead doors needed to move buses in and out of the garage. However, caution must be exercised in applying infrared heating in areas where buses are parked or stored for extended periods; the buses may absorb most of the heat, which is then lost when they leave the garage. This is especially true during the morning pull-out. Infrared heating is more successfully applied in the service lane or at fixed repair positions. Air curtains should be considered for high-traffic doorways to limit heat loss and infiltration of cold air.

Where air quality monitoring systems are considered for controlling ventilation equipment, maintainability is a key factor in determining the success of the application. The high concentration of particulate matter in bus emissions can adversely affect the performance of the monitoring equipment, which often has filtering media at sampling ports to protect the sensors and instrumentation. Location of sampling ports, effects of emissions fouling, and calibration requirements should be considered when selecting the monitoring equipment to control the ventilation systems and air quality of the garage. Nitrogen dioxide and CO exposure limits published by OSHA and the EPA should be consulted to determine the contaminant levels at which exhaust fans should be activated.

EFFECTS OF ALTERNATIVE FUEL USE

Because of legislation limiting contaminant concentrations in diesel bus engine emissions, the transit industry has begun using buses that operate on alternative fuels. Such fuels include methanol, ethanol, hydrogen, compressed natural gas (CNG), liquefied natural gas (LNG), and liquefied petroleum gas (LPG). The flammability, emission, and vapor dispersion characteristics of these fuels differ from the conventional fuels for which current code requirements and design standards were developed. For this reason the requirements may not be valid for garage facilities in which alternative-fuel vehicles are maintained, serviced, and stored. The designer should consult current literature regarding the design of HVAC systems for these facilities rather than relying on conventional practice. One source is the Alternative Fuels Data Center at the U.S. Department of Energy in Washington, DC.

For facilities housing CNG buses, NFPA *Standard* 52 provides requirements for indoor fueling and gas processing/storage areas. It requires a separate mechanical ventilation system providing at least 5 air changes per hour for these areas. The ventilation system should operate continuously, or be activated by a continuously monitoring natural gas detector when a gas concentration of not more than one-fifth the lower flammability limit is present. The fueling or compression equipment should be interlocked to shut down in the event of a failure in the mechanical ventilation system. Supply inlets should be located near floor level, and exhaust outlets at high points in the roof or exterior wall structure.

DOT (1996) guidelines for CNG facilities address bus storage and maintenance areas as well as fueling areas. Recommendations include minimizing the potential for "dead air zones" and gas pockets (which may necessitate coordination with architectural and structural designers); using a normal ventilation rate of 6 air changes per hour, and increasing that rate by an additional 6 air changes per hour in the event of a gas release; using nonsparking exhaust fans rated for use in Class 1, Division 2 areas (as defined by NFPA *Standard* 70); and, increasing the minimum ventilation rate in smaller facilities to maintain similar dilution levels as would be found in larger facilities. Open-flame heating equipment should not be used, and the surface temperature of heating units should not exceed 430°C. Consideration should also be given to de-energizing supply fans that discharge near the ceiling level in the event of a gas release to avoid spreading the gas plume. The DOT guideline has more information concerning these recommendations.

For facilities housing LNG-fueled buses, the only published requirements are found in NFPA *Standard* 57, which are limited to fueling areas. It also requires a separate mechanical ventilation system providing at least 5 air changes per hour for indoor fueling areas. Again, the ventilation system should operate continuously, or be activated by a continuously monitoring natural gas detection system when a gas concentration of not more than one-fifth the lower flammability limit is present; and the fueling equipment should be interlocked to shut down in the event of a failure in the mechanical ventilation system.

NFPA *Standard* 58 is the only document that contains provisions relating specifically to LPG-fueled buses. This standard prohibits indoor fueling of all LPG vehicles, allowing only an "adequately ventilated" weather shelter or canopy, although the term adequately ventilated is not defined by any prescriptive rate. However, vehicles are allowed to be stored and serviced indoors provided they are not parked near sources of heat, open flames or similar sources of ignition, or "inadequately ventilated" pits. The standard does not specify any required ventilation rates for these repair and storage facilities, although it does require a minimum ventilation rate of 0.005 $m^3/(s \cdot m^2)$ in building and structures housing LPG distribution facilities.

No U.S. standards relate specifically to hydrogen powered vehicles. NFPA *Standard* 50A provides general requirements for point-of-use gaseous hydrogen systems, and provides limited guidance.

BUS TERMINALS

Bus terminals vary considerably in physical configuration. Most terminals consist of a fully enclosed space containing passenger waiting areas, ticket counters, and some retail areas. Buses load and unload outside the building, generally under a canopy for weather protection. In larger cities, where space is at a premium and bus service is extensive or integrated with subway service, comprehensive customer services and multiple levels with attendant busway tunnels and/or ramps may be required.

Waiting rooms and consumer spaces should have a controlled environment in accordance with normal practice for public terminal occupancy. The space should be pressurized against intrusion of the busway environment. Pressurized vestibules should be installed at each doorway to further reduce contaminant migration. Waiting rooms and passenger concourse areas are subject to a highly variable people load. The occupant density may reach 1 m^2 per person; during periods of extreme congestion, 0.3 to 0.5 m^2 per person.

Basically, there are two types of bus service: urban-suburban and long distance. Urban-suburban service is characterized by frequent bus movements and the requirement of rapid loading and unloading. Therefore, ideal passenger platforms are long and narrow, and buses can drive through and do not have to backup. Long-distance operations and those with greater headways generally use sawtooth gate configurations.

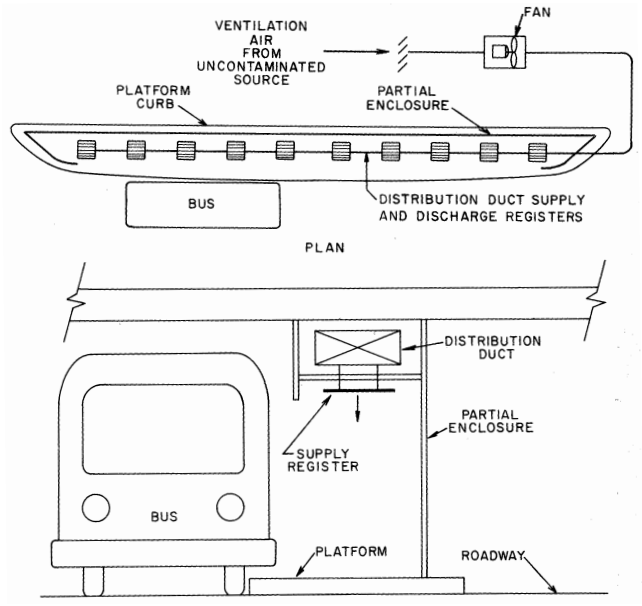

Fig. 11 Partially Enclosed Platform, Drive-Through Type

Either natural or forced ventilation can be used. When natural ventilation is selected, the bus levels should be open on all sides, and the slab-to-ceiling dimension should be sufficiently high, or the space contoured, to permit free air circulation. Jet fans improve the natural airflow with relatively low energy. Mechanical systems that ventilate open platforms or gate positions should be configured to serve the bus operating areas, as shown in Figures 11 and 12.

PLATFORMS

Naturally ventilated drive-through platforms may expose passengers to inclement weather and strong winds. Enclosed platforms (except for an open front) with appropriate mechanical equipment should be considered. Even partially enclosed platforms may trap contaminants and require mechanical ventilation.

Multilevel bus terminals have limited headroom, thus restricting natural ventilation. For such terminals, mechanical ventilation should be selected, and all platforms should be partially or fully enclosed. Ventilation should induce little contaminated air from the busway. Figure 11 shows a partially enclosed drive-through platform with an air distribution system. Supply air velocity should be limited to 1.3 m/s to avoid drafty conditions on the platform. Partially enclosed platforms require large amounts of outside air to hinder fume penetration; experience indicates that a minimum of 0.085 m^3/s per square metre of platform area is required during rush hours and about half of this quantity during the remaining time.

Platform air quality remains essentially the same as that of the ventilation air introduced. Because of the piston effect, however, some momentary higher concentrations of contaminants occur on the platform. Separate ventilation systems with two-speed fans for each platform permit operational flexibility. Fans should be controlled automatically to conform to bus operating schedules. In cold climates, mechanical ventilation may need to be reduced during extreme winter weather.

Fully enclosed platforms are strongly recommended for large terminals with heavy bus traffic. They can be pressurized adequately and ventilated with the normal heating and cooling air quantities, depending on the tightness of construction and the number of boarding doors and other openings. Conventional air distribution can be used; air should not be recirculated. Openings around doors and in the enclosure walls are usually adequate to relieve air pressure unless platform construction is extraordinarily tight.

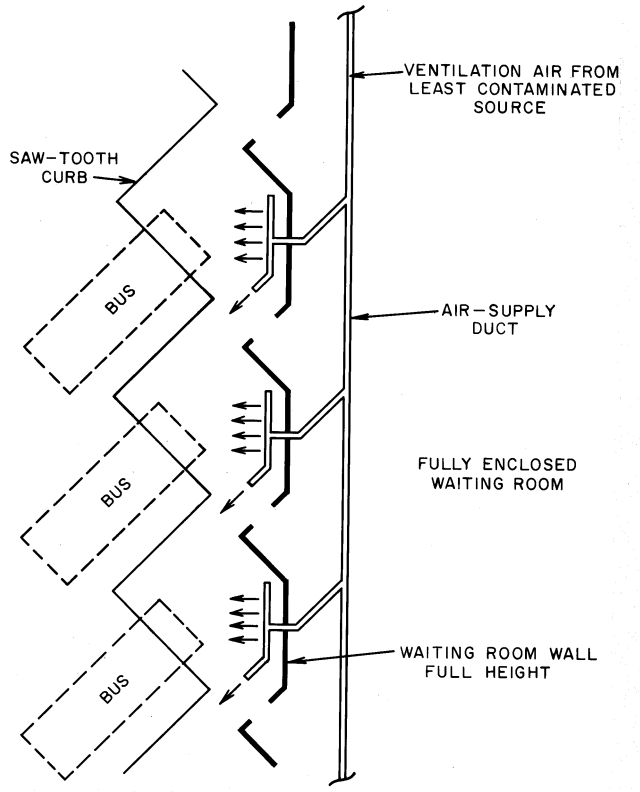

Fig. 12 Fully Enclosed Waiting Room with Sawtooth Gates

BUS OPERATION AREAS

Most buses are powered by diesel engines. Certain models have small auxiliary gasoline engines to drive the air-conditioner. Tests performed on the volume and composition of exhaust gases emitted from diesel engines in various traffic conditions indicate large variations depending on temperature and humidity; manufacturer, size, and adjustment of the engine; and the fuel burned.

Contaminants

The components of diesel exhaust gases that affect the ventilation design are oxides of nitrogen, hydrocarbons, formaldehyde, odor constituents, aldehydes, smoke particulates, and a relatively small amount of carbon monoxide. Diesel engines operating in enclosed spaces reduce visibility and create odors and contaminants. Table 6 lists major health-threatening contaminants typically found in diesel engine exhaust gas. The nature of bus engines should be determined for each project, however.

The U.S. Code of Federal Regulations (CFR) Occupational Safety and Health Standards, Subpart Z, sets the contaminant levels for an 8-hour time-weighted average (TWA) exposure as follows: carbon monoxide (CO), 58 mg/m^3, nitric oxide (NO),

Table 6 Approximate Diesel Bus Engine Emissions (ppm)

	Idling	Cruising		
	0.055 m^3/s	Accelerating 0.225 m^3/s	0.163 m^3/s	Decelerating 0.143 m^3/s
Carbon monoxide	215	500	230	130
Hydrocarbons	390	210	90	330
Oxides of nitrogen (NO_x)	60	850	235	30
Formaldehydes (HCHO)	9	17	11	30

Note: For more data on diesel bus and truck engine emissions, see Watson et al. (1988).

30 mg/m^3, and formaldehyde (HCHO), 0.92 mg/m^3. Subpart Z also sets the short-term exposure ceiling as 9 mg/m^3 for nitrogen dioxide (NO_2) and 2.5 mg/m^3 for formaldehyde.

ACGIH (1998) recommends threshold limit values (TLVs) for an 8-hour TWA exposure of 29 mg/m^3 for CO, 31 mg/m^3 for NO, and 5.6 mg/m^3 for NO_2. It also recommends short-term exposure limits (STELs) of 9.4 mg/m^3 for NO_2 and 0.37 mg/m^3 for formaldehyde.

Oxides of nitrogen occur in two basic forms: NO_2 and NO. Nitrogen dioxide is the major contaminant to be considered in the design of a bus terminal ventilation system. Exposure to concentrations of 19 mg/m^3 (10 ppm) and higher causes health problems. Furthermore, NO_2 affects light transmission, causing visibility reduction. It is intensely colored and absorbs light over the entire visible spectrum, especially at shorter wavelengths. Odor perception is immediate at 0.79 mg/m^3 and can be perceived by some at levels as low as 0.23 mg/m^3.

Terminal operation also affects the quality of surrounding ambient air. The dilution rate and the location and design of the intakes and discharges control the impact of the terminal on ambient air quality. State and local regulations, which require consideration of local atmospheric conditions and ambient contaminant levels, must be followed.

Calculation of Ventilation Rate

To calculate the ventilation rate, the total amount of engine exhaust gases should be determined using the bus operating schedule, the amount of time that buses are in different modes of operation (i.e., cruising, decelerating, idling, and accelerating) and Table 6. The designer must ascertain the grade (if any) in the terminal and whether the platforms are drive-through, drive-through with bypass lanes, or sawtooth. Bus headways, speed, and operating modes must also be evaluated.

For instance, with sawtooth platforms, the departing bus must accelerate backward, brake, and then accelerate forward. The drive-through platform requires a different mode of operation. Certain codes prescribe a maximum idling time for engines, usually 3 to 5 min. Normally, 1 to 2 min of engine operation is required to build up brake air pressure.

The discharged contaminant quantities should be diluted by natural and/or forced ventilation to acceptable, legally prescribed levels. To maintain odor control and visibility, the exhaust gas contaminants should be diluted with outside air in the proportion of 75 to 1. Where urban-suburban operations are involved, the ventilation rate varies considerably throughout the day and between weekdays and weekends. Control of fan speed or blade pitch should be used to conserve energy. It follows that the required airflow may be reduced by removing contaminant emissions as quickly as possible. This can be achieved by mounting exhaust capture hoods on the ceiling above each of the bus exhaust stacks. The exhaust air collected by the capture hoods is then discharged outside of the facility through a dedicated exhaust system.

Effects of Alternative Fuel Use

As indicated in the section on Bus Garages, alternative fuels are being more widely used in lieu of conventional diesel. Alternative fuel buses are more likely to be operated on urban-suburban routes than on long distance bus service.

Current codes and design standards developed for conventional fuels may not be valid for alternative fuel buses. Special attention should be given to the design of the HVAC and electrical systems for these facilities in case of a fuel tank or fuel line leak on an alternative fuel bus. Research continues in this application and further information may be available from U.S. DOT Federal Transit Administration and NFPA.

Natural Gas (NG) Buses. Fuel burned in LNG and CNG buses has a composition of up to 98% methane (CH_4). Methane burns in a self-sustained reaction only when the volume percentage of fuel and air is within specific limits. The lower and upper flammability or explosive limits (LEL and UEL) for methane are 5.3% and 15.0% by volume, respectively. The fuel-air mixture at standard conditions burns only in this range and in the presence of a source of ignition or when the ignition temperature of 540°C is exceeded.

Although natural gas bus engine emissions include unburned methane, the design of the ventilation system must be based on maintaining the facility air quality below the LEL in the event of a natural gas leak. A worst case scenario would be a fuel line or fuel tank leak or a sudden high pressure release of a CNG bus fuel cell through its pressure relief device (PRD).

For instance, a typical CNG bus may be equipped with fuel tanks each holding gas at 25 MPa and 21°C. If the PRD on a single fuel tank were to open, the contents of the tank would escape rapidly and after one minute 50% of the fuel would be released to the surroundings. After 2 min, 80% would have been released, and 90% after 3 min.

Because such a large quantity of fuel is released in such a brief period, the prompt activation of purging ventilation is essential. Where installed, a methane detection system should activate purging ventilation and an alarm at 20% of the LEL. Placement of the methane detectors is very important and stagnant areas, bus travel lanes, and bus loading areas must be considered. Additionally, although methane is lighter than air (relative density = 0.55), some research has indicated that it may not rise immediately after a leak. In the case of a CNG bus PRD release, the rapid throttle-like flow through the small diameter orifice of the device may actually cool the fuel, making it denser than air. Under these conditions, the fuel may migrate towards the floor until thermal equilibrium with the surrounding environment is reached, at which time buoyancy drives the fuel-air mixture to the ceiling. Thus, the designer may consider locating methane detectors at both ceiling and floor levels.

Although no specific ventilation criteria has been published for natural gas vehicles in bus terminals, NFPA *Standard* 52 recommends a blanket rate of 5 air changes per hour (ACH) in fueling areas. Also, the Federal Transit Administration guidelines for CNG transit facility design recommend a slightly more conservative 6 ACH normal ventilation rate for bus storage areas, with a 12 ACH purge ventilation rate upon methane sensor activation. The designer can also calculate a purging ventilation rate based on the volumetric flow rate of methane released, the duration of the release, and the volume of the facility. The volume of the facility has a significant effect on the amount of ventilation required to maintain maximum average concentrations of methane below 10% of the LEL; e.g., the larger the facility, the lower the number of air changes that are required. However, concentrations of methane exceeding the LEL can be expected in the immediate area of the leak regardless of the ventilation rate used. Plume size and location and duration of unsafe concentrations may be determined using a comprehensive modeling analysis such as computational fluid dynamics.

Source of Ventilation Air

Because dilution is the primary means of contaminant level control, the source of ventilation air is extremely important. The cleanest available ambient air, which in an urban area is generally above the roof, should be used. Surveys of ambient air contaminant levels should be conducted and the most favorable source located. The possibility of short circuiting of exhaust air due to prevailing winds and building airflow patterns should also be evaluated.

Control by Contaminant Level Monitoring

Time clocks or tapes coordinated with bus movement schedules and smoke monitors (obscurity meters) provide the most useful means of controlling the ventilation system.

Instrumentation is available for monitoring various contaminants, namely electrochemical cells for NO_2 and CO. Control by

instrumentation can be simplified by monitoring carbon dioxide (CO_2) levels, as studies have shown a relationship between the levels of various diesel engine contaminants and CO_2. However, the mix and quantity of contaminants varies with the rate of operation and the condition of the bus engines. Therefore, if CO_2 is monitored, actual conditions under specific bus traffic conditions should be determined in order to verify the selected CO_2 settings.

Dispatcher's Booth

The dispatcher's booth should be kept under positive pressure to prevent the intrusion of engine fumes. Because the booth is occupied for sustained periods, normal interior comfort conditions and OSHA contaminant levels must be maintained.

RAPID TRANSIT

Today's high-performance, air-conditioned subway vehicles consume most of the energy required to operate rapid transit and are the greatest source of heat in underground areas of the system. Therefore, minimizing the traction power consumed has a strong effect on the operating cost and comfort. The environmental control system (ECS) maintains a reasonably comfortable environment during normal operations and assists in keeping patrons safe during a fire emergency. The large amount of heat produced by the rolling stock, if not properly controlled, can cause patron discomfort, shorten equipment life, and increase maintenance. Tropical climates present an additional stress that makes environment control more critical.

Temperature, humidity, air velocity, air pressure change, and rate of air pressure change are among the conditions needed to determine ECS performance. These conditions are affected by the time of day (morning, evening, or off-peak), the circumstance (normal, congested, or emergency operations), and the location in the system (tunnels, station platforms, entrances, and stairways). The *Subway Environmental Design Handbook* (DOT 1976), based on unproven experience but validated by field and model tests, provides comprehensive and authoritative design aids.

Operations are normal when trains are moving through the system according to schedule and passengers are traveling smoothly through stations to and from transit vehicles. Since this is the predominant category of operations, considerable effort is made to optimize performance of the ECS during normal operations.

Congested operations result from delays or operational problems that prevent the free flow of trains. Trains may wait in stations, or stop at predetermined locations in tunnels. Delays usually range from 30 s to 20 min, although longer delays may occasionally be experienced. Passenger evacuation or exposure of passengers to danger does not occur during congested operations. The analyses focus on the ventilation required to support the continued operation of train air-conditioning units and thus maintain patron comfort during congested operations.

Emergency operations generally result from a malfunction of the transit vehicle. The most serious emergency is a train on fire stopped in a tunnel, disrupting traffic, and requiring passenger evacuation. The analyses focus on determining the ventilation required to maintain a single evacuation path from the train clear of smoke and hot gases.

Patron comfort is a function of ambient temperature and humidity, air velocity, and the time of exposure to an environment. For example, a person that enters a 29°C station from a 33°C outdoors will momentarily feel more comfortable. However, in a short time, usually in about 6 min, the person's metabolism will adjust to the new environment and he will feel nearly as uncomfortable as before. If a train were to arrive during this period, the relatively high temperature of the station would be acceptable. The Relative Warmth Index (RWI) provides a means quantifying this transient effect thus allowing the designer to select an appropriate design temperature based on the transient sensation of comfort rather than the steady-state sensation of comfort. This temperature is higher (often 3 to 5 K) than that which would be selected by the steady-state approach and hence results in reduced cooling or air-conditioning requirements).

DESIGN CONCEPTS

The factors to be considered, although interrelated, may be divided into four categories: natural ventilation, mechanical ventilation, emergency ventilation, and station air conditioning.

Natural Ventilation

Natural ventilation in subway systems (infiltration and exfiltration) is primarily the result of train operation in tightly fitting trainways, where air generally moves in the direction of train travel. The positive pressure in front of a train expels air through portals and station entrances; the negative pressure in the wake of the train induces airflow through these same openings.

Considerable short-circuiting occurs in subway structures when two trains traveling in opposite directions pass each other, especially in stations or in tunnels with porous walls (walls with intermittent openings to allow air passage between tracks) or nonporous walls. Such short circuiting reduces the net ventilation rate and causes increased air velocities on station platforms and in station entrances. During the time of peak operation and peak ambient temperatures, it can cause an undesirable heat buildup.

To help counter these negative effects, ventilation shafts are customarily placed near the interfaces between tunnels and stations. Shafts in the approach tunnel are often called blast shafts; part of the air pushed ahead of the train is expelled through them. Relief shafts in the departure tunnel relieve the negative pressure created during the departure of the train and induce outside air through the shaft rather than through station entrances. Additional ventilation shafts may be provided between stations (or between portals, for underwater crossings), as dictated by tunnel length. The high cost of such ventilation structures necessitates a design for optimum effectiveness. Internal resistance due to offsets and bends should be kept to a minimum, and shaft cross-sectional areas should be approximately equal to the cross-sectional area of a single-track tunnel (DOT 1976).

Mechanical Ventilation

Mechanical ventilation in subways (1) supplements the ventilation effect created by train piston action, (2) expels heated air from the system, (3) introduces cool outside air, (4) supplies makeup air for exhaust, (5) restores the cooling potential of the heat sink through extraction of heat stored during off-hours or system shutdown, (6) reduces the flow of air between the tunnel and the station, (7) provides outside air for passengers in stations or tunnels in an emergency or during other unscheduled interruptions of traffic, and (8) purges smoke from the system in case of fire.

The most cost-effective design for mechanical ventilation is one that serves two or more purposes. For example, a vent shaft provided for natural ventilation may also be used for emergencies if a fan is installed in parallel with a bypass (Figure 13).

Several vent shafts working together may be capable of meeting many, if not all, of the eight objectives. Depending on shaft location and the situation, a shaft with the bypass damper open and the fan damper closed may serve as a blast or relief shaft. With the fan in operation and the bypass damper closed, air can be supplied or exhausted by mechanical ventilation, depending on the direction of fan rotation.

Except for emergencies, fan rotation is usually predetermined based on the overall ventilation concept. If subway stations are not air conditioned, the hot air in the subway should be exchanged at a maximum rate with cooler outside air. If stations are air conditioned

below the ambient temperature, the inflow of warmer outside air should be limited and controlled.

Figure 14 illustrates a typical tunnel ventilation system between two subway stations. Here the flow of heated tunnel air into a cooler station is kept to a minimum. The dividing wall separating Tracks No. 1 and 2 is discontinued in the vicinity of the emergency fans. As shown in Figure 14A, air pushed ahead of the train on Track No. 2 diverts partially to the emergency fan bypasses and partially into the wake of a train on Track No. 1 as a result of pressure differences. Figure 14B shows an alternative operation with the same ventilation system. When outdoor temperatures are favorable, the mid-tunnel fans operate as exhaust fans, with makeup air introduced through the emergency fan bypasses. This system can also provide or supplement station ventilation. To achieve this goal, emergency fan bypasses would be closed, and the makeup air for mid-tunnel exhaust fans would enter through station entrances.

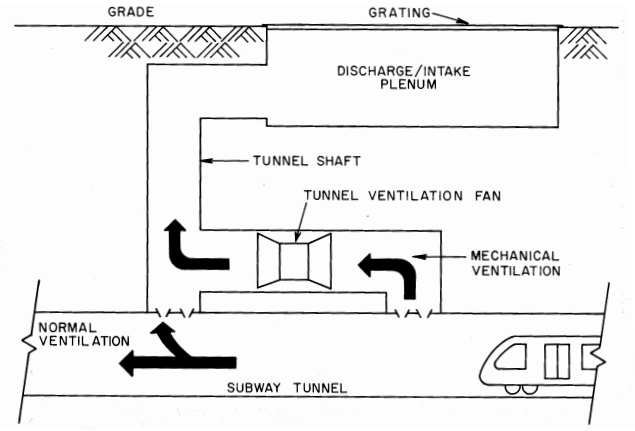

Fig. 13 Tunnel Ventilation Shaft

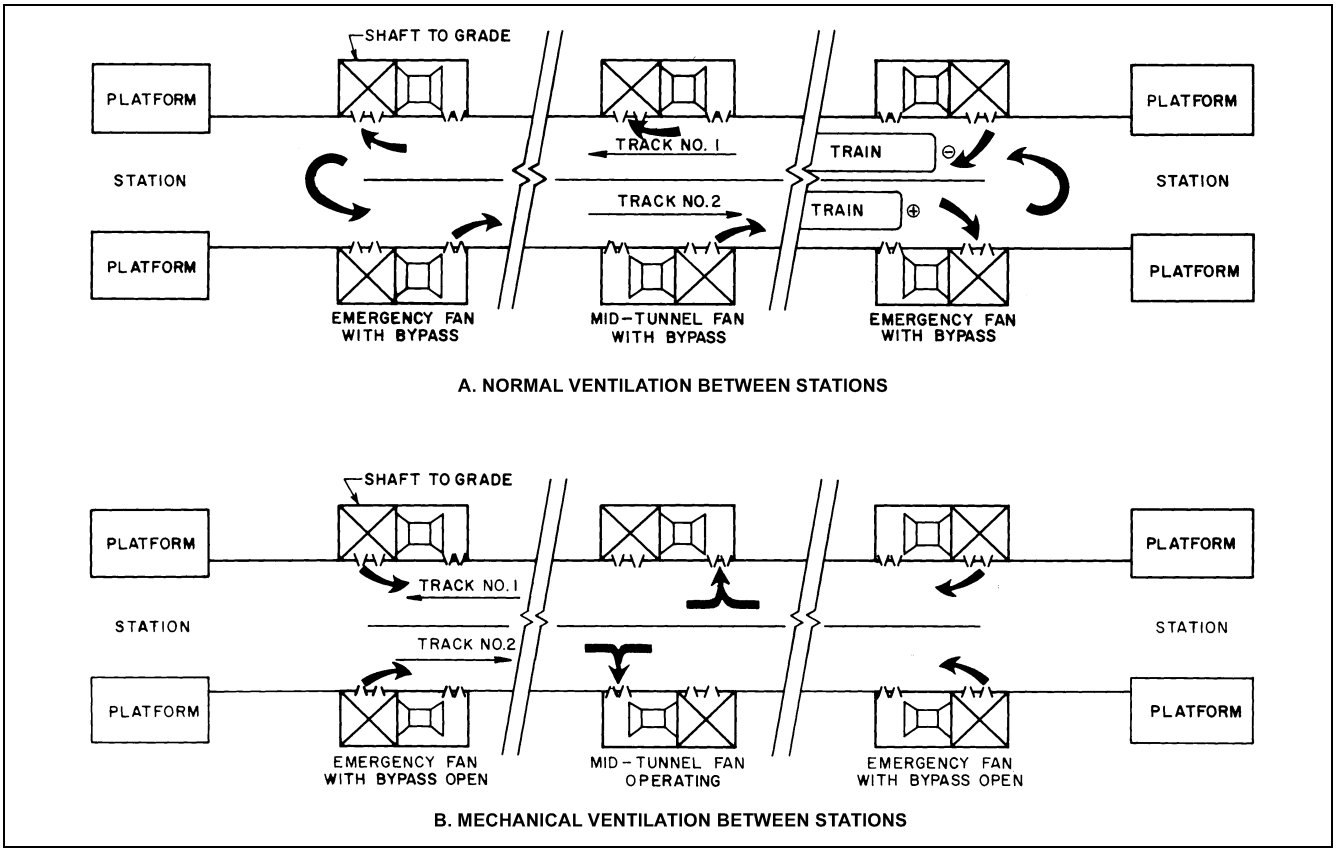
A more direct ventilation system removes station heat at its primary source, the underside of the train. Figure 15 illustrates trackway ventilation. Tests have shown that such ventilation not only reduces the upwelling of heated air onto platform areas, but also removes significant portions of the heat generated by dynamic braking resistor grids and air-conditioning condensers underneath the train (DOT 1976). Ideally, makeup air for the exhaust should be introduced at track level to provide a positive control over the direction of airflow (Figure 15A).

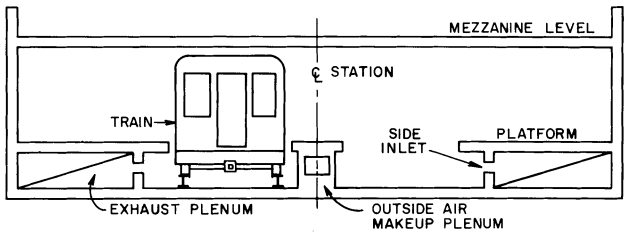
An underplatform exhaust without makeup supply air, as illustrated in Figure 15B, is the least effective and, under certain conditions, could cause heated tunnel air to flow into the station. Figure 15C shows a cost-effective compromise in which makeup air is introduced at the ceiling above the platform. Although the heat removal effectiveness may not be as good as that of the system illustrated in Figure 15A, the inflow of hot tunnel air that might occur without supply air makeup is negated.

Emergency Ventilation

During a subway tunnel fire, mechanical ventilation is a major part of the control strategy. An increase in air supply over that required for combustion reduces the progression of the fire by lowering the flame temperature. Further, ventilation can control the direction of smoke migration to permit safe evacuation of passengers and facilitate access by fire fighters (see NFPA *Standard* 130 and the section on Road Tunnels).

Emergency ventilation must allow for the unpredictable location of a disabled train or the source of fire and smoke. Therefore,





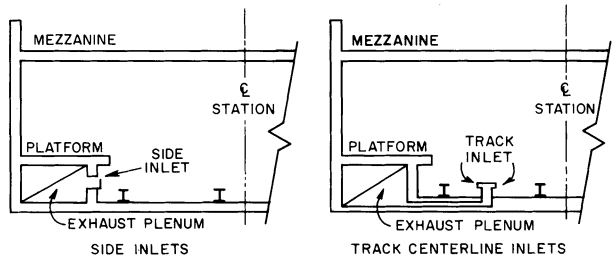


Fig. 14 Tunnel Ventilation Concept

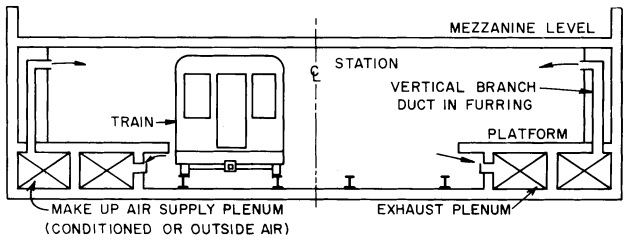
emergency ventilation fans should have nearly full reverse flow capability so that fans on either side of a stalled train can operate together to control the direction of airflow and counteract the migration of smoke. When a train is stalled between two stations and smoke is present, outside air is supplied from the nearest station and contaminated air is exhausted at the opposite end of the train (unless the location of the fire dictates otherwise). Passengers can then be evacuated along walkways in the tunnel via the shortest route (Figure 16).



Provisions must be made to (1) quickly assess any emergency situation; (2) communicate the situation to central control; (3) establish the location of the train; and (4) quickly start, stop, and reverse emergency ventilation fans from the central console to establish smoke control. Mid-tunnel and station trackway ventilation fans may be used to enhance the emergency ventilation; therefore, these fans must withstand elevated temperatures for a long period and have reverse flow capacity.

B. NO MAKEUP AIR SUPPLY

C. MAKEUP AIR SUPPLY AT CEILING LEVEL

Fig. 15 Trackway Ventilation Concepts (Cross-Sections)

Station Air Conditioning

Higher approach speeds and closer headways, made possible by computerized train control, have increased the amount of heat gains in a subway. The net internal sensible heat gain in a typical double-track subway station, with 40 trains per hour per track traveling at top speeds of 80 km/h, may reach 1.5 MW even after heat is removed by the heat sink, by station underplatform exhausts, and by tunnel ventilation. To remove such a quantity of heat by station ventilation with outside air at a temperature rise of 1.5 K, for example, requires roughly 660 m^3/s.

Not only would such a system be costly, but the air velocities on station platforms would be objectionable to passengers. The same amount of sensible heat gain, plus latent heat, plus outside air load with a station design temperature 4 K lower than ambient, could be handled by about 2.2 MW of refrigeration. Even if station air conditioning is initially more expensive, long-term benefits include (1) reduced design airflow rates, (2) improved environment for passengers, (3) increased equipment life, (4) reduced maintenance of equipment and structures, and (5) increased acceptance of the subway as a viable means of public transportation.

Air conditioning should be considered for other ancillary station areas such as concourses, concession areas, and transfer levels. However, unless these walk-through areas are designed to attract patronage to concessions, the cost of air conditioning is not usually warranted.

The physical configuration of the platform level usually determines the cooling distribution pattern. Areas with high ceilings, local hot spots due to train location, high-density passenger accumulation, or high-level lighting may need spot cooling. Conversely, where train length equals platform length and ceiling height above the platform is limited to 3 to 3.5 m, isolation of heat sources and application of spot cooling is not usually feasible.

The use of available space in the station structure for air distribution systems should be of prime concern because of the high cost of underground construction. Overhead distribution ductwork, which adds to building height in commercial construction, could add to the depth of excavation in subway construction. The space beneath a subway platform is normally an excellent area for low-cost distribution of supply, return, and/or exhaust air.

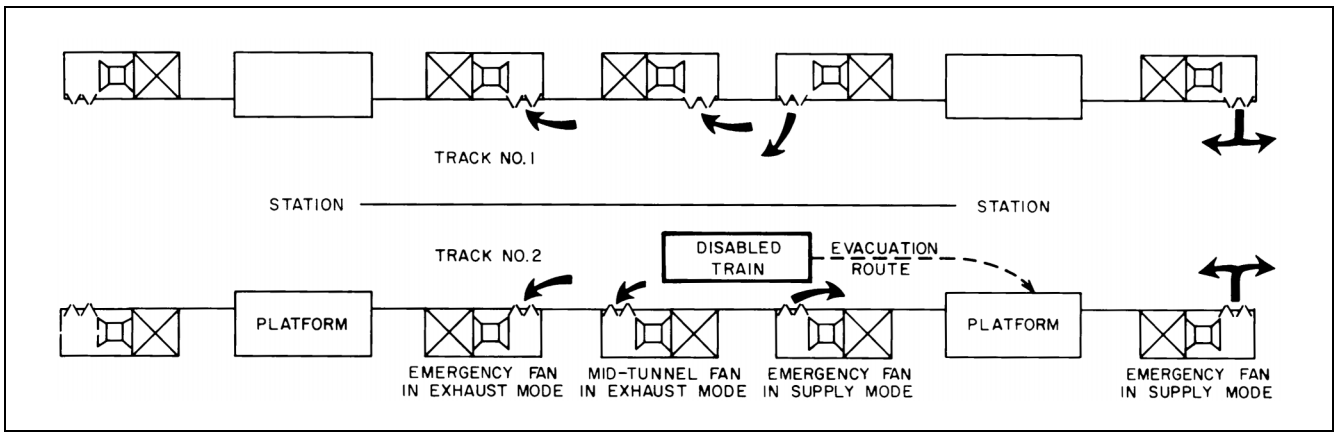

Fig. 16 Emergency Ventilation Concept

DESIGN METHOD

A subway may have to satisfy two separate sets of environmental criteria: one for normal operations and one for emergencies. Criteria for normal operations generally include limits on temperature and humidity for various times of the year, a minimum ventilation rate to dilute contaminants generated in the subway, and limits on air velocity and the rate of air pressure change to which commuters may be exposed. Some of these criteria are subjective and may vary based on demographics. Criteria for emergencies generally include a minimum purge time for sections of the subway in which smoke or fire may occur and minimum and maximum fan-induced tunnel air velocities.

Given a set of criteria, a set of outdoor design conditions, and appropriate tools for estimating interior heat loads, earth heat sink, ventilation, air velocity, and air pressure changes, design engineers select the elements of the environmental control system. Controls for air temperature, air velocity, air quality, and air pressure should be considered. The system selected generally includes a combination of unpowered ventilation shafts, powered ventilation shafts, underplatform exhaust, and air conditioning.

The train propulsion/braking systems and the configurations of tunnels and stations greatly affect the subway environment, which must often be considered during the early stages of design. The factors affecting a subway environmental control system are discussed in this section. The Subway Environmental Design Handbook (DOT 1976) and NFPA *Standard* 130, Standard for Fixed Guideway Transit Systems, have additional information.

Comfort Criteria

Because of the transient nature of a person's exposure to the subway environment, comfort criteria are not as strict as for continuous occupancy. As a general principle, the environment in a subway station should provide a smooth transition between outside conditions and those in the transit vehicles. Based on nuisance concerns, peak air velocities in public areas should be limited to 5 m/s.

Air Quality

Air quality in a subway system is influenced by many factors, some of which are not under the direct control of the HVAC engineer. Some particulates, gaseous contaminants, and odorants existing on the outside can be prevented from entering the subway system by the judicious location of ventilation shafts. Particulate matter, including iron and graphite dust generated by train operations, is best controlled by a regular cleaning of the subway. However, the only viable way to control gaseous contaminants such as ozone (from electrical equipment) and CO_2 (generated by human respiration) is through adequate ventilation from outside. A minimum of 0.0035 m^3/s outside air per person should be introduced into tunnels and stations to dilute gaseous contaminants.

Pressure Transients

The passage of trains through aerodynamic discontinuities in the subway causes changes in static pressure. These pressure transients can irritate passengers' ears and sinuses. Pressure transients may also cause additional load on various structures (e.g., acoustical panels) and equipment (e.g., fans). Based on nuisance factors, if the total change in pressure is greater than 700 Pa, the rate of static pressure change should be kept below 400 Pa/s.

During emergencies, ventilation must be provided to control smoke and reduce air temperatures to permit passenger evacuation and fire-fighting operations. The minimum air velocity in the affected tunnel section should be sufficient to prevent the smoke from backlayering (i.e., flowing in the upper cross-section of the tunnel in the direction opposite to the forced outside ventilation air). The method for ascertaining this minimum velocity is provided in DOT (1997). The maximum air velocity experienced by evacuating passengers should be 11 m/s.

Interior Heat Loads

Heat in a subway system is generated mostly by (1) train braking; (2) train acceleration; (3) car air conditioning and miscellaneous equipment; (4) station lights, people, and equipment; and (5) ventilation (outside) air.

Deceleration. From 40 to 60% of the heat generated in a subway arises from the braking of trains. Many rapid transit vehicles use nonregenerative braking systems, in which the kinetic energy of the train is dissipated as heat through the dynamic and/or friction brakes, rolling resistance, and aerodynamic drag.

Acceleration. Heat is also generated as the train accelerates. Many operational trains use cam-controlled variable resistance elements to regulate voltage across dc traction motors during acceleration. Electrical power is dissipated by these resistors and by the third rail as heat in the subway system. Heat released during acceleration also includes that due to traction motor losses, rolling resistance, and aerodynamic drag and generally amounts to 10 to 20% of the total heat released in a subway.

For closely spaced stations, more heat is generated because trains frequently only accelerate or brake, and operate little at constant speed.

Car Air Conditioning. Most new cars are fully climate controlled. Air-conditioning equipment removes patron and lighting heat from the cars and transfers it, along with the condenser fan heat and compressor heat, into the subway. Air-conditioning capacities generally range from 35 kW per car for the shorter cars (about 15 m) up to about 70 kW for the longer cars (about 22 m). Heat from car air conditioners and other accessories is generally 25 to 30% of total heat generated in a subway.

Other Sources. Heat also comes from people, lighting, induced outside air, and miscellaneous equipment (fare vending machines, escalators, and the like). These sources generate 10 to 30% of total heat released in a subway. In a typical analysis of heat balance in a subway, a control volume about each station that includes the station and its approach and departure tunnels is defined.

Heat Sink

The amount of heat flow from subway walls to subway air varies on a seasonal basis, as well as for morning and evening rush-hour operations. Short periods of abnormally high or low outside air temperature may cause a temporary departure from the heat sink effect in portions of a subway that are not heated or air conditioned. This departure causes a change in the subway air temperature. However, the change from normal is diminished by the thermal inertia of the subway structure. During abnormally hot periods, heat flow to the subway structure increases. Similarly, during abnormally cold periods, heat flow from the subway structure to the air increases.

For subways where daily station air temperatures are held constant by heating and cooling, heat flux from station walls is negligible. Depending on the infiltration of station air into the adjoining tunnels, heat flux from tunnel sections may also be reduced. Other factors affecting the heat sink component are type of soil (dense rock or light, dry soil), migrating groundwater, and the surface configuration of the tunnel walls (ribbed or flat).

Measures to Limit Heat Loads

Various measures have been proposed to limit the interior heat load in subway systems. Among these are regenerative braking, thyristor motor controls, track profile optimization, and underplatform exhausts.

Electrical regenerative braking converts kinetic energy to electrical energy for use by other trains. Flywheel energy storage, an alternative form of regenerative braking, stores part of the

braking energy in high-speed flywheels for subsequent use in vehicle acceleration. Using these methods, the reduction in heat generated by braking is limited by present technology to approximately 25%.

Conventional cam-controlled propulsion applies a set of resistance elements to regulate traction motor current during acceleration. Electrical energy dissipated by these resistors appears as waste heat in a subway. Thyristor motor controls replace the acceleration resistors with solid-state controls, which reduce acceleration heat loss by about 10% on high-speed subways and about 25% on low-speed subways.

Track profile optimization refers to a trackway that is lower between stations. With this type of track, less power is used for acceleration, because some of the potential energy of the standing train is converted to kinetic energy as the train accelerates toward the tunnel low point. Conversely, some of the kinetic energy of the train at maximum speed is converted to potential energy as it approaches the next station. This profile reduces the maximum vehicle heat loss from acceleration and braking by about 10%.

An **underplatform exhaust** uses a hood to remove some of the heat generated by vehicle underfloor equipment (e.g., resistors and air-conditioning condensers) from the station environment. Exhaust ports beneath the edge of the station platform withdraw heated air under the car.

For preliminary calculations, it may be assumed that (1) train heat release (due to braking and train air conditioning) in the station box is about two-thirds of the control volume heat load and (2) the underplatform exhaust is about 50% effective.

A quantity of air equal to that withdrawn by the underplatform exhaust enters the control volume from outside. Thus, when the ambient temperature is higher than the station design temperature, an underplatform exhaust reduces the subway heat load by removing undercar heat, but it increases the heat load by drawing in outside air. A proposed technique to reduce the uncontrolled infiltration of outside air is to provide a complementary supply of outside air on the opposite side of the underplatform exhaust ports. While in principle the underplatform exhaust with complementary supply tends to reduce the mixing of outside air with air in public areas of the subway, test results on such systems are unavailable.

RAILROAD TUNNELS

Railroad tunnels serving diesel locomotive operation require ventilation to remove residual diesel exhaust so that the succeeding train can be exposed to a relatively clean environment. Ventilation is also required to prevent the locomotives from overheating. For short tunnels, the ventilation generated by the piston effect of the train followed by natural ventilation is usually sufficient to purge the tunnel of diesel exhaust in a reasonable time period. Mechanical ventilation for locomotive cooling is also usually not required because the time a train is in the tunnel is typically less than the time it would take for a locomotive to overheat. Under certain conditions, however, such as excessively slow trains or during hot weather, overheating can become a problem. For long tunnels, mechanical ventilation is required to purge the tunnel following the passage of a train. Mechanical ventilation may also be required for locomotive cooling, depending on the speed of the train and the number and arrangement of locomotives used.

The diesel locomotive is essentially an electrically driven vehicle. The diesel engine drives a generator which in turn supplies electrical power to the traction motors. The power of these engines ranges from about 750 to 4500 kW.

Since the overall efficiency of the locomotive is generally under 30%, most of energy generated by the combustion process must be dissipated as heat to the surrounding environment. Most of this heat is released above the locomotive via the exhaust stack and the radiator (Figure 17). When operating in a tunnel, this heat

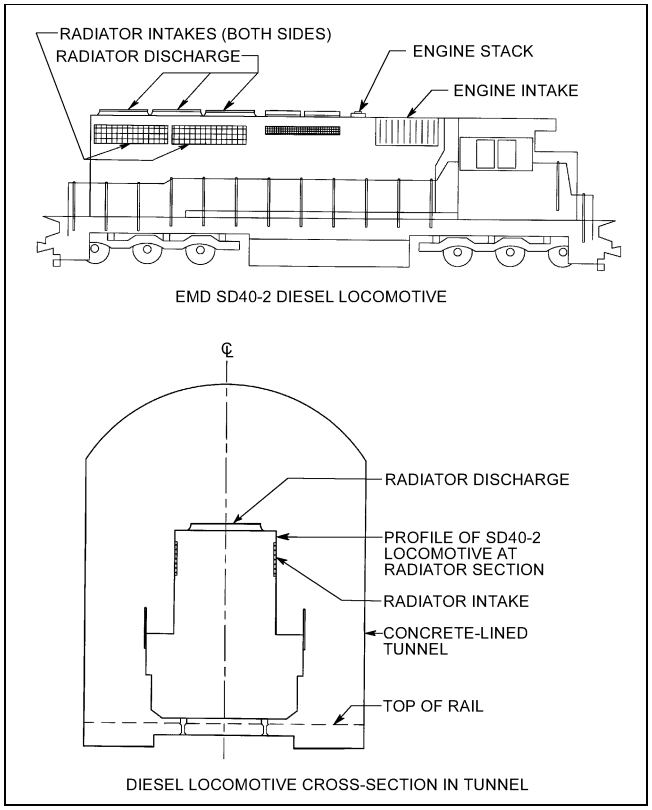

Fig. 17 Typical Diesel Locomotive Arrangement

is confined to the region surrounding the train. Most commercial trains are powered by more than one locomotive, so the last unit is subjected to the heat released from the preceding units. If sufficient ventilation is not provided, the air temperature entering the radiator of the last unit will exceed its allowable limit. Depending on the engine protection system, the locomotive will either shut down or drop to a lower throttle position. When this occurs, the train slows down. But, as discussed in the next section, the train relies on its speed to generate sufficient ventilation for cooling. As a result a domino effect takes place, which may cause the train to stall in the tunnel.

DESIGN CONCEPTS

Most long railroad tunnels (over 8 km) in the western hemisphere that serve diesel operation use a ventilation concept that includes a combination of a tunnel door and a system of fans and dampers, all located at one end of the tunnel. When a train moves through the tunnel, ventilating air required for locomotive cooling is generated by the piston effect of the train moving toward or away from the closed portal door. This effect often creates a sufficient flow of air past the train for self-cooling. Under certain conditions when the piston effect cannot provide the required airflow, a fan supplements the effect. This mode of fan operation is commonly referred to as “cooling.” When the train leaves the tunnel, the tunnel is purged of residual smoke and diesel contaminants by running the fans with the door closed to move fresh air from one end of the tunnel to the other. This mode of fan operation is referred to as “purge.” Because the airflow and pressure required for the cooling and purge modes may be substantially different, separate fans or variable-volume fans may be required to perform the two operations. Also, dampers are provided to relieve the pressure across the door to facilitate its operation while the train is in the tunnel.

The application of this basic ventilation concept varies depending on such factors as the length and grade of the tunnel, type and speed of the train, environmental and other site constraints, and traffic. A design for a 14.5 km long tunnel (Levy and Danziger 1985) extends the basic concept by including a mid-tunnel door and a partitioned shaft that connects to the tunnel on opposite sides of the mid-tunnel door. The combination of the mid-tunnel door and the partitioned shaft divide the tunnel into two segments, each having its own ventilation. Thus, the ventilation requirement of each segment is satisfied independently. The need for such a system was dictated by the length of the tunnel, the relatively low speed of the trains, and the train traffic pattern.

Locomotive Cooling Requirements

A breakdown of the heat emitted by a locomotive to the surrounding air can be determined by performing an energy balance. Starting with the locomotive fuel consumption rate as a function of throttle position, the heat release rates at the engine exhaust stack and radiator discharge as provided by the engine manufacturer, and the gross power delivered by the engine shaft, the amount of miscellaneous heat radiated by the engine can be determined:

$$q_m = FH - q_S - q_R - P_G \tag{12}$$

where

q_m = miscellaneous heat radiated from locomotive engine
F = locomotive fuel consumption
H = heating value of fuel
q_S = heat rejected at engine exhaust stack
q_R = heat rejected at radiator discharge
P_G = gross power at engine shaft

Because the locomotive auxiliaries are driven off the engine shaft with the remaining power used for traction power via the main engine generator, the heat released by the main engine generator is as follows:

$$q_G = (P_G - L_A)(1 - \varepsilon_G) \tag{13}$$

where

q_G = main generator heat loss
L_A = power driving locomotive auxiliaries
ε_G = main generator efficiency

Heat loss from the traction motors and gear trains is as follows:

$$q_{TM} = P_G - L_A - q_G - P_{TE} \tag{14}$$

where

q_{TM} = heat loss from traction motors and gear trains
P_{TE} = locomotive tractive effort power

The total locomotive heat release rate q_T is

$$q_T = q_S + q_R + q_m + L_A + q_G + q_{TM} \tag{15}$$

For a locomotive consist containing N locomotives, the average air temperature approaching the last locomotive is

$$t_{AN} = t_{AT} + \frac{q_T(N-1)}{\rho c_p Q_R} \tag{16}$$

where

t_{AN} = average tunnel air temperature approaching the Nth unit
t_{AT} = average tunnel air temperature approaching locomotive consist
ρ = density of tunnel air approaching locomotive consist
c_p = specific heat of air
Q_R = tunnel airflow rate relative to the train

The inlet air temperature to the locomotive radiators is used to judge the adequacy of the ventilation. For most locomotive units running at maximum throttle position, the maximum allowable inlet air temperature recommended by locomotive manufacturers is about 46°C. Field tests conducted in operating tunnels (Aisiks and Danziger 1969, Levy and Elpidorou 1991) have shown, however, that some units can operate continuously with radiator inlet temperatures as high as 57°C. The allowable inlet temperature for each locomotive type should be obtained from the manufacturer when contemplating a design.

To determine the airflow rate required to prevent locomotive overheating, the relationship between the average tunnel air temperature approaching the last unit and the radiator inlet air temperature must be known or conservatively estimated. This relationship, however, depends on such variables as the number of locomotives in the consist, the air velocity relative to the train, tunnel cross-section, type of tunnel lining, and locomotive orientation (i.e., facing forward or backward). For trains traveling under 30 km/h, Levy and Elpidorou (1991) showed that a reasonable estimate would be to assume the radiator inlet air temperature to be about 6 K higher than the average temperature approaching the unit. For trains moving at 50 km/h or more, a reasonable estimate is to assume that the radiator inlet air temperature is equal to the average temperature approaching the unit. When the last unit of the consist is facing forward, thereby putting the exhaust stack ahead of its own radiators, the stack heat release rate must be included when evaluating the radiator inlet air temperature.

Tunnel Aerodynamics

When designing a ventilation system for a railroad tunnel, the airflow and pressure distribution throughout the tunnel as a function of train type, train speed, and mechanical ventilation system operations must be determined. This information is required to determine: (1) whether sufficient ventilation is provided for locomotive cooling; (2) the pressures the fans are required to deliver; and (3) the pressures the structural and ventilation elements of the tunnel must be designed to withstand.

The following equation (DOT 1997) relates the piston effect of the train, the steady-state airflow delivered by the fans to the tunnel, and the pressure across the tunnel door. The expression assumes the leakage across the tunnel door is negligible. Figure 18 shows the dimensional variables on a schematic of a typical tunnel.

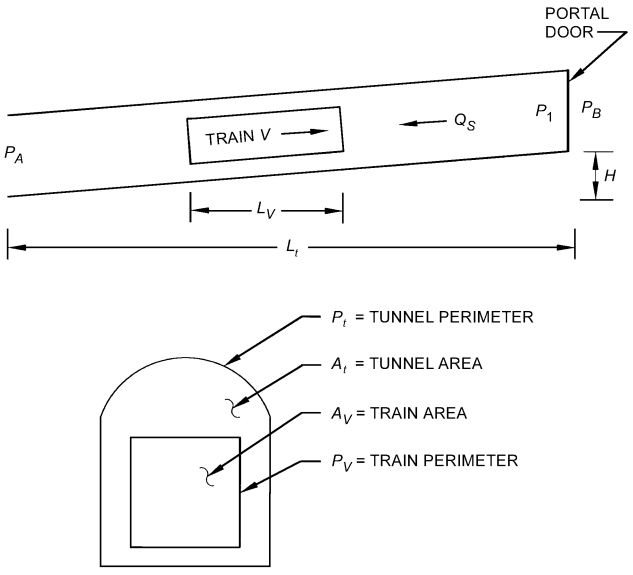

Fig. 18 Railroad Tunnel Aerodynamic Related Variables

$$\frac{\Delta p}{\rho} = \frac{(p_A - p_B)}{\rho} - Hg + \left[\frac{(A_V^2 + A_V A_t C_{DVB})}{(A_t - A_v)^2} + \frac{A_V C_{DVF}}{A_t}\right]\frac{(A_t V + Q_s)^2}{2A_t^2} + \frac{f_t L_V P_t (A_V V + Q_s)^2}{8(A_t - A_V)^3} + \frac{\lambda_V L_V P_V (A_t V + Q_s)^2}{8(A_t - A_V)^3} + \frac{f_t (L_t - L_V) P_t Q_s^2}{8A_t^3} + \frac{K Q_s^2}{2A_t^2} \quad (17)$$

where

Δp = static pressure across tunnel door, Pa
p_A = barometric pressure at Portal A, Pa
p_B = barometric pressure at Portal B, Pa
H = difference in elevation between portals, m
ρ = density of air, kg/m^3
g = acceleration of gravity = 9.807 m/s^2
A_V = train cross-sectional area, m^2
A_t = tunnel cross-sectional area, m^2
V = velocity of train, m/s)
Q_S = airflow delivered by fan, m^3/s
C_{DVB} = drag coefficient at back end of train
C_{DVF} = drag coefficient at front end of train
L_t = tunnel length, m
L_V = train length, m
f_t = tunnel wall friction factor
λ_V = train skin friction factor
P_t = tunnel perimeter, m
P_V = train perimeter, m
K = miscellaneous tunnel loss coefficient

The pressure across the tunnel door generated by train piston action only is evaluated by setting Q_S equal to zero. The airflow rate relative to the train required to evaluate locomotive cooling requirements is

$$Q_{rel} = A_t V + Q_S \quad (18)$$

where

Q_{rel} = airflow rate relative to train, m^3/s

Typical values for C_{DVB} and C_{DVF} are about 0.5 and 0.8, respectively. Because trains passing through a tunnel are often more than a kilometre long, the parameter that most affects the magnitude of the pressure generated is the train skin friction coefficient. For dedicated coal or grain trains, which essentially use uniform cars throughout, a value of 0.09 for the skin friction coefficient results in pressure predictions which closely conform to those observed at various tunnels (Flathead, Cascade, Moffat, Mount Macdonald). For trains with a nonuniform makeup of cars, the skin friction coefficient may be as high as 1.5 times that of a uniform distribution.

The wall surface friction factor corresponds to the coefficient used in the Darcy-Weisbach equation for friction losses in pipe flow. Typical effective values for tunnels constructed with a formed concrete lining having a ballasted track range from 0.015 to 0.017.

Tunnel Purge

Train operations through a tunnel require that the leading end of a train be exposed to an environment that is relatively free of smoke and diesel contaminants emitted by preceding trains. The tunnel is usually purged by displacing the contaminated tunnel air with fresh air by mechanical means after a train has left the tunnel. With the tunnel door closed, air is either supplied to or exhausted from the tunnel, thereby moving fresh air from one end to the other. Observations at the downstream ends of tunnels have found that an effective purge time is usually based on displacing 1.25 times the tunnel volume with fresh air.

The time for purging is primarily determined by operating schedule needs. Too long a time limits traffic, while too short a time may require very high ventilation rates with resulting high electrical energy demand and consumption. Consequently, multiple factors must be considered, including the overall ventilation concept, when establishing purge time.

DIESEL LOCOMOTIVE FACILITIES

Diesel locomotive facilities include shops where locomotives are maintained and repaired, enclosed servicing areas where supplies are replenished, and overbuilds where locomotives routinely operate inside an enclosed space. In general, these areas should be kept under slightly negative pressure to aid in the removal of fumes and contaminants. Ventilation should be accomplished using 100% outside air with no recirculation. However, recirculation may be acceptable to maintain space temperature during unoccupied periods when engines are not running. Heat recovery devices should be considered in colder climates when heating is needed.

Maintenance and Repair Areas

ASHRAE *Standard* 62 and most model codes require a minimum outdoor air ventilation rate of 0.0075 m^3/(s·m^2) in vehicle repair garages, with no recirculation recommended. Because the interior ceiling height is usually large in locomotive shops, the designer should consider making a volumetric analysis of contaminant generation and air exchange rates rather than using the above value as a blanket standard. The section on Contaminants at the end of this section has more information on diesel engine exhaust emissions.

Information in the section on Bus Garages applies to locomotive shops, especially for below-grade pits, battery charging areas, and paint spray booths. However, diesel locomotives generally have much larger engines (ranging up to 4500 kW). Ventilation is needed to reduce crew and worker exposure to exhaust gas contaminants and to remove rejected heat from the engine radiators. Diesel engines should not be operated in shops where possible. The shop practices should reflect this and policies established to define engine speeds and time limits. Some shops require locomotives to be load tested at higher engine speeds. One dedicated area where engines are operated should be identified and hoods used to capture engine exhaust. If hoods are impractical because of physical obstructions, then dilution ventilation must be used.

In designing hoods, the physical location of each exhaust on each type of locomotive must be identified so that each hood can be centered and as close as possible to each exhaust point. Local and state railroad clearance regulations must be followed along with occupational safety requirements. Hoods should not increase the backpressure on the locomotive exhaust by designing a throat velocity that is at least twice the exhaust discharge velocity. Duct design should include access doors and provisions for cleaning the oily residue that increases the risk of fire. Fans and other equipment in the airstream should be selected with regard to the elevated temperatures and the effects of the emission's residue.

Sometimes high ceilings or overhead cranes limit the use of hoods. The *Manual for Railway Engineering* (AREA 1996) notes that six (6) air changes per hour is usually sufficient to provide adequate dilution for idling locomotives and for short runs at a higher speed. The design should take advantage of the thermal buoyancy of the hot gases and exhaust them high before they cool and drop to the floor. Locomotive radiator cooling fans recirculate cooled gases making them more difficult to remove. Makeup air should be introduced into the shop at floor level and tempered as needed.

Heating of shops is necessary in colder climates for the comfort of workers and to prevent freezing of equipment and building piping. Heating may consist of a combination of perimeter convectors to offset building transmission losses, underfloor slab or infrared radiation for workers, and makeup air units for ventilation. Where natural gas is available and codes allow, direct-fired gas heaters can be an economical compromise for obtaining a high degree of worker comfort. Usually air curtains or door heaters are not needed because of infrequent opening.

Enclosed Servicing Areas

While most locomotive servicing is done outside, some railroads use enclosed servicing areas for protection from weather and extreme cold. Operations include refilling fuel tanks, replenishing sand (used to aid traction), draining toilet holding tanks, checking lubrication oil and radiator coolant levels, and performing minor repairs. Generally, the time a locomotive spends in the servicing area is less than one hour. Ventilation is needed to reduce crew and worker exposure to exhaust gas contaminants and to remove rejected heat from engine radiators. The designer should also consider the presence of vapors from fuel oil dispensing and silica dust from sanding operations. Heating may be included depending on the need for worker comfort and the operations performed.

Ventilation of servicing areas should be similar to that for maintenance and repair areas. Hoods rather than dilution ventilation should be used where possible. However, the locating of exhaust points may be difficult due to the coupling of different locomotives together in consists of two or more. Also, elevated sanding towers and distribution piping may interfere. The designer should be aware that contaminant levels may be higher in servicing areas than in shops due to constantly idling locomotives and their occasional higher speed movement in and out of the facility. For dilution ventilation, the designer should ascertain the operation and make a volumetric analysis of contaminant generation and air exchange rates.

For heating, the designer should consider the use of infrared radiation for workers. As with maintenance and repair areas, direct-fired gas heaters may be economical. Air curtains or door heaters may be justified due to the frequent opening of doors or lack of doors.

Overbuilds

With increasing real estate costs, the space above tracks and stations platforms are more commonly built over to enclose the locomotive operation area. Ventilation is needed to reduce crew and passenger exposure to exhaust and to remove rejected heat from engine radiators and train air conditioners. Overbuilds are generally not heated.

Diesel locomotives are more appropriately termed diesel-electric locomotives because the transmission is actually an electric generator (alternator) driven by the diesel engine supplying power to electric traction motors. The throttle, which usually has eight position (notches), controls engine speed and power. Modern passenger trains use auxiliary power from the locomotive, termed head end power (HEP) to provide electricity for lighting, heating, ventilating, air conditioning, receptacles, and other use throughout the train.

Exhaust emissions from passenger diesel locomotives in overbuilds are higher than idling locomotives because of the HEP power requirements. The designer should determine the types of locomotives and operating practices in the proposed overbuild. As with shops and servicing areas, hoods are recommended. According to *Ventilation Requirements for Overbuild Construction* (Amtrak 1991) the temperature at the source will be between 175 and 375°C. A typical design could have hoods approximately 5.5 and 7 m above the top of the rail with throat velocities between 9.1 and 11.2 m/s. For dilution ventilation, the designer should make a volumetric analysis of contaminant generation and air exchange rates.

Contaminants

The components of diesel exhaust gases that affect the ventilation system design are oxides of nitrogen (NO_x) hydrocarbons (HC), formaldehyde, sulfur dioxide (SO_2), odor constituents, aldehydes, smoke particulate, and carbon monoxide (CO). Operation of diesel engines in enclosed spaces causes visibility obstruction and odors, as well as contaminants. A diesel locomotive that has been operating for several minutes in a lightly loaded mode often produces large amounts of visible smoke and emissions from accumulated, unburned fuel.

Information in the section on Bus Operation Areas, except for engine emissions' data, applies to diesel locomotives. The *Tunnel Engineering Handbook* describes that all exhaust gas contaminants will be maintained with acceptable limits as long as the oxides of nitrogen are maintained in specified acceptable limits. Table 7 provides approximate data on the contaminants found in a typical locomotive's engine exhaust gases and other design information. The designer should determine the nature of the applicable locomotive engines for each project, and consult the manufacturers.

Table 7 Typical Diesel Locomotive Emission Data

Throttle Pos. (Notch)	Engine Speed, rpm	Engine Power, kW	Exhaust Volume, m^3/s	Exhaust Temp., °C	NO_x, g/min	CO, g/min	HC, g/min	SO_2, g/min
Engine Nominal Power = 2400 kW, with Head End Power (HEP)

EQUIPMENT

The ability of an enclosed vehicular facility to function depends mostly on the effectiveness and reliability of its ventilation system. The ventilation system must be capable of operating effectively under the most adverse environmental and traffic conditions and during periods when not all equipment is operational. For a tunnel, the ventilation system should also have more than one dependable source of power to prevent an interruption of service.

FANS

The fan manufacturer should be prequalified and should be responsible under one contract for furnishing and installing the fans, bearings, drives (including variable-speed components), motors, vibration devices, sound attenuators, discharge and inlet dampers, and limit switches.

The prime concerns in selecting the type, size and number of fans include the total theoretical ventilating air capacity required and a reasonable safety factor. Selection is also influenced by the manner in which reserve ventilation capacity is provided when a fan is inoperative and during repair of equipment or of the power supply.

Selection of fans (number and size) to meet normal and reserve capacity requirements is based on the principle of parallel fan operation. Actual capacities can be determined by plotting fan performance and system curves on the same pressure-volume diagram.

It is important that fans selected for parallel operation operate in the region of their performance curves so that the transfer of capacity back and forth between fans does not occur. This is accomplished by selecting a fan size and speed such that the duty point, no matter how many fans are operating, falls well below the unstable range of fan performance. Fans operating in parallel should be of equal size and have identical performance curves. If flow is regulated by speed control, all fans should operate at the same speed. If flow is regulated by dampers or inlet vane controls, all dampers or inlet vanes should be at the same angle. For axial flow fans, blades on all fans should be at the same pitch or stagger angle.

Jet fans can be used for longitudinal ventilation to provide a positive means of smoke and temperature management in tunnels. This ventilation concept has been proven by the Memorial Tunnel Fire Ventilation Test Program (MHD/FHWA 1995). Jet fans deliver relatively small air quantities at high velocity. The energy, which is transmitted in the form of thrust, induces airflow through the tunnel in the desired direction. Jet fans can be unidirectional or reversible.

Number and Size of Fans

The number and size of fans should be selected by comparing several fan arrangements. Comparison should be based on feasibility, efficiency, and overall economy of the arrangement and the duty required. Several factors should be studied, including (1) annual power cost for operation, (2) annual capital cost of the equipment (usually capitalized over an assumed equipment life of 30 years for rapid transit tunnel fans and 50 years for road tunnel fans), and (3) annual capital cost of the structure required to house equipment (usually capitalized over an arbitrary structure life of 50 years).

Two views are held regarding the proper number and size of fans. The first advocates a few large-capacity fans; the second prefers numerous small units. In most cases, a compromise arrangement produces the greatest efficiency. Regardless of the design philosophy, the number and size of fans should be selected to build sufficient flexibility into the system to meet the varying ventilation demands created by daily and seasonal traffic fluctuations and emergency conditions.

The size of jet fans is usually limited by the space available for their installation in the tunnel. They are typically mounted on the tunnel ceiling, over the traffic lanes or on the walls. Jet fans are sometimes placed in niches to minimize the vertical height of the tunnel boundary. Such a mounting reduces the thrust of the fan.

For longitudinal ventilation using jet fans, the required number of fans (once the fan size and tunnel airflow requirements have been determined) is defined by the total thrust required to overcome the tunnel resistance (pressure loss) divided by the individual jet fan thrust (which is a function of the mean velocity in the tunnel). Jet fans installed longitudinally should be kept at least 100 fan diameters apart so that the jet velocity does not affect the performance of the downstream fan(s). Fans installed side by side should be kept at least two (2) fan diameters between centers.

Type of Fan

Normally, the ventilation system of a vehicular facility requires large air volumes at relatively low pressure. Some fans have low efficiencies under these conditions, so the choice of suitable fan type is often limited to either centrifugal, vane axial or jet fan.

Special Considerations. Special attention must be given to any fan in areas with **flow and pressure transients** caused by train passage. If the transient tends to increase flow to the fan (i.e., the positive flow in front of a train to an exhaust fan or negative flow behind the train to a supply fan), it is important that blade loading does not become high enough to produce long-term fatigue failures.

If the disturbance tends to decrease flow to the fan (i.e., the negative flow behind the train to an exhaust fan or the positive flow in front of the train to a supply fan), the fan performance characteristic must have adequate margins to prevent an aerodynamic stall.

The ability to **rapidly reverse** the rotation of tunnel supply, exhaust, and emergency fans is usually important in an emergency. This requirement must be considered in the selection and design of the fan and drive system.

Fan Design and Operation

Fans and components (e.g., blade-positioning mechanisms, drives, bearings, motors, controls, etc.) that are required to operate in the exhaust airstream during a fire or a smoke emergency should be capable of operating at maximum speed under the temperature conditions specified by the following standards or calculations:

- Rapid transit tunnels, NFPA *Standard* 130
- Road tunnels, NFPA *Standard* 502
- Rail tunnels, at maximum expected temperatures based on computer simulations or other calculations

Fans and dampers that are operated infrequently or for emergency service only should be operated at least once every three months to ensure that all rotating elements are in good condition and are properly lubricated. The period of operation should be long enough to achieve stabilized temperatures in the bearings and motor windings. Multispeed motors should be operated at all speeds.

Inlet boxes can be used to protect the bearings and drives of centrifugal fans from the high temperatures, corrosive gases, and particles present in the exhaust air during the emergency operating mode. This arrangement requires that special attention be given to the design of the fan shaft due to the overhung drive loads as discussed in the following section on Fan Shafts.

Axial flow fans that must be reversible should be able to be rapidly reversed from maximum design speed in one direction to maximum design speed in the opposite direction. The time from rotation at full speed in one direction to full speed in the opposite direction should be less than 60 s. The design should include the effects of any temperature changes associated with the reversal of the flow direction. All components of these fans should be designed for a minimum of four reversal cycles per year for 50 years without damage.

Housings for variable-pitch axial flow fans should be furnished with flow-measuring instruments designed to measure the airflow in both directions. Capped connections should be provided for

measuring the pressure developed across the fan. The fan should be protected from operating in a stall region.

To minimize blade failure in axial flow fans, the following precautions should be taken:

- Blades should be secured to the hub with positive locking devices.
- The fan inlet (and discharge if reversible) should be protected to prevent the entry of foreign objects which could damage the rotating assembly.
- The natural frequency (both static and rotating) of the blade and the maximum stress on the surface of the blade during operation at all points on the fan characteristic curve should be measured during the factory tests.
- For rapid transit systems, fans that are subjected to flow and pressure reversals caused by train passage should be designed (and tested to verify) to withstand 4 000 000 cycles of flow reversals.

When the fan includes a variable frequency drive (VFD), a factory test using a production version of the VFD should be conducted to ensure adequate operation and compatibility.

Jet fan blades should be made of such material that their strength in a fire emergency is sufficient to withstand the temperature specified. The design calculations for the fans should consider the fan or fans at the fire location to be destroyed by the fire.

Fan Shafts. Fan shafts should be designed so that the maximum deflection of the assembled fan components, including the forces associated with the fan drive, does not exceed 0.42 mm per metre of shaft length between centers of bearings. For centrifugal fans where the shaft overhangs the bearing, the maximum deflection at the centerline of the fan drive pulley should not exceed 0.42 mm per metre of shaft length between the center of the bearing and the center of the fan drive pulley.

Good practice suggests that the fundamental bending mode frequency of the assembled shaft, wheel, or rotor be more than 50% higher than the highest fan speed. The first resonant speed of all rotational components should be at least 125% above the maximum speed. The fan assembly should be designed to withstand for at least 3 min all stresses and loads resulting from an overspeed test at 110% of the maximum design fan speed.

Bearings. Fan and motor bearings should have a minimum equivalent L10 rated life of 10 000 hours as defined by the Anti-Friction Bearing Manufacturers Association. Special attention must be given to belt-driven fans as the improper tensioning (over tension) of the belts can drastically reduce the life of the bearings that support the drive, the belts and possibly the life of the shafts as well.

Axial flow and jet fans. Each fan motor bearing and fan bearing should be equipped with a monitoring system that senses individual bearing vibrations and temperatures and provides a warning alarm if either rises above the normal range.

Centrifugal fans. Due to their low speed (generally less than 450 rpm), centrifugal fans are not always provided with bearing vibration sensors, but they do require temperature sensors with warning alarm and automatic fan shutdown. Bearing pedestals for centrifugal fans should provide rigid support for the bearing with negligible impediments to airflow. The static and dynamic loading of the shaft and impeller and the maximum force due to the tension in the belts should be considered.

Corrosion-Resistant Materials. Choosing a particular material or coating to protect a fan from corrosive gas is a matter of economics. The selection of the material and/or coating should be based on the site environment, the fan duty, and an expected service life of 50 years.

Sound. For the normal ventilation mode, the construction documents should specify the following:

- Speed and direction of airflow and number of fans operating
- Maximum dBA rating or NC curve or curves acceptable under installed conditions and the locations at the fan inlet and exhaust stack outlet where these requirements apply
- That jet fans meet OSHA or local requirements, which will probably require silencers 1 or 2 diameters in length
- That the dBA rating measured at locations such as intake louvers, discharge louvers, or discharge stacks may not exceed OSHA or local requirements
- That if the measured sound values exceed the specified maximum values, the fan manufacturer must furnish and install the acoustic treatment needed to bring the sound level to an acceptable value

DAMPERS

Dampers play a major role in overall tunnel safety and the successful operation of a tunnel ventilation system. A damper's day-to-day function is to regulate fresh air to maintain comfortable temperatures in the tunnel area through natural or fan forced ventilation. Dampers also perform a pressure relief function as they allow air to be pushed out of openings in front of trains and sucked into areas behind trains as they travel through the tunnel. Additionally, they are used, in conjunction with fans, to dilute or remove carbon monoxide, flammable gases, or other toxic fumes from the tunnel. However, their most important function is to control heat and smoke during a fire emergency. In this function, dampers and fans are used to exhaust the smoke caused by the fire, and control the smoke so people can safely evacuate the tunnel.

Damper Design

Tunnel damper design requires a thorough understanding of the design criteria, installation methods, environmental surroundings, life expectancy, and maintainability and a general understanding of the operating system. Damper construction varies from one tunnel project to another, but the general construction is based on the following design criteria:

- Maximum fan operating pressure
- Day-to-day and rogue train pressures
- Maximum temperature
- Maximum velocity
- Corrosion protection desired
- Maintainability and life expectancy of the equipment
- Maximum damper module size limitations

Fan Pressure. The maximum operating pressure that the damper will withstand during normal or emergency ventilation is typically the maximum pressure that the fan can generate at shutoff. This pressure is generally between 1 and 12.5 kPa.

Day-to-Day and Rogue Train Pressures. Some dampers in the track area of a train tunnel see much higher positive and negative pressure pulses, caused by the piston action of trains moving through the tunnel, than the maximum pressure generated by the fan. A closed damper is subjected to a positive pressure in front of a train and a negative pressure behind it as the train travels through the tunnel. This pressure reversal subjects the damper blades and components to reverse bending loads that must be evaluated to prevent premature fatigue failure. The magnitude of the pulsating pressure depends on such factors as maximum train speed, length of the tunnel, clearance between the train and the tunnel walls, and amount of air that can be pushed through the open dampers and/or the station entrances.

This pulsating pressure is part of normal day-to-day operation. However, a rogue train condition could occur once or twice during the life of a tunnel ventilation system. This condition occurs when a train operates at high speed during an emergency or during a runaway. Dampers must be designed both for day-to-day fatigue and for maximum train-speed conditions.

Design specifications should require that the damper and its components meet reverse bending load criteria for anywhere from 1 to 6 million reverse bend cycles for the normal day-to-day train operation. This number of reverse bend cycles equates to a train passing by a damper once every 5 to 20 min for 30 to 50 years. This number can be adjusted for each application. Additionally, the specifying engineer should indicate what pressure could result from a once or twice in a lifetime rogue train condition.

Typically, actuators for tunnel dampers must be sized to operate against the maximum fan pressure. Because reversing pressure only occurs for a short duration, and because trains will not normally be traveling down the track during an emergency ventilation situation, the actuators are not expected to operate under such conditions.

Temperature. The maximum temperature can vary for each tunnel project. Some specifying engineers use the temperature limits set by NFPA. One typical tunnel specification states that the dampers, actuators, and accessories shall meet the operational requirements of the emergency ventilation fans as described in NFPA *Standard* 130, which states, "Emergency ventilation fans, their motors, and all related components exposed to the exhaust airflow shall designed to operate in an ambient atmosphere of 250°C for a minimum of one hour with actual values to be determined by design analysis."

Some tunnel design engineers have specified higher temperature criteria based on additional design considerations. A few automobile tunnels have been designed for the possibility of two truck tankers with flammable liquids exploding from an accident in the tunnel, which could subject the tunnel dampers to much higher temperatures. Projects of this type or others with special design considerations have been designed for maximum temperatures up to 425°C. In any event, the specifying engineer must evaluate the design conditions for each tunnel project and determine what the maximum temperature could be.

Dampers, and especially damper actuators, must be specially constructed to operate reliably in high temperature conditions for extended periods. Verifying that the proposed equipment can provide this required safety function is important. Because standard test procedures have not been developed, a custom, high-temperature test of a sample damper and actuator should be considered for inclusion in the equipment specifications.

Air Velocity. The maximum velocity for a tunnel damper design is determined from the maximum flow that can be expected to go through the damper during any one of its operating conditions. That flow can occur during normal ventilation or during an emergency set of conditions. Additionally, the flow could come from more than one fan depending on design. Actuators for tunnel dampers are typically selected to operate against the maximum flow that the dampers will see in their worst case scenario. Thus, the specifying engineer must advise what the maximum flow will be.

Corrosion Protection. Materials of construction for tunnel jobs vary considerably, and their selection is usually determined from one or more of the following reasons:

- Initial project cost
- Environmental conditions
- Life expectancy of the equipment
- Success or failure of previous materials used on similar projects
- Engineer's knowledge and/or experience of the materials required to provide corrosion protection
- Design criteria; specifically, pressure, temperature, and velocity

The corrosion resistant characteristics of a damper should be determined by the environment in which it will operate. A damper installation near saltwater or heavy industrial areas may need superior corrosion protection than one in a rural, nonindustrialized city. Dampers exposed to underground indoor environments may need less corrosion protection. However, many underground dampers are also exposed to rain, snow, and sleet. These and other factors must be evaluated by the engineer before a proper specification can be written.

Tunnel dampers have been made from commercial-quality galvanized and hot-dipped galvanized steel, anodized aluminum, aluminum with a duranodic finish, carbon steel with various types of finishes, 304, 304L, 316, 316L, and 317 stainless steel.

Maintainability and Life Expectancy of Equipment. These issues are of great concern when specifying dampers may be difficult to access for servicing, inspection, or maintenance on a regular basis. Additionally, the equipment may be difficult to replace, should it fail prematurely. Reasons could be that the damper was marginally designed for the pressures, temperatures, corrosion resistance, etc. required for the application.

Thus, some clients and specifying engineers purposely design the dampers of a more robust construction. They specify heavier material and/or more corrosion resistant materials than may be required for the application in hopes of reducing operational problems and cost while extending the life expectancy of the product. Typical methods used by specifying engineers to design dampers of a more robust construction are

- Limiting blade, frame, and linkage deflections to a maximum of $L/360$
- Selecting actuators for 200 to 300% of actual damper torque required
- Using large safety factors for stresses and deflections of high stress components.
- Specifying heavier material sizes and gages than necessary
- Using more corrosion resistant materials and finishes than required

Numerous specifications include a Quality Assurance (QA) or System Assurance Program (SAP) to assure that the required levels of performance are met. Others include an experience criteria that requires manufacturers to have five installations with five or more years of operating experience. This specification requires a list of projects and the names of contacts that the customer can communicate with regarding the product performance. These techniques help insure that reliable products are supplied.

Maximum Damper Module Size. The maximum damper module size is one of the most important initial cost factors. Many dampers can be fabricated as a single module assembly or in several sections that can be field assembled into a single module damper. However, some damper openings are very large and it may not be practical to manufacture the damper in a one-piece frame construction due to shipping, handling, and/or installation problems.

Generally speaking, the initial damper cost is less with fewer modules because they have fewer blades, frames, jackshafts, actuators, and mullion supports. However, other factors such as job site access, lifting capabilities, and installation labor costs must also be included in the initial cost analysis. These factors change for each project and the specifying engineer must evaluate each application.

Damper Applications and Types

Dampers allow or restrict flow in the tunnel. **Fan isolation dampers** (FID) can be installed in multiple-fan systems (1) to isolate any parallel, nonoperating fan from those operating to prevent short circuiting and consequent pressure and flow loss through the inoperative fan; (2) to prevent serious windmilling of an inoperative fan; and (3) to provide a safe environment for maintenance and repair work on each fan. Single-fan installations also may have a FID to prevent serious windmilling due to natural or piston-effect drafts and to facilitate fan maintenance.

Ventilation dampers (VD) control the amount of fresh air supplied to and exhausted from the tunnel and station areas. In some cases, these dampers may also serve as the **smoke exhaust dampers** (SED) and/or **fire dampers** (FD) depending on their location

and the design. Two types of ventilation dampers are generally used: (1) the trapdoor type, which is installed in a vertical duct such that the door lies horizontal when closed; and (2) the multiple-blade louver type with parallel operating blades. Both types are usually driven by an electric or pneumatic actuator, which is operated by the fan controller. During normal operation, the damper usually closes when the fan is shut off and opens when the fan is turned on.

The trapdoor damper is simple and works satisfactorily where a vertical duct enters a plenum-type fan room through an opening in the floor. This damper is usually constructed of steel plate, reinforced with welded angle iron, is hinged on one side and closes by gravity against the embedded angle frame of the opening. The opening mechanism is usually a shaft sprocket-and-chain device. The drive motor and gear drive mechanism or actuator must develop sufficient force to open the damper door against the maximum static pressure differential that the fan can develop. This pressure can be obtained from fan performance curves. Limit switches start and stop the gear-motor drive or actuator at the proper position.

Fan isolation and ventilation dampers placed in other than vertical ducts should have multiblade louvers. These dampers usually consist of a rugged channel frame, the flanges of which are bolted to the flanges of the fan, duct, wall, or floor opening. Damper blades are assembled with shafts that turn in bearings mounted on the outside of the channel frame. This arrangement requires access outside the duct for bearing and shaft lubrication, maintenance, and space for linkages to operate. Multiple-blade dampers should have blade edge and/or end seals to meet the air leakage requirements for the application.

The trapdoor-type damper, if properly fabricated, is inherently a low leakage design due to its mass and the overlap at its edges. Multiblade dampers can also be of a low leakage design, but they must be carefully constructed to ensure tightness on closing. The pressure drop across a fully opened damper and the leakage rate across a fully closed damper should be verified by the appropriate test procedure in AMCA *Standard* 500. A damper that leaks excessively under pressure can cause the fan to rotate counter to its power rotation, thus making restarting dangerous and possibly damaging the fans' drive motor.

Actuators and Accessory Selections

Tunnel damper specifications typically call for dampers, actuators and accessories to meet the operational requirements of the **emergency ventilation fans** described by NFPA *Standard* 130. Damper actuators are also normally specified to be electric or pneumatic. This requirement is determined by the designer or the customer and is, in most cases, decided by the available power or the initial and/or long term operating cost.

Pneumatic Actuators. Pneumatic actuators are available in many designs and sizes. Rack and pinion, air cylinder, or Scotch yoke configurations are common. They can all be supplied in a double-acting (air supplied to operate the damper in both directions) or a spring-return construction. A spring-return design uses air to power it in one direction and a spring to drive it in the opposite direction. The spring return is selected when it is desirable to have the damper fail to the open or closed position upon a loss of air supply. Many manufacturers make pneumatic actuators, and several manufacture both double-acting and spring-return designs capable of operating at 250°C for one hour.

Electric Actuators. Electric actuators are also available in a variety of designs and sizes. They can be supplied to be powered in both directions to open and close the damper. In this case, the actuator usually fails in its last position upon loss of power. Electric actuators are also available that are powered in one direction and spring driven in the opposite direction. As with the pneumatic design, the spring return is selected when it is desirable to have the damper fail to the open or closed position upon a loss of power. There are fewer electric than pneumatic actuator manufacturers and most of them do not market a spring-return design, especially in the larger torque models. Also, very few electric actuators are manufactured that are capable of operating at 250°C for one hour—particularly for the spring-return designs.

Actuator Selection. Actuators for tunnel dampers are typically sized to operate against the maximum flow or velocity and pressure conditions that will occur in the worst case scenario. The maximum air velocity corresponds to the maximum flow that is expected to go through the damper during any of its operating conditions. That flow can occur during normal operation or during an emergency. Additionally, this flow could come from more than one fan depending on the design. The maximum pressure that the damper will see during normal or emergency ventilation is typically the maximum pressure that the fan can generate at shutoff.

Additionally, actuators are sized (1) to overcome the frictional resistance of blade bearings, linkage pivots, jackshafting assemblies, etc. and (2) to compress the blade and jamb seals to meet the specified leakage requirements. Thus, in order to properly select the actuator, the specifying engineer must determine what the maximum flow or velocity and pressure conditions will be, as well as the leakage criteria.

Safety factors, regarding actuator selection, are not always addressed in tunnel damper specifications. This could result in potential operational problems if a manufacturer were to select his actuators close to the operating torque required. These dampers are expected to function for many years and in some cases are not maintained as frequently as they should be. Additionally, damper manufacturers determine their torque requirements based on square, plumb, and true installations. All of these factors, plus the fact that dirt and debris buildup can increase damper torque, suggests that a minimum safety factor of at least 50% should be specified. Greater safety factors can be specified for some applications; however, larger actuators require larger drive shafts, which results in a higher initial cost.

Supply Air Intake

Supply air intakes require careful design to ensure that the quality of air drawn into the system is the best available. Such factors as recirculation of exhaust air or intake of contaminants from nearby sources should be considered.

Louvers or grilles are usually installed over air intakes for aesthetic, security, or safety reasons. Bird screens are also necessary if openings between louver blades or grilles are large enough to allow birds to enter.

Due to the large air volume required in some ventilation systems, it may not be possible for intake louvers to have sufficiently low face velocities to be weatherproof. Therefore, intake plenums, shafts, fan rooms, and fan housings need water drains. Blowing snow can also fill the fan room or plenum, but this snow usually does not stop the ventilation system from operating satisfactorily if additional floor drains are located in the area of the louvers.

Noise elimination devices may have to be installed in fresh air intakes to keep fan and air noise from disturbing the outside environment. If sound reduction is required, the total system—fan, fan plenum, building, fan housing, and air intake (location and size)—should be investigated. Fan selection should also be based on a total system, including the pressure drop that results from sound attenuation devices.

Exhaust Outlets

Exhaust air should be discharged away from the street level and away from areas with human occupancy. Contaminant concentrations in the exhaust air are not of concern if the system is working effectively. However, odors and entrained particulate matter make this air undesirable in occupied areas. Exhaust stack discharge velocity should be high enough to disperse contaminants into the atmosphere. A minimum of 10 m/s is usually necessary.

In the past, evasé (flared) outlets were used to regain some static pressure and thereby reduce the energy consumption of the exhaust fan. Unless the fan discharge velocity is in excess of 10 m/s, however, the energy saving may not offset the cost of the evasé.

In a vertical or near-vertical exhaust fan discharge connection to an exhaust duct or shaft, rainwater will run down the inside of the stack into the fan. This water will dissolve material deposited from vehicle exhausts on the inner surface of the stack and become extremely corrosive. Therefore, fan housing should be made of a corrosion-resistant material or specially coated to protect the metal from corrosion.

Discharge louvers and gratings should be sized and located so that their discharge is not objectionable to pedestrians or contaminate intake air louvers; at the same time, the air resistance across the louver or grating should be minimized. Discharge velocities through sidewalk gratings are usually limited to 2.5 m/s. Bird screens should be provided if the exhaust air is not continuous (24 h, 7 days a week) and the openings between the louver blades are large enough to allow birds to enter.

The corrosion-resistant characteristics of the louver or grating should be determined by the corrosiveness of the exhaust air and the installation environment. The pressure drop across the louvers should be verified by the appropriate test procedure in AMCA *Standard* 500.

MODERN laboratories require regulated temperature, humidity, relative static pressure, air motion, air cleanliness, sound, and exhaust. This chapter addresses biological, chemical, animal, and physical laboratories. Within these generic categories, some laboratories have unique requirements. This chapter provides an overview of the heating, ventilating, and air-conditioning (HVAC) characteristics and design criteria for laboratories, including a brief overview of architectural and utility concerns. This chapter does not cover pilot plants, which are essentially small manufacturing units.

The function of a laboratory is important in determining the appropriate HVAC system selection and design. Air-handling, hydronic, control, life safety, and heating and cooling systems must function as a unit and not as independent systems. HVAC systems must conform to applicable safety and environmental regulations.

Providing a safe environment for all personnel is a primary objective in the design of HVAC systems for laboratories. A vast amount of information is available, and HVAC engineers must study the subject thoroughly to understand all the factors that relate to proper and optimum design. This chapter serves only as an introduction to the topic of laboratory HVAC design.

HVAC systems must integrate with architectural planning and design, electrical systems, structural systems, other utility systems, and the functional requirements of the laboratory. The HVAC engineer, then, is a member of a team that includes other facility designers, users, industrial hygienists, safety officers, operators, and maintenance staff. Decisions or recommendations by the HVAC engineer may significantly affect construction, operation, and maintenance costs.

Laboratories frequently use 100% outside air, which broadens the range of conditions to which the systems must respond. They seldom operate at maximum design conditions, so the HVAC engineer must pay particular attention to partial load operations that are continually changing due to variations in internal space loads, exhaust requirements, external conditions, and day-night variances.

Most laboratories will be modified at some time. Consequently, the HVAC engineer must consider to what extent laboratory systems should be adaptable for other needs. Both economics and integration of the systems with the rest of the facility must be considered.

The preparation of this chapter is assigned to TC 9.10, Laboratory Systems.

LABORATORY TYPES

Laboratories can be divided into the following generic types:

- **Biological laboratories** are those that contain biologically active materials or involve the chemical manipulation of these materials. This includes laboratories that support such disciplines as biochemistry, microbiology, cell biology, biotechnology, immunology, botany, pharmacology, and toxicology. Both chemical fume hoods and biological safety cabinets are commonly installed in biological laboratories.
- **Chemical laboratories** support both organic and inorganic synthesis and analytical functions. They may also include laboratories in the material and electronic sciences. Chemical laboratories commonly contain a number of fume hoods.
- **Animal laboratories** are areas for manipulation, surgical modification, and pharmacological observation of laboratory animals. They also include animal holding rooms, which are similar to laboratories in many of the performance requirements but have an additional subset of requirements.
- **Physical laboratories** are spaces associated with physics; they commonly incorporate lasers, optics, nuclear material, high- and low-temperature material, electronics, and analytical instruments.

HAZARD ASSESSMENT

Laboratory operations potentially involve some hazard; nearly all laboratories contain some type of hazardous materials. A comprehensive hazard assessment, which must be completed before the laboratory can be designed, should be performed by the owner's designated **safety officers**. They include, but are not limited to, the chemical hygiene officer, radiation safety officer, biological safety officer, and fire and loss prevention official. The hazard assessment should be incorporated into the chemical hygiene plan, radiation safety plan, and biological safety protocols.

Hazard study methods such as hazard and operability analysis (HAZOP) can be used to evaluate design concepts and certify that the HVAC design conforms to the applicable safety plans. The nature and quantity of the contaminant, types of operations, and degree of hazard dictate the types of containment and local exhaust devices. For functional convenience, operations posing less hazard potential are conducted in devices that use directional airflows for personnel protection (e.g., laboratory fume hoods and biological safety cabinets). However, these devices do not provide absolute containment. Operations having a significant hazard potential are conducted in devices that provide greater protection but are more restrictive (e.g., sealed glove boxes).

The design team should visit similar laboratories to assess successful design approaches and safe operating practices. Each laboratory is somewhat different. Its design must be evaluated using appropriate, current standards and practices rather than duplicating existing and possibly outmoded facilities.

Other regulations and guidelines may apply to laboratory design. All applicable institutional, local, state, and federal requirements should be identified prior to the start of design.

DESIGN PARAMETERS

The following design parameters must be established for a laboratory space:

- Temperature and humidity, both indoor and outdoor
- Air quality from both process and safety perspectives, including the need for air filtration and special treatment (e.g., charcoal, HEPA, or other filtration of supply or exhaust air)
- Equipment and process heat gains, both sensible and latent
- Minimum ventilation rates
- Equipment and process exhaust quantities
- Exhaust and air intake locations
- Style of the exhaust device, capture velocities, and usage factors
- Need for standby equipment and emergency power
- Alarm requirements
- Potential changes in the size and number of fume hoods
- Anticipated increases in internal loads
- Room pressurization requirements

It is important to (1) review design parameters with the safety officers and scientific staff, (2) determine limits that should not be exceeded, and (3) establish the desirable operating conditions. For areas requiring variable temperature or humidity, these parameters must be carefully reviewed with the users to establish a clear understanding of expected operating conditions and system performance.

Because laboratory HVAC systems often incorporate 100% outside air systems, the selection of design parameters has a substantial effect on capacity, first cost, and operating costs. The selection of proper and prudent design conditions is very important.

Internal Thermal Considerations

In addition to the heat gain from people and lighting, laboratories frequently have significant sensible and latent loads from equipment and processes. Often, data for equipment used in laboratories is unavailable or the equipment has been custom built. Heat release from animals that may be housed in the space can be found in Chapter 10 of the 1997 *ASHRAE Handbook—Fundamentals* and in Alereza and Breen (1984).

Careful review of the equipment to be used, a detailed understanding of how the laboratory will be used, and prudent judgment are required to obtain good estimates of the heat gains in a laboratory. The convective portion of heat released from equipment located within exhaust devices can be discounted. Heat from equipment that is directly vented or heat from water-cooled equipment should not be considered part of the heat released to the room. Any unconditioned makeup air that is not directly captured by an exhaust device must be included in the load calculation for the room. In many cases, additional equipment will be obtained by the time a laboratory facility has been designed and constructed. The design should allow for this additional equipment.

Internal load as measured in watts per square metre is the average continuous internal thermal load discharged into the space. It is not a tabulation of the connected electrical load because it is rare for all equipment to operate simultaneously, and most devices operate with a duty cycle that keeps the average electrical draw below the nameplate information. When tabulating the internal sensible heat load in a laboratory, the duty cycle of the equipment should be obtained from the manufacturer. This information, combined with the nameplate data for the item, may provide a more accurate assessment of the average thermal load.

The HVAC system designer should evaluate equipment nameplate ratings, applicable use and usage factors, and overall diversity. Much laboratory equipment includes computers, automation, sample changing, or robotics; this can result in high levels of use even during unoccupied periods. The HVAC designer must evaluate internal heat loads under all anticipated laboratory operating modes. Due to highly variable equipment heat gain, individual laboratories should have dedicated temperature controls.

Two cases encountered frequently are (1) building programs based on generic laboratory modules and (2) laboratory spaces that are to be highly flexible and adaptive. Both situations require the design team to establish heat gain on an area basis. The values for area-based heat gain vary substantially for different types of laboratories. Heat gains of 50 to 270 W/m^2 or more are common for laboratories with high concentrations of equipment.

Architectural Considerations

The integration of utility systems into the architectural planning, design, and detailing is essential to providing successful research facilities. The architect and the HVAC system engineer must seek an early understanding of each other's requirements and develop integrated solutions. HVAC systems may fail to perform properly if the architectural requirements are not addressed correctly. Quality assurance of the installation is just as important as proper specifications. The following play key roles in the design of research facilities:

Modular Planning. Most laboratory programming and planning is based on developing a module that becomes the base building block for the floor plan. Laboratory planning modules are frequently 3 to 3.6 m wide and 6 to 9 m deep. The laboratory modules may be developed as single work areas or combined to form multiple-station work areas. Utility systems should be arranged to reflect

the architectural planning module, with services provided for each module or pair of modules, as appropriate.

Development of Laboratory Units. National Fire Protection Association (NFPA) *Standard* 45 requires that laboratory units be designated. Similarly, the International, Uniform, and Building Officials and Code Administrators International (BOCA) model codes require the development of control areas. Laboratory units or control areas should be developed, and the appropriate hazard levels should be determined early in the design process. The HVAC designer should review the requirements for maintaining separations between laboratories and note requirements for exhaust ductwork to serve only a single laboratory unit.

Additionally, NFPA *Standard* 45 requires that no fire dampers be installed in laboratory exhaust ductwork. Building codes offer no relief from maintaining required floor-to-floor fire separations. These criteria and the proposed solutions should be reviewed early in the design process with the appropriate building code officials. The combination of the two requirements commonly necessitates the construction of dedicated fire-rated shafts from each occupied floor to the penthouse or building roof.

Provisions for Adaptability and Flexibility. Research objectives frequently require changes in laboratory operations and programs. Thus, laboratories must be flexible and adaptable, able to accommodate these changes without significant modifications to the infrastructure. For example, the utility system design can be flexible enough to supply ample cooling to support the addition of heat-producing analytical equipment without requiring modifications to the HVAC system. Adaptable designs should allow programmatic research changes that require modifications to the laboratory's infrastructure within the limits of the individual laboratory area and/or interstitial and utility corridors. For example, an adaptable design would allow the addition of a fume hood without requiring work outside that laboratory space. The degree of flexibility and adaptability for which the laboratory HVAC system is designed should be determined from discussion with the researchers, laboratory programmer, and laboratory planner. The HVAC designer should have a clear understanding of these requirements and their financial impact.

Early Understanding of Utility Space Requirements. The amount and location of utility space are significantly more important in the design of research facilities than in that of most other buildings. The available ceiling space and the frequency of vertical distribution shafts are interdependent and can significantly affect the architectural planning. The HVAC designer must establish these parameters early, and the design must reflect these constraints. The designer should review alternate utility distribution schemes, weighing their advantages and disadvantages.

High-Quality Envelope Integrity. Laboratories that have stringent requirements for the control of temperature, humidity, relative static pressure, and background particle count generally require architectural features to allow the HVAC systems to perform properly. The building envelope may need to be designed to handle relatively high levels of humidification and slightly negative building pressure without moisture condensation in the winter or excessive infiltration. Some of the architectural features that the HVAC designer should evaluate include

- Vapor barriers—position, location, and kind
- Insulation—location, thermal resistance, and kind
- Window frames and glazing
- Caulking
- Internal partitions—their integrity in relation to air pressure, vapor barriers, and insulation value
- Finishes—vapor permeability and potential to release particles into the space
- Doors
- Air locks

Air Intakes and Exhaust Locations. Mechanical equipment rooms and their air intakes and exhaust stacks must be located to avoid intake of fumes into the building. As with other buildings, air intake locations must be chosen to minimize fumes from loading docks, cooling tower discharge, vehicular traffic, etc.

LABORATORY EXHAUST AND CONTAINMENT DEVICES

FUME HOODS

The Scientific Equipment and Furniture Association (SEFA 1996) defines a laboratory fume hood as "a ventilated enclosed work space intended to capture, contain, and exhaust fumes, vapors, and particulate matter generated inside the enclosure. It consists basically of side, back and top enclosure panels, a floor or counter top, an access opening called the face, a sash(es), and an exhaust plenum equipped with a baffle system for airflow distribution." Figure 1 shows the basic elements of a general-purpose benchtop fume hood.

Fume hoods may be equipped with a variety of accessories, including internal lights, service outlets, sinks, air bypass openings, airfoil entry devices, flow alarms, special linings, ventilated base storage units, and exhaust filters. Undercounter cabinets for storage of flammable materials require special attention to ensure safe installation. NFPA *Standard* 30, *Flammable and Combustible Liquids Code*, does not recommend venting these cabinets; however, ventilation is often required to avoid accumulation of toxic or hazardous vapors. Ventilation of these cabinets by a separately ducted supply and exhaust that will maintain the temperature rise of the cabinet interior within the limits defined by NFPA *Standard* 30 should be considered.

Types of Fume Hoods

The following are the primary types of fume hoods and their applications:

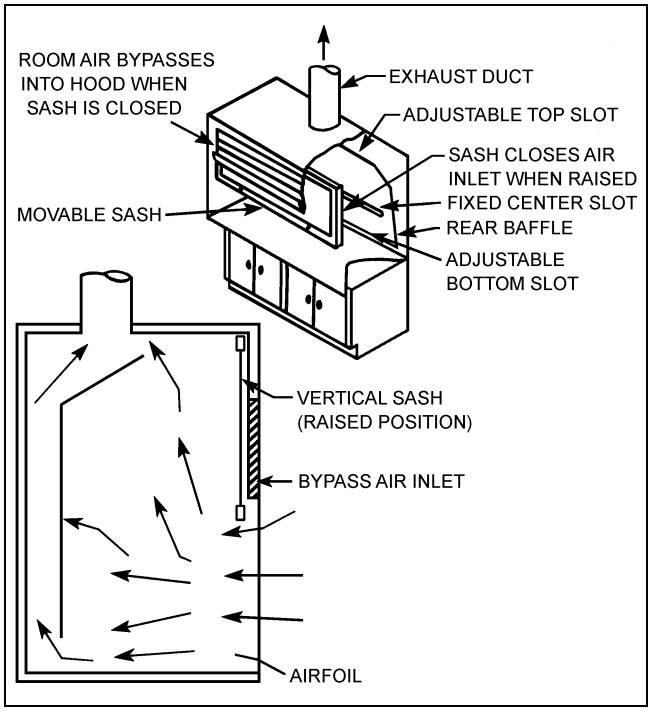

Fig. 1 Bypass Fume Hood with Vertical Sash and Bypass Air Inlet

Standard (approximately constant volume airflow with variable face velocity). Hood that meets basic SEFA definition. Sash may be vertical, horizontal, or combination type.

Application: Research laboratories—frequent or continuous use. Moderate to highly hazardous processes; varying procedures.

Bypass (approximately constant volume airflow with approximately constant face velocity). Standard vertical sash hood modified with openings above and below the sash. The openings are sized to minimize the change in the face velocity, which is generally to 3 or 4 times the full-open velocity, as the sash is lowered.

Application: Research laboratories—frequent or continuous use. Moderate to highly hazardous processes; varying procedures.

Variable Volume (constant face velocity). Hood has an opening or bypass designed to provide a prescribed minimum air intake when the sash is closed and an exhaust system designed to vary airflow in accordance with sash opening. Sash may be vertical, horizontal, or a combination of both.

Application: Research laboratories—frequent or continuous use. Moderate to highly hazardous processes; varying procedures.

Auxiliary Air (approximately constant volume airflow with approximately constant face velocity). A plenum above the face receives air from a secondary air supply that provides partially conditioned or unconditioned outside air.

Application: Research laboratories—frequent or continuous use. Moderate to highly hazardous processes; varying procedures.

Note: Many organizations restrict the use of this type of hood.

Process (approximately constant volume airflow with approximately constant face velocity). Standard hood without a sash. By some definitions, this is not a fume hood. Considered a ventilated enclosure.

Application: Process laboratories—intermittent use. Low-hazard processes; known procedures.

Radioisotope. Standard hood with special integral work surface, linings impermeable to radioactive materials, and structure strong enough to support lead shielding bricks. The interior must be constructed to prevent radioactive material buildup and allow complete cleaning. The ductwork should have flanged neoprene gasketed joints with quick disconnect fasteners that can be readily dismantled for decontamination. High-efficiency particulate air (HEPA) and/or charcoal filters may be needed in the exhaust duct.

Application: Process and research laboratories using radioactive isotopes.

Perchloric Acid. Standard hood with special integral work surfaces, coved corners, and nonorganic lining materials. Perchloric acid is an extremely active oxidizing agent. Its vapors can form unstable deposits in the ductwork that present a potential explosion hazard. To alleviate this hazard, the exhaust system must be equipped with an internal water washdown and drainage system, and the ductwork must be constructed of smooth, impervious, cleanable materials that are resistant to acid attack. The internal washdown system must completely flush the ductwork, exhaust fan, discharge stack, and fume hood inner surfaces. The ductwork should be kept as short as possible with minimum elbows. Perchloric acid exhaust systems with longer duct runs may need a zoned washdown system to avoid water flow rates in excess of the capacity to drain the water from the hood. Because perchloric acid is an extremely active oxidizing agent, organic materials should not be used in the exhaust system in places such as joints and gaskets. Ducts should be constructed of a stainless steel material, with a chromium and nickel content not less than that of 316 stainless steel, or of a suitable nonmetallic material. Joints should be welded and ground smooth. A perchloric acid exhaust system should only be used for work involving perchloric acid.

Application: Process and research laboratories using perchloric acid. Mandatory use because of explosion hazard.

California. Special hood with sash openings on multiple sides (usually horizontal).

Application: For enclosing large and complex research apparatus that require access from two or more sides.

Walk-In. Standard hood with sash openings to the floor. Sash can be either horizontal or vertical.

Application: For enclosing large or complex research apparatus. Not designed for personnel to enter while operations are in progress.

Distillation. Standard fume hood with extra depth and 1/3- to 1/2-height benches.

Application: Research laboratory. For enclosing tall distillation apparatus.

Canopy. An open hood with an overhead capture structure.

Application: Not a true fume hood. Useful for heat or water vapor removal from some work areas. Not to be substituted for a fume hood. Not recommended when workers must bend over the source of heat or water vapor.

Fume Hood Sash Configurations

The work opening has operable glass sash(es) for observation and shielding. A sash may be vertically operable, horizontally operable, or a combination of both. A vertically operable sash can incorporate single or multiple vertical panels. A horizontally operable sash incorporates multiple panels that slide in multiple tracks, allowing the open area to be positioned across the face of the hood. The combination of a horizontally operable sash mounted within a single vertically operable sash section allows the entire hood face to be opened for setup. Then the opening area can be limited by closing the vertical panel, with only the horizontally sliding sash sections used during experimentation. Either multiple vertical sash sections or the combination sash arrangement allow the use of larger fume hoods with limited opening areas, resulting in reduced exhaust airflow requirements. Fume hoods with vertically rising sash sections should include provisions around the sash to prevent the bypass of ceiling plenum air into the fume hood.

Fume Hood Performance

Containment of hazards in a fume hood is based on the principle that a flow of air entering at the face of the fume hood, passing through the enclosure, and exiting at the exhaust port prevents the escape of airborne contaminants from the hood into the room.

The following variables affect the performance of the fume hood:

- Face velocity
- Size of face opening
- Sash position
- Shape and configuration of entrance
- Shape of any intermediate posts
- Inside dimensions and location of work area relative to face area
- Location of service fittings inside the fume hood
- Size and number of exhaust ports
- Back baffle and exhaust plenum arrangement
- Bypass arrangement, if applicable
- Auxiliary air supply, if applicable
- Arrangement and type of replacement supply air outlets
- Air velocities near the hood
- Distance from openings to spaces outside the laboratory
- Movements of the researcher within the hood opening
- Location, size, and type of research apparatus placed in the hood
- Distance from the apparatus to the researcher's breathing zone

Air Currents. Air currents external to the fume hood can jeopardize the hood's effectiveness and expose the researcher to materials used in the hood. Detrimental air currents can be produced by

- Air supply distribution patterns in the laboratory
- Movements of the researcher
- People walking past the fume hood
- Thermal convection
- Opening of doors and windows

Caplan and Knutson (1977, 1978) conducted tests to determine the interactions between room air motion and fume hood capture velocities with respect to the spillage of contaminants into the room. Their tests indicated that the effect of room air currents is significant and of the same order of magnitude as the effect of the hood face velocity. Consequently, improper design and/or installation of the replacement air supply lowers the performance of the fume hood.

Disturbance velocities at the face of the hood should be no more than one-half and preferably one-fifth the face velocity of the hood. This is an especially critical factor in designs that use low face velocities. For example, a fume hood with a face velocity of 0.5 m/s could tolerate a maximum disturbance velocity of 0.25 m/s. If the design face velocity were 0.3 m/s, the maximum disturbance velocity would be 0.15 m/s.

To the extent possible, the fume hood should be located so that traffic flow past the hood is minimal. Also, the fume hood should be placed to avoid any air currents generated from the opening of windows and doors. To ensure the optimum placement of the fume hoods, the HVAC system designer must take an active role early in the design process.

Use of Auxiliary Air Fume Hoods. AIHA *Standard* Z9.5 discourages the use of auxiliary air fume hoods. These hoods incorporate an air supply at the fume hood to reduce the amount of room air exhausted. The following difficulties and installation criteria are associated with auxiliary air fume hoods:

- The auxiliary air supply must be introduced outside the fume hood to maintain appropriate velocities past the researcher.
- The flow pattern of the auxiliary air must not degrade the containment performance of the fume hood.
- Auxiliary air must be conditioned to avoid blowing cold air on the researcher; often the air must be cooled to maintain the required temperature and humidity within the hood.
- Auxiliary air may introduce additional heating and cooling loads in the laboratory.
- Only vertical sash may be used in the hood.
- Controls for the exhaust, auxiliary, and supply airstreams must be coordinated.
- Additional coordination of utilities during installation is required to avoid spatial conflicts caused by the additional duct system.
- Humidity control can be difficult.

Fume Hood Performance Criteria. ASHRAE *Standard* 110, Method of Testing Performance of Laboratory Fume Hoods, describes a quantitative method of determining the containment performance of a fume hood. The method requires the use of a tracer gas and instruments to measure the amount of tracer gas that enters the breathing zone of a mannequin; this simulates the containment capability of the fume hood as a researcher conducts operations in the hood.

The following tests are commonly used to judge the performance of the fume hood: (1) face velocity test, (2) flow visualization test, (3) large volume flow visualization, (4) tracer gas test, and (5) sash movement test. These tests should be performed under the following conditions:

- Usual amount of research equipment in the hood; the room air balance set
- Doors and windows in their normal positions
- Fume hood sash set in varying positions to simulate both static and dynamic performance

All fume hoods should be tested annually and their performance certified. The following descriptions partially summarize the test procedures. ASHRAE *Standard* 110 provides specific requirements and procedures.

Face Velocity Test

The desired face velocity should be determined by the safety officer and the researcher. The velocity is a balance between safe operation of the fume hood, airflow needed for the hood operation, and energy cost. Face velocity measurements are taken on a vertical/horizontal grid, with each measurement point representing not more than 0.1 m^2. The measurements should be taken with a device that is accurate in the intended operating range, and an instrument holder should be used to improve accuracy. Computerized multipoint grid measurement devices provide the greatest accuracy.

Flow Visualization

1. Swab a strip of titanium tetrachloride along both walls and the hood deck in a line parallel to the hood face and 150 mm back into the hood. *Caution*: Titanium tetrachloride forms smoke and is corrosive to the skin and extremely irritating to the eyes and respiratory system.
2. Swab a 200 mm circle on the back of the hood. Define air movement toward the face of the hood as reverse airflow and lack of movement as dead airspace.
3. Swab the work surface of the hood, being sure to swab lines around all equipment in the hood. All smoke should be carried to the back of the hood and out.
4. Test the operation of the deck airfoil bypass by running the cotton swab under the airfoil.
5. Before going to the next test, move the cotton swab around the face of the hood; if there is any outfall, the exhaust capacity test (large capacity flow visualization) should not be made.

Large Volume Flow Visualization

Appropriate measures should be taken prior to undertaking a smoke test to avoid accidental activation of the building's smoke detection system.

1. Ignite and place a smoke generator near the center of the work surface 150 mm behind the sash. Some smoke sources generate a jet of smoke that produces an unacceptably high challenge to the hood. Care is required to ensure that the generator does not disrupt the hood performance, leading to erroneous conclusions.
2. After the smoke bomb is ignited, pick it up with tongs and move it around the hood. The smoke should not be seen or smelled outside the hood.

Tracer Gas Test

1. Place the sulfur hexafluoride gas ejector in the required test locations (i.e., the center and near each side). Similarly position a mannequin with a detector in its breathing zone in the corresponding location at the hood.
2. Release the tracer gas and record measurements over a 5 min time span.
3. After testing with the mannequin is complete, remove it, traverse the hood opening with the detector probe, and record the highest measurement.

Sash Movement Test

Verify containment performance of the fume during operation of the fume hood sash as described in ASHRAE *Standard* 110.

BIOLOGICAL SAFETY CABINETS

A biological safety cabinet protects the researcher and, in some configurations, the research materials as well. Biological safety

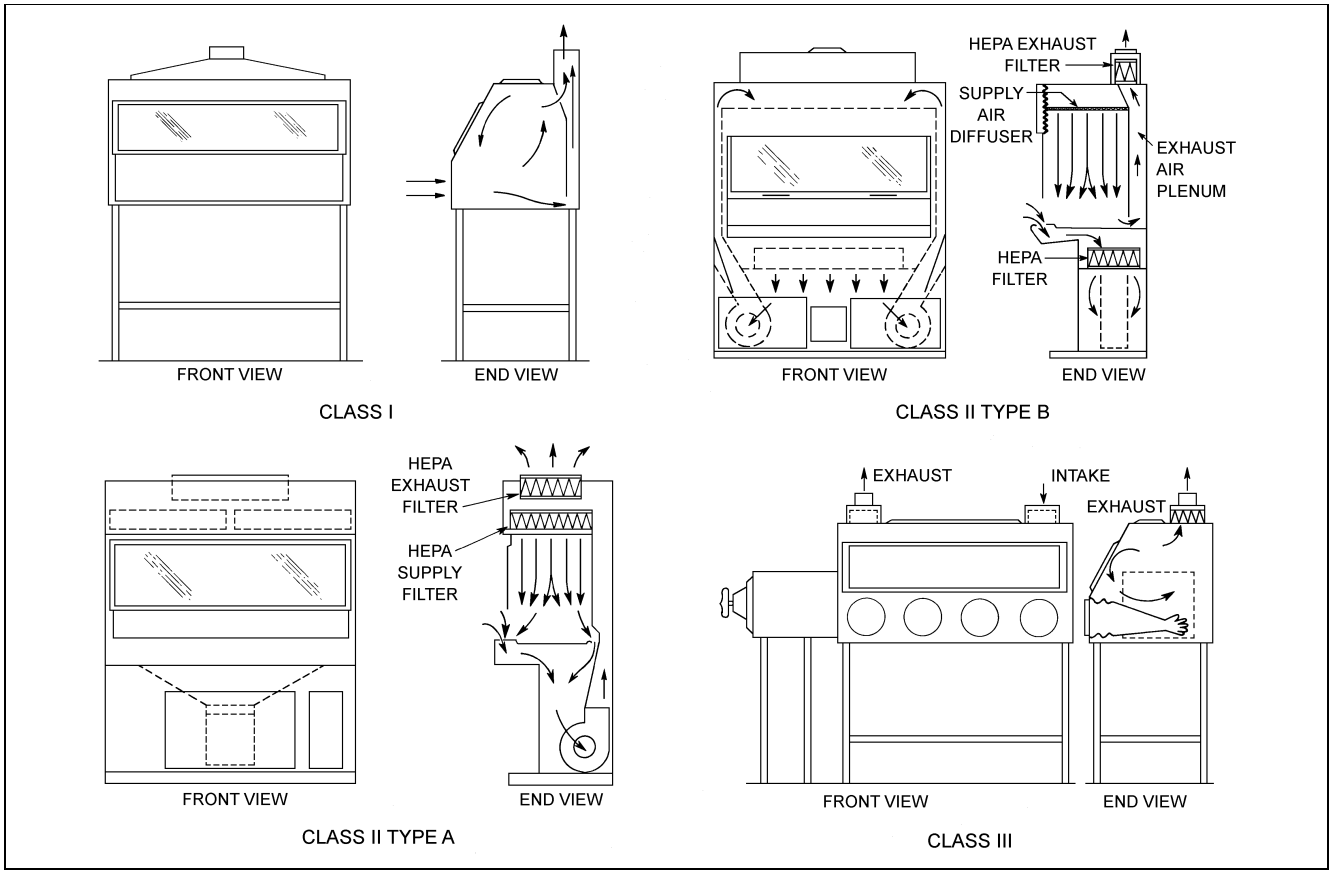

Fig. 2 Types of Biological Safety Cabinets

cabinets are sometimes called safety cabinets, ventilated safety cabinets, laminar flow cabinets, and glove boxes. Biological safety cabinets are categorized into six groups (several are shown in Figure 2):

Class I	Similar to chemical fume hood, no research material protection, 100% exhaust through a HEPA filter
Class II	
Type A	70% recirculation within the cabinet; 30% exhaust through a HEPA filter; common plenum configuration; can be recirculated into the laboratory
Type B1	30% recirculation within the cabinet; 70% exhaust through a HEPA filter; separate plenum configuration, must be exhausted to the outside
Type B2	100% exhaust through a HEPA filter to the outside
Type B3	70% recirculation within the cabinet; 30% exhaust through a HEPA filter; common plenum configuration; must be exhausted to the outside
Class III	Special applications; 100% exhaust through a HEPA filter to the outside; researcher manipulates material within cabinet through physical barriers (gloves)

Several key decisions must be made by the researcher prior to the selection of a biological safety cabinet (Eagleston 1984). An important difference in biological safety cabinets is their ability to handle chemical vapors properly (Stuart et al. 1983). Of special concern to the HVAC engineer are the proper placement of the biological safety cabinet in the laboratory and the room's air distribution. Rake (1978) concluded the following:

> "A general rule of thumb should be that, if the crossdraft or other disruptive room airflow exceeds the velocity of the air curtain at the unit's face, then problems do exist. Unfortunately, in most laboratories such disruptive room airflows are present to various extent. Drafts from open windows and doors are the most hazardous sources because they can be far in excess of 1 m/s and accompanied by substantial turbulence. Heating and air-conditioning vents perhaps pose the greatest threat to the safety cabinet because they are much less obvious and therefore seldom considered…. It is imperative then that all room airflow sources and patterns be considered before laboratory installation of a safety cabinet."

Class II biological safety cabinets should only be placed in the laboratory in compliance with NSF International *Standard* 49, Class II (Laminar Flow) Biohazard Cabinetry. Assistance in procuring, testing, and evaluating performance parameters of Class II biological safety cabinets is available from NSF as part of the standard. The cabinets should be located away from drafts, active walkways, and doors. The air distribution system should be designed to avoid air patterns that impinge on the cabinet.

The different biological safety cabinets have varying static pressure resistance requirements. Generally, Class II Type A cabinets have pressure drops ranging between 1 and 25 Pa. Class II Type B1 cabinets have pressure drops in the range of 150 to 300 Pa, and Class II Type B2 cabinets have pressure drops ranging from 370 to 570 Pa. The manufacturer must be consulted to verify specific requirements.

The pressure requirements also vary based on filter loadings and the intermittent operation of individual biological safety cabinets. Exhaust systems for biological safety cabinets must be designed with these considerations in mind. Care must be exercised when manifolding biological safety cabinet exhausts to ensure that the varying pressure requirements are met.

The manufacturer of the biological safety cabinet may be able to supply the transition to the duct system. The transition should

include an access port for testing and balancing and an airtight damper for decontamination. As with any containment ductwork, high-integrity duct fabrication and joining systems are necessary. The responsible safety officer should be consulted to determine the need for and placement of isolation dampers to facilitate decontamination operations.

Class I Cabinets

The Class I cabinet is a partial containment device designed for research operations with low- and moderate-risk etiologic agents. It does not provide protection for the materials used in the cabinet. Room air flows through a fixed opening and prevents aerosols that may be generated within the cabinet enclosure from escaping into the room. Depending on cabinet usage, air exhausted through the cabinet may be HEPA filtered prior to being discharged into the exhaust system. The fixed opening through which the researcher works is usually 200 mm high. To provide adequate personnel protection, the air velocity through the fixed opening is usually at least 0.4 m/s.

If approved by the appropriate safety officer, it is possible to modify the Class I cabinet to contain chemical carcinogens by adding appropriate exhaust air treatment and increasing the velocity through the opening to 0.5 m/s. Large pieces of research equipment can be placed in the cabinet if adequate shielding is provided.

The Class I cabinet is not appropriate for containing systems that are vulnerable to airborne contamination because the air flowing into the cabinet is untreated. Also, the Class I cabinet is not recommended for use with highly infectious agents because an interruption of the inward airflow may allow aerosolized particles to escape.

Class II Cabinets

Class II cabinets provide protection to personnel, product, and the environment. The cabinets feature an open front with inward airflow and HEPA-filtered recirculated and exhaust air.

The Class II Type A cabinet has a fixed opening with a minimum inward airflow velocity of 0.4 m/s. The average minimum downward velocity of the internal airflow is 0.4 m/s. The Class II Type A cabinet is suitable for use with agents meeting Biosafety Level 2 criteria (DHHS 1993), and, if properly certified, can meet Biosafety Level 3. However, because approximately 70% of the airflow is recirculated, the cabinet is not suitable for use with flammable, toxic, or radioactive agents.

The Class II Type B1 cabinet has a vertical sliding sash and maintains an inward airflow of 0.5 m/s at a sash opening of 200 mm. The average downward velocity of the internal airflow is 0.5 m/s. The Class II Type B1 cabinet is suitable for use with agents meeting Biosafety Level 3. Approximately 70% of the internal airflow is exhausted through HEPA filters; this allows the use of biological agents treated with limited quantities of toxic chemicals and trace amounts of radionuclides, provided the work is performed in the direct exhaust area of the cabinet.

The Class II Type B2 cabinet maintains an inward airflow velocity of 0.5 m/s through the work opening. The cabinet is 100% exhausted through HEPA filters to the outdoors; all downward velocity air is drawn from the laboratory or other supply source and is HEPA filtered prior to being introduced into the work space. The Class II Type B2 cabinet may be used for the same level of work as the Class II Type B1 cabinet. In addition, the design permits use of toxic chemicals and radionuclides in microbiological studies.

The Class II Type B3 cabinet maintains an inward airflow velocity of 0.5 m/s and is similar in performance to the Class II Type A cabinet.

In Class II Type A and Type B3 cabinets, exhaust air delivered to the outlet of the cabinet by internal blowers must be handled by the laboratory exhaust system. This arrangement requires a delicate balance between the cabinet and the laboratory's exhaust system, and it may incorporate a thimble-type connection between the cabinet and the laboratory exhaust ductwork. **Thimble (or canopy) connections** incorporate an air gap between the biological safety cabinet and the exhaust duct. The exhaust system must pull more air than is exhausted by the biological safety cabinet to make air flow in through the gap. The designer should confirm the amount of air to be drawn through the air gap. A minimum flow is required to provide the specified level of containment, and a maximum flow cannot be exceeded without causing an imbalance through aspiration.

Class II Type B1 and Type B2 cabinets rely on the building exhaust system to pull the air from the cabinet's work space and through the exhaust HEPA filters. The pressure resistance that must be overcome by the building exhaust system can be obtained from the cabinet manufacturer. Because containment in this type of cabinet depends on the building's exhaust system, the exhaust fan(s) should have redundant backups.

Class III Cabinets

The Class III cabinet is a gastight, negative pressure containment system that physically separates the agent from the worker. These cabinets provide the highest degree of personnel protection. Work is performed through arm-length rubber gloves attached to a sealed front panel. Room air is drawn into the cabinet through HEPA filters. Particulate material entrained in the exhaust air is removed by HEPA filtration or incineration before discharge to the atmosphere. A Class III system may be designed to enclose and isolate incubators, refrigerators, freezers, centrifuges, and other research equipment. Double-door autoclaves, liquid disinfectant dunk tanks, and pass boxes are used to transfer materials into and out of the cabinet.

Class III systems can contain highly infectious materials and radioactive contaminants. Although there are operational inconveniences with these cabinets, they are the equipment of choice when a high degree of personnel protection is required. It should be noted that explosions have occurred in Class III cabinets used for research involving volatile substances.

MISCELLANEOUS EXHAUST DEVICES

Snorkels are used in laboratories to remove heat or nontoxic particulates that may be generated from benchtop research equipment. Snorkels usually have funnel-shaped inlet cones connected to 75 to 150 mm diameter flexible or semiflexible ductwork extending from the ceiling to above the benchtop level.

Typically, **canopy hoods** are used to remove heat or moisture generated by a specific piece of research apparatus (e.g., steam sterilizer) or process. Canopy hoods cannot contain hazardous fumes adequately to protect the researcher.

The **laboratory**, if maintained at negative relative static pressure, provides a second level of containment, protecting occupied spaces outside of the laboratory from operations and processes undertaken therein.

LAMINAR FLOW CLEAN BENCHES

Laminar flow clean benches are available in two configurations—horizontal (crossflow) and vertical (downflow). Both configurations filter the supply air and usually discharge the air out the front opening into the room. Clean benches protect the experiment or product but do not protect the researcher; therefore, they should not be used with any potentially hazardous or allergenic substances. Clean benches are not recommended for any work involving hazardous biological, chemical, or radionuclide materials.

COMPRESSED GAS STORAGE AND VENTILATION

Gas Cylinder Closets

Most laboratory buildings require storage closets for cylinders of compressed gases, which may be inert, flammable, toxic, corrosive, or poisonous. The requirements for storage and ventilation are covered in building codes and NFPA standards and codes (NFPA 15, 30, 45, 50A, 55, 58, 70, and 90A). Water sprinklers are usually required, but other types of fire suppression may be needed based on the gases stored. Explosion containment requires a separate structural study, and closets generally require an outside wall for venting. One design used by a large chemical manufacturer to house gases with explosion potential specifies a completely welded 6 mm steel inner liner for the closet, heavy-duty door latches designed to hold under the force of an internal explosion, and venting out the top of the closet.

The closet temperature should not exceed 52°C per NFPA *Standard* 55. Ventilation for cylinder storage is established in NFPA *Standard* 55 at a minimum of 55 L/(s · m^2). Ventilation rates can be calculated by determining both the amount of gas that could be released by complete failure of the cylinder outlet piping connection and the time the release would take, and then finding the dilution airflow required to reduce any hazard below the maximum allowable limit. Design principles for biohazardous materials may be different than for chemical hazards. An investigation for biohazard containment can start with NFPA *Standard* 99, Health Care Facilities.

Ventilation air is usually exhausted from the closet; makeup air comes from the surrounding space through openings in and around the door or through a transfer duct. That makeup air must be added into the building air balance. Ventilation for a closet to contain materials with explosion potential must be carefully designed, with safety considerations taken into account. NFPA *Standard* 68 is a reference on explosion venting.

Cylinder closet exhausts should be connected through a separate duct system to a dedicated exhaust fan or to a manifold system in which constant volume can be maintained under any possible manifold condition. A standby source of emergency power should be considered for the exhaust system fan(s).

Gas Cylinder Cabinets

Compressed gases that present a physical or health hazard are often placed in premanufactured gas cylinder cabinets. Gas cylinder cabinets are available for single-, dual-, or triple-cylinder configurations and are commonly equipped with valve manifolds, fire sprinklers, exhaust connections, access openings, and operational and safety controls. The engineer must fully understand safety, material, and purity requirements associated with specific compressed gases when designing and selecting cylinder cabinets and the components that make up the compressed gas handling system.

Exhaust from the gas cylinder cabinets is provided at a high rate. Air is drawn into the gas cylinder cabinet from the surrounding space through a filtered opening, usually on the lower front of the cylinder cabinet. Depending on the specific gas in the cabinet, the exhaust system may require emission control equipment and a source of emergency power.

LABORATORY VENTILATION SYSTEMS

The total airflow rate for a laboratory is dictated by one of the following:

1. Total amount of exhaust from containment and exhaust devices
2. Cooling required to offset internal heat gains
3. Minimum ventilation rate requirements

Fume hood exhaust requirements (including evaluation of alternate sash configurations as described in the section on Fume Hoods) must be determined in consultation with the safety officers. The HVAC engineer must determine the expected heat gains from the research equipment after consulting with the research staff (see the section on Internal Thermal Considerations).

Minimum airflow rates are generally in the range of 6 to 10 air changes per hour when the space is occupied; however, some spaces (e.g., animal holding areas) may have minimum airflow rates established by specific standards or by internal facility policies. For example, the National Institutes of Health (NIH 1996a, 1996b) recommend a minimum of 6 air changes per hour for occupied laboratories but a minimum of 15 air changes per hour for animal housing and treatment areas. The maximum airflow rate for the laboratory should be reviewed to ensure that appropriate supply air delivery methods are chosen such that supply airflows do not impede the performance of the exhaust devices.

Laboratory ventilation systems can be arranged for either constant volume or variable volume airflow. The specific type should be selected with the research staff, safety officers, and maintenance personnel. Special attention should be given to unique areas such as glass washing areas, hot and cold environmental rooms and labs, fermentation rooms, and cage washing rooms. Emergency power systems to operate the laboratory ventilation equipment should be considered based on hazard assessment or other specific requirements. Care should be taken to ensure that an adequate amount of makeup air is available whenever exhaust fans are operated on emergency power. Additional selection criteria are described in the sections on Hazard Assessment and Operation and Maintenance.

Usage Factor

In many laboratories, all hoods and safety cabinets are seldom needed at the same time. A system **usage factor** represents the maximum number of exhaust devices with sashes open or in use simultaneously. The system usage factor depends on

- Type and size of facility
- Total number of fume hoods
- Number of fume hoods per researcher
- Type of fume hood controls
- Type of laboratory ventilation systems
- Number of devices that must operate continuously due to chemical storage requirements or contamination prevention
- Number of current and projected research programs

Usage factors should be applied carefully when sizing equipment. For example, teaching laboratories may have a usage factor of 100% when occupied by students. If too low a usage factor is selected, design airflow and containment performance cannot be maintained. It is usually expensive and disruptive to add capacity to an operating laboratory's supply or exhaust system. Detailed discussions with research staff are required to ascertain maximum usage rates of exhaust devices.

Noise

Noise level in the laboratory should be considered at the beginning of the design so that noise criterion (NC) levels suitable for scientific work can be achieved. For example, at the NIH, sound levels of NC 45 (including fume hoods) are required in regularly occupied laboratories. The requirement is relaxed to NC 55 for instrument rooms. If noise criteria are not addressed as part of the design, NC levels can be 65 or greater, which is unacceptable to most occupants. Sound generated by the building HVAC equipment should be evaluated to ensure that excessive levels do not escape to the outdoors. Remedial correction of excessive sound levels can be difficult and expensive.

SUPPLY AIR SYSTEMS

Supply air systems for laboratories provide the following:

- Thermal comfort for occupants
- Minimum and maximum airflow rates
- Replacement for air exhausted through fume hoods, biological safety cabinets, or other exhaust devices
- Space pressurization control
- Environmental control to meet process or experimental criteria

The design parameters must be well defined for selection, sizing, and layout of the supply air system. Installation and setup should be verified as part of the commissioning process. Design parameters are covered in the section on Design Parameters, and commissioning is covered in the section on Commissioning.

Laboratories in which chemicals and compressed gases are used generally require nonrecirculating or 100% outside air supply systems. The selection of 100% outside air supply systems versus return air systems should be made as part of the hazard assessment process, which is discussed in the section on Hazard Assessment. A 100% outside air system must have a very wide range of heating and cooling capacity, which requires special design and control.

Supply air systems for laboratories include both constant volume and variable volume systems that incorporate either single-duct reheat or dual-duct configurations, with distribution through low-, medium-, or high-pressure ductwork.

Filtration

The filtration for the air supply depends on the requirements of the laboratory. Conventional chemistry and physics laboratories commonly use 85% dust spot efficient filters (ASHRAE *Standard* 52.1). Biological and biomedical laboratories usually require 85 to 95% dust spot efficient filtration. HEPA filters should be provided for spaces where research materials or animals are particularly susceptible to contamination from external sources. HEPA filtration of the supply air is necessary for such applications as environmental studies, studies involving specific pathogen-free research animals or nude mice, dust-sensitive work, and electronic assemblies. In many instances, biological safety cabinets or laminar flow clean benches (which are HEPA filtered) may be used rather than HEPA filtration for the entire laboratory.

Air Distribution

Air supplied to a laboratory must be distributed to keep temperature gradients and air currents to minimum. Air outlets (preferably nonaspirating diffusers) must not discharge into the face of a fume hood, a biological safety cabinet, or an exhaust device. Acceptable room air velocities are covered in the sections on Fume Hoods and Biological Safety Cabinets. Special techniques and diffusers are often needed to introduce the large air quantities required for a laboratory without creating disturbances at exhaust devices.

EXHAUST SYSTEMS

Laboratory exhaust systems remove air from containment devices and from the laboratory itself. The exhaust system must be controlled and coordinated with the supply air system to maintain correct pressurization. Additional information on the control of exhaust systems is included in the section on Control.

Design parameters must be well defined for selection, sizing, and layout of the exhaust air system. Installation and setup should be verified as part of the commissioning process. See the sections on Design Parameters and Commissioning.

Laboratory exhaust systems should be designed for high reliability and ease of maintenance. One method of achieving this is to provide redundant exhaust fans and to sectionalize equipment so that maintenance work may be performed on an individual exhaust fan while the system is operating. Another option is to use predictive maintenance procedures to detect problems prior to failure and to allow for scheduling shutdowns for maintenance. To the extent possible, components of exhaust systems should allow maintenance without exposing maintenance personnel to the exhaust airstream. Access to filters and the need for bag-in, bag-out filter housings should be considered during the design process.

Depending on the effluent of the processes being conducted, the exhaust airstream may require filtration, scrubbing, or other emission control to remove environmentally hazardous materials. Any need for emission control devices must be determined early in the design so that adequate space can be provided and cost implications can be recognized.

Types of Exhaust Systems

Laboratory exhaust systems can be constant volume, variable volume, or high-low volume systems with low-, medium-, or high-pressure ductwork. Each fume hood may have its own exhaust fan, or fume hoods may be manifolded and connected to central exhaust fans. Maintenance, functional requirements, and safety must be considered when selecting an exhaust system. Part of the hazard assessment analysis is to determine the appropriateness of variable volume systems and the need for individually ducted exhaust systems. Laboratories with a high hazard potential should be analyzed carefully before variable volume airflow is selected. Airflow monitoring and pressure-independent control may be required even with constant volume systems. In addition, fume hoods or other devices in which extremely hazardous or radioactive materials are used should receive special review to determine whether they should be connected to a manifolded exhaust system.

All exhaust devices installed in a laboratory are seldom used simultaneously at full capacity. This allows the HVAC engineer to conserve energy and, potentially, to reduce equipment capacities by installing a variable volume system that includes an overall system usage factor. The selection of an appropriate usage factor is discussed in the section on Usage Factor.

Manifolded Exhaust Systems. These can be classified as pressure-dependent or pressure-independent. **Pressure-dependent systems** are constant volume only and incorporate manually adjusted balancing dampers for each exhaust device. If an additional fume hood is added to a pressure-dependent exhaust system, the entire system must be rebalanced, and the speed of the exhaust fans may need to be adjusted. Because pressure-independent systems are more flexible, pressure-dependent systems are not common in current designs.

A **pressure-independent system** can be constant volume, variable volume, or a mix of the two. It incorporates pressure-independent volume regulators with each device. The system offers two advantages: (1) the flexibility to add exhaust devices without having to rebalance the entire system and (2) variable volume control.

The volume regulators can incorporate either direct measurement of the exhaust airflow rate or positioning of a calibrated pressure-independent air valve. The input to the volume regulator can be (1) a manual or timed switch to index the fume hood airflow from minimum to operational airflow, (2) sash position sensors, or (3) fume hood cabinet pressure sensors. The section on Control covers this topic in greater detail. Running many exhaust devices into the manifold of a common exhaust system offers the following benefits:

- Lower ductwork cost
- Fewer pieces of equipment to operate and maintain
- Fewer roof penetrations and exhaust stacks
- Opportunity for energy recovery
- Centralized locations for exhaust discharge
- Ability to take advantage of exhaust system diversity
- Ability to provide a redundant exhaust system by adding one spare fan per manifold

Individually Ducted Exhaust Systems. These comprise a separate duct, exhaust fan, and discharge stack for each exhaust device or laboratory. The exhaust fan can be single-speed, multiple-speed, or variable-speed and can be configured for constant volume, variable volume, or a combination of the two. An individually ducted exhaust system has the following potential benefits:

- Provision for installation of special exhaust filtration or treatment systems
- Customized ductwork and exhaust fan corrosion control for specific applications
- Provision for selected emergency power backup
- Simpler initial balancing

Maintaining correct flow at each exhaust fan requires (1) periodic maintenance and balancing and (2) consideration of the flow rates with the fume hood sash in different positions. One problem encountered with individually ducted exhaust systems occurs when an exhaust fan is shut down. In this case, air is drawn in reverse flow through the exhaust ductwork into the laboratory because the laboratory is maintained at a negative pressure.

A challenge in designing independently ducted exhaust systems for multistory buildings is to provide extra vertical ductwork, extra space, and other provisions for the future installation of additional exhaust devices. In multistory buildings, dedicated fire-rated shafts are required from each floor to the penthouse or roof level. As a result, individually ducted exhaust systems (or vertically manifolded systems) consume greater floor space than horizontally manifolded systems. However, less height between floors may be required.

Ductwork Leakage

Ductwork should have low leakage rates and should be tested to confirm that the specified leakage rates have been attained. Leaks from positive pressure exhaust ductwork can contaminate the building, so they must be kept to a minimum. Designs that minimize the amount of positive-pressure ductwork are desirable. All positive-pressure ductwork should be of the highest possible integrity. The fan discharge should connect directly to the vertical discharge stack. Careful selection and proper installation of airtight flexible connectors at the exhaust fans are essential, including providing flexible connectors on the exhaust fan inlet only. Flexible connectors are not used on the discharge side of the exhaust fan because a connector failure could result in the leakage of hazardous fumes into the equipment room. Machine rooms that house exhaust fans should be ventilated to minimize exposure to exhaust effluent (e.g., leakage from the shaft openings of exhaust fans).

The leakage of the containment devices themselves must also be considered. For example, in vertical sash fume hoods, the clearance to allow sash movement creates an opening from the top of the fume hood into the ceiling space or area above. The air introduced through this leakage path also contributes to the exhaust airstream. The amount that such leakage sources contribute to the exhaust airflow depends on the fume hood design. Edge seals can be placed around sash tracks to minimize leaks. Although the volumetric flow of air exhausted through a fume hood is based on the actual face opening, appropriate allowances for air introduced through paths other than the face opening must be included.

Materials and Construction

The selection of materials and the construction of exhaust ductwork and fans depend on the following:

- Nature of the effluents
- Ambient temperature
- Effluent temperature
- Length and arrangement of duct runs
- Constant or intermittent flow
- Flame spread and smoke developed ratings
- Duct velocities and pressures

Effluents may be classified generically as organic or inorganic chemical gases, vapors, fumes, or smoke; and qualitatively as acids, alkalis (bases), solvents, or oils. Exhaust system ducts, fans, dampers, flow sensors, and coatings are subject to (1) corrosion, which destroys metal by chemical or electrochemical action; (2) dissolution, which destroys materials such as coatings and plastics; and (3) melting, which can occur in certain plastics and coatings at elevated temperatures.

Common reagents used in laboratories include acids and bases. Common organic chemicals include acetone, ether, petroleum ether, chloroform, and acetic acid. The HVAC engineer should consult with the safety officer and scientists because the specific research to be conducted determines the chemicals used and therefore the necessary duct material and construction.

The ambient temperature in the space housing the ductwork and fans affects the condensation of vapors in the exhaust system. Condensation contributes to the corrosion of metals, and the chemicals used in the laboratory may further accelerate corrosion.

Ducts are less subject to corrosion when runs are short and direct, the flow is maintained at reasonable velocities, and condensation is avoided. Horizontal ductwork may be more susceptible to corrosion if condensate accumulates in the bottom of the duct. Applications with moist airstreams (cage washers, sterilizers, etc.) may require condensate drains that are connected to process sewers.

If flow through the ductwork is intermittent, condensate may remain for longer periods because it will not be able to reevaporate into the airstream. Moisture can also condense on the outside of ductwork exhausting cold environmental rooms.

Flame spread and smoke developed ratings, which are specified by codes or insurance underwriters, must also be considered when selecting duct materials.

In determining the appropriate duct material and construction the HVAC engineer should

- Determine the types of effluents (and possibly combinations) handled by the exhaust system
- Classify effluents as either organic or inorganic, and determine whether they occur in the gaseous, vapor, or liquid state
- Classify decontamination materials
- Determine the concentration of the reagents used and the temperature of the effluents at the hood exhaust port (this may be impossible in research laboratories)
- Estimate the highest possible dew point of the effluent
- Determine the ambient temperature of the space housing the exhaust system
- Estimate the degree to which condensation may occur
- Determine whether flow will be constant or intermittent (intermittent flow conditions may be improved by adding time delays to run the exhaust system long enough to dry the duct interior prior to shutdown)
- Determine whether insulation, watertight construction, or sloped and drained ductwork are required
- Select materials and construction most suited for the application

Considerations in selecting materials include resistance to chemical attack and corrosion, reaction to condensation, flame and smoke ratings, ease of installation, ease of repair or replacement, and maintenance costs.

Appropriate materials can be selected from standard references and by consulting with manufacturers of specific materials. Materials for chemical fume exhaust systems and their characteristics include the following:

Galvanized steel. Subject to acid and alkali attack, particularly at cut edges and under wet conditions; cannot be field welded without destroying galvanization; easily formed; low in cost.

Stainless steel. Subject to acid and chloride compound attack depending on the nickel and chromium content of the alloy;

relatively high in cost. The most common stainless steel alloys used for laboratory exhaust systems are 304 and 316. Cost increases with increasing chromium and nickel content.

Asphaltum-coated steel. Resistant to acids; subject to solvent and oil attack; high flame and smoke rating; base metal vulnerable when exposed by coating imperfections and cut edges; cannot be field welded without destroying galvanization; moderate cost.

Epoxy-coated steel. Epoxy phenolic resin coatings on mild black steel can be selected for particular characteristics and applications; they have been successfully applied for both specific and general use, but no one compound is inert or resistive to all effluents. Requires sand blasting to prepare the surface for a shop-applied coating, which should be specified as pinhole-free, and field touch-up of coating imperfections or damage caused by shipment and installation; cannot be field welded without destroying coating; cost is moderate.

Polyvinyl-coated galvanized steel. Subject to corrosion at cut edges; cannot be field welded; easily formed; moderate in cost.

Fiberglass. When additional glaze coats are used, this is particularly good for acid applications, including hydrofluoric acid. May require special fire suppression provisions. Special attention to hanger types and spacing is needed to prevent damage.

Plastic materials. Have particular resistance to specific corrosive effluents; limitations include physical strength, flame spread and smoke developed rating, heat distortion, and high cost of fabrication. Special attention to hanger types and spacing is needed to prevent damage.

Borosilicate glass. For specialized systems with high exposure to certain chemicals such as chlorine.

FIRE SAFETY FOR VENTILATION SYSTEMS

Most local authorities have laws that incorporate NFPA *Standard* 45, Fire Protection for Laboratories Using Chemicals. Laboratories located in patient care buildings require fire standards based on NFPA *Standard* 99, Health Care Facilities. NFPA *Standard* 45 design criteria include the following:

Air balance. "The air pressure in the laboratory work areas shall be negative with respect to adjacent corridors and non-laboratory areas." (para 6-3.3)

Controls. "Controls and dampers…shall be of a type that, in the event of failure, will fail in an open position to assure a continuous draft." (para. 6-5.7)

Diffuser locations. "The location of air supply diffusion devices shall be chosen to avoid air currents that would adversely affect performance of laboratory hoods…" (para. 6-3.4)

Fire dampers. "Automatic fire dampers shall not be used in laboratory hood exhaust systems. Fire detection and alarm systems shall not be interlocked to automatically shut down laboratory hood exhaust fans…" (para. 6-10.3)

Hood alarms. "A flow monitor shall be installed on each new laboratory hood." (para.6-8.7.1)

"A flow monitor shall also be installed on existing hoods whenever any modifications or changes are made…" (para. 6-8.7.2)

Hood placement. "For new installations, laboratory hoods shall not be located adjacent to a single means of access or high traffic areas." (para. 6-9.2)

Recirculation. "Air exhausted from laboratory hoods or other special local exhaust systems shall not be recirculated." (para. 6-4.1)

"Air exhausted from laboratory work areas shall not pass unducted through other areas." (para. 6-4.3)

The designer should review the entire NFPA *Standard* 45 and local building codes to determine applicable requirements. Then the designer should inform the other members of the design team of their responsibilities (such as proper fume hood placement). Incorrect placement of exhaust devices is a frequent design error and a common cause of costly redesign work.

CONTROL

Laboratory controls must regulate temperature and humidity, control and monitor laboratory safety devices that protect personnel, and control and monitor secondary safety barriers used to protect the environment outside the laboratory from laboratory operations (West 1978). Reliability, redundancy, accuracy, and monitoring are important factors in controlling the lab environment. Many laboratories require precise control of temperature, humidity, and airflows; components of the control system must provide the necessary accuracy and corrosion resistance if they are exposed to corrosive environments.

Laboratory controls should provide **fail-safe operation**, which should be defined jointly with the safety officer. A fault tree can be developed to evaluate the impact of the failure of any control system component and to ensure that safe conditions are maintained.

Thermal Control

Temperature in laboratories with a constant volume air supply is generally regulated with a thermostat that controls the position of a control valve on a reheat coil in the supply air. In laboratories with a variable volume ventilation system, room exhaust device(s) are generally regulated as well. The room exhaust device(s) are modulated to handle greater airflow in the laboratory when additional cooling is needed. The exhaust device(s) may determine the total supply air quantity for the laboratory.

Most microprocessor-based laboratory control systems are able to use proportional-integral-derivative (PID) algorithms to eliminate the error between the measured temperature and the temperature set point. Anticipatory control strategies increase accuracy in temperature regulation by recognizing the increased reheat requirements associated with changes in the ventilation flow rates and adjusting the position of reheat control valves before the thermostat measures space temperature changes (Marsh 1988).

Constant Air Volume (CAV) Versus Variable Air Volume (VAV) Room Airflow Control

In the past, the only option for airflow in a laboratory setting was fixed airflow. Many laboratories used chemical fume hoods controlled by on-off switches located at the hood that significantly affected the actual air balance and airflow rate in the laboratory. Now, true CAV or VAV control can be successfully achieved. The question is which system is most appropriate for a contemporary laboratory.

Many laboratories that were considered CAV systems in the past were not truly constant. Even when the fume hoods operated continuously and were of the bypass type, considerable variations in airflow could occur. The variations in airflow resulted from

- Static pressure changes due to filter loading
- Wet or dry cooling coils
- Wear of fan belts that change fan speed
- Position of chemical fume hood sash or sashes
- Outside wind speed and direction
- Position of doors and windows

Current controls can achieve good conformance to the requirements of a CAV system, subject to normal deviations in control performance (i.e., the dead band characteristics of the controller and the hysteresis present in the control system). The same is true for VAV systems, although they are more complex.

Systems may be either uncontrolled or controlled. An uncontrolled CAV system can be designed with no automatic controls associated with airflow other than two-speed fan motors to reduce flow during unoccupied periods. These systems are balanced by

means of manual dampers and adjustable drive pulleys. They provide reasonable airflow rates relating to design values but do not provide true CAV under varying conditions, maintain constant fume hood face velocity, or maintain relative static pressures in the spaces. For laboratories that are not considered hazardous and do not have stringent safety requirements, uncontrolled CAV may be satisfactory.

For laboratories housing potentially hazardous operations (i.e., involving toxic chemicals or biological hazards), a true CAV or VAV system ensures that proper airflow and room pressure relationships are maintained at all times. A true CAV system requires volume controls on the supply and exhaust systems.

The principal advantages of a VAV system are its ability to (1) ensure that the face velocities of chemical fume hoods are maintained within a set range and (2) reduce energy use by reducing laboratory airflow. The appropriate safety officer and the users should concur with the choice of a VAV system or a CAV system with reduced airflow during unoccupied periods. Consideration should be given to providing laboratory users with the ability to reset VAV systems to full airflow volume in the event of a chemical spill. Education of the laboratory occupants in proper use of the system is essential. The engineer should recognize that the use of variable volume exhaust systems may result in higher concentrations of contaminants in the exhaust airstream, which may increase corrosion, which influences the selection of materials.

Room Pressure Control

For the laboratory to act as a secondary confinement barrier, the air pressure in the laboratory must be maintained slightly negative with respect to adjoining areas. Exceptions are sterile facilities or clean spaces that may need to be maintained at a positive pressure with respect to adjoining spaces. See Chapter 25, Nuclear Facilities, for examples of secondary containment for negative pressure control.

The common methods of room pressure control include manual balancing, direct pressure, volumetric flow tracking, and cascade control. All methods modulate the same control variable—supply airflow rate; however, each method measures a different variable.

Direct Pressure Control. This method measures the pressure differential across the room envelope and adjusts the amount of supply air into the laboratory to maintain the required differential pressure. Challenges encountered include (1) maintaining the pressure differential when the laboratory door is open, (2) finding suitable sensor locations, (3) maintaining a well-sealed laboratory envelope, and (4) obtaining and maintaining accurate pressure sensing devices. The direct pressure control arrangement requires tightly constructed and compartmentalized facilities and may require a vestibule on entry/exit doors. Engineering parameters pertinent to envelope integrity and associated flow rates are difficult to predict.

Because direct pressure control works to maintain the pressure differential, the control system automatically reacts to transient disturbances. Entry/exit doors may need a switch to disable the control system when they are open. Pressure controls recognize and compensate for unquantified disturbances such as stack effects, infiltration, and influences of other systems in the building. Expensive, complex controls are not required, but the controls must be sensitive and reliable. In noncorrosive environments, controls can support a combination of exhaust applications, and they are insensitive to minimum duct velocity conditions. Successful pressure control provides the desired directional airflow but cannot guarantee a specific volumetric flow differential.

Volumetric Flow Tracking Control. This method measures both the exhaust and supply airflows and controls the amount of supply air to maintain the desired pressure differential. Volumetric control requires that the air at each supply and exhaust point be controlled. It does not recognize or compensate for unquantified disturbances such as stack effects, infiltration, and influences of other systems in the building. Flow tracking is essentially independent of room door operation. Engineering parameters are easy to predict, and extremely tight construction is not required. Balancing is critical and must be addressed across the full operating range.

Controls may be located in corrosive and contaminated environments; however, the controls may be subject to fouling, corrosive attack, and/or loss of calibration. Flow measurement controls are sensitive to minimum duct velocity conditions. Volumetric control may not guarantee directional airflow.

Cascade Control. This method measures the pressure differential across the room envelope to reset the flow tracking differential set point. Cascade control includes the merits and problems of both direct pressure control and flow tracking control; however, first cost is greater and the control system is more complex to operate and maintain.

Fume Hood Control

Criteria for fume hood control differ depending on the type of hood. The exhaust volumetric flow is kept constant for standard, auxiliary air, and air-bypass fume hoods. In variable volume fume hoods, the exhaust flow is varied to maintain a constant face velocity. Selection of the fume hood control method should be made in consultation with the safety officer.

Constant volume fume hoods can further be split into either pressure-dependent or pressure-independent systems. Although simple in configuration, the pressure-dependent system is unable to adjust the damper position in response to any fluctuation in system pressure across the exhaust damper.

Variable volume fume hood control strategies can be grouped into two categories. The first either measures the air velocity entering a small sensor in the wall of the fume hood or determines face velocity by other techniques. The measured variable is used to infer the average face velocity based on an initial calibration. This calculated face velocity is then used to modulate the exhaust flow rate to maintain the desired face velocity.

The second category of variable volume fume hood control measures the fume hood sash opening and computes the exhaust flow requirement by multiplying the sash opening by the face velocity set point. The controller then adjusts the exhaust device (e.g., by a variable-frequency drive on the exhaust fan or a damper) to maintain the desired exhaust flow rate. The control system may measure the exhaust flow for closed-loop control, or it may use linear calibrated flow control dampers.

STACK HEIGHTS AND AIR INTAKES

Laboratory exhaust stacks should release effluent to the atmosphere without producing undesirable high concentrations at fresh air intakes, operable doors and windows, and locations on or near the building where access is uncontrolled.

Three primary factors that influence the proper disposal of effluent gases are stack/intake separation, stack height, and stack height plus momentum. Chapter 15 of the 1997 *ASHRAE Handbook—Fundamentals* covers the criteria and formulas to calculate the effects of these physical relationships. For complex buildings or buildings with unique terrain or other obstacles to the airflow around the building, either scale model wind tunnel testing or computational fluid dynamics should be considered. However, standard k-ε computational fluid dynamics methods as applied to airflow around buildings need further development (Murakami et al. 1996; Zhou and Stathopoulos 1996).

Stack/Intake Separation

Separation of the stack discharge and air intake locations allows the atmosphere to dilute the effluent. Separation is simple to calculate with the use of short to medium-height stacks; however, to achieve adequate atmospheric dilution of the effluent, greater separation than is physically possible may be required,

and the building roof near the stack will be exposed to higher concentrations of the effluent.

Stack Height

Chapter 15 of the 1997 *ASHRAE Handbook—Fundamentals* describes a geometric method to determine the stack discharge height high enough above the turbulent zone around the building that little or no effluent gas impinges on air intakes of the emitting building. The technique is conservative and generally requires tall stacks that may be visually unacceptable or fail to meet building code or zoning requirements. Also, the technique does not ensure acceptable concentrations of effluents at air intakes (e.g., if there are large releases of hazardous materials or elevated intake locations on nearby buildings). A minimum stack height of 3 m is required by AIHA *Standard* Z9.5 and is recommended by Appendix A of NFPA *Standard* 45.

Stack Height plus Momentum

To increase the effective height of the exhaust stacks, both the volumetric flow and the discharge velocity can be increased to increase the discharge momentum (Momentum Flow = Density × Volumetric Flow × Velocity). The momentum of the large vertical flow in the emergent jet lifts the plume a substantial distance above the stack top, thereby reducing the physical height of the stack and making it easier to screen from view. This technique is particularly suitable when (1) many small exhaust streams can be clustered together or manifolded prior to the exhaust fan to provide the large volumetric flow and (2) outside air can be added through automatically controlled dampers to provide constant exhaust velocity under variable load. The drawbacks to the second arrangement are the amount of energy consumed to achieve the constant high velocity and the added complexity of the controls to maintain constant flow rates. Dilution equations presented in Chapter 15 of the 1997 *ASHRAE Handbook—Fundamentals* or mathematical plume analysis (e.g., Halitsky 1989) can be used to predict the performance of this arrangement, or performance can be validated through wind tunnel testing. Current mathematical procedures tend to have a high degree of uncertainty, and the results should be judged accordingly.

Architectural Screens

Rooftop architectural screens around exhaust stacks are known to adversely affect exhaust dispersion. In general, air intakes should not be placed within the same screen enclosure as laboratory exhausts. Petersen et al. (1997) describe a method of adjusting dilution predictions of Chapter 15 of the 1997 *ASHRAE Handbook—Fundamentals* using a stack height adjustment factor, which is essentially a function of screen porosity.

Criteria for Suitable Dilution

An example criterion based on Halitsky (1988) is that the release of 7.5 L/s of pure gas through any stack in a moderate wind (5 to 30 km/h) from any direction with a near-neutral atmospheric stability (Pasquill Gifford Class C or D) must not produce concentrations exceeding 3 ppm at any air intake. This criterion is meant to simulate an accidental release such as would occur in a spill of an evaporating liquid or after the fracture of the neck of a small lecture bottle of gas in a fume hood.

The intent of this criterion is to limit the concentration of exhausted gases at the air intake locations to levels below the odor thresholds of gases released in fume hoods, excluding highly odorous gases such as mercaptans. Laboratories that use extremely hazardous substances should conduct a chemical-specific analysis based on published health limits. A more lenient limit may be justified for laboratories with low levels of chemical usage. Project-specific requirements must be developed in consultation with the safety officer.

The equations in Chapter 15 of the 1997 *ASHRAE Handbook—Fundamentals* are presented in terms of dilution, defined as the ratio of stack exit concentration to receptor concentration. The exit concentration, and therefore the dilution required to meet the criterion, varies with the total volumetric flow rate of the exhaust stack. For the above criterion with the emission of 7.5 L/s of a pure gas, a small stack with a total flow rate of 500 L/s will have an exit concentration of 7.5/500 or 15 000 ppm. A dilution of 1:5000 is needed to achieve an intake concentration of 3 ppm. A larger stack with a flow rate of 5000 L/s will have a lower exit concentration of 7.5/5000 or 1500 ppm and would need a dilution of only 1:500 to achieve the 3 ppm intake concentration.

The above criterion is preferred over a simple dilution standard because a defined release scenario (7.5 L/s) is related to a defined intake concentration (3 ppm) based on odor thresholds or health limits. A simple dilution requirement may not yield safe intake concentrations for a stack with a low flow rate.

APPLICATIONS

LABORATORY ANIMAL FACILITIES

Laboratory animals must be housed in comfortable, clean, temperature- and humidity-controlled rooms. Animal welfare must be considered in the design; the air-conditioning system must provide the microenvironment in the animal's primary enclosure or cage specified by the facility's veterinarian (Woods 1980, Besch 1975, ILAR 1996). Early detailed discussions with the veterinarian concerning airflow patterns, cage layout, and risk assessment help ensure a successful animal room HVAC design. The elimination of research variables (fluctuating temperature and humidity, drafts, and spread of airborne diseases) is another reason for a high-quality air-conditioning system. See Chapter 21 for additional information on environments for laboratory animals.

Temperature and Humidity

Due to the nature of research programs, air-conditioning design temperature and humidity control points may be required. Research animal facilities require more precise environmental control than farm animal or production facilities because variations affect the experimental results. A totally flexible system permits control of the temperature of individual rooms to within ±1 K for any set point in a range of 18 to 29°C. This flexibility requires significant capital expenditure, which can be mitigated by designing the facility for selected species and their specific requirements.

Table 1 lists dry-bulb temperatures recommended by ILAR (1996) for several common species. In the case of animals in confined spaces, the range of daily temperature fluctuations should be kept to a minimum. Relative humidity should also be controlled. ASHRAE *Standard* 62 recommends that the relative humidity in habitable spaces be maintained between 30 and 60% to minimize growth of pathogenic organisms. ILAR (1996) suggests the acceptable range of relative humidity is 30 to 70%.

Table 1 Recommended Dry-Bulb Temperatures for Common Laboratory Animals (ILAR 1996)

Animal	Temperature, °C
Mouse, rat, hamster, gerbil, guinea pig	18 to 26
Rabbit	16 to 22
Cat, dog, nonhuman primate	18 to 29
Farm animals and poultry	16 to 27

Note: The above ranges permit the scientific personnel who will use the facility to select optimum conditions (set points). The ranges do not represent acceptable fluctuation ranges.

Table 2 Heat Generated by Laboratory Animals

Species	Mass, kg	Heat Generation, Watts per Normally Active Animal		
		Sensible	Latent	Total
Mouse	0.021	0.33	0.16	0.49
Hamster	0.118	1.18	0.58	1.76
Rat	0.281	2.28	1.12	3.40
Guinea pig	0.41	2.99	1.47	4.46
Rabbit	2.46	11.49	5.66	17.15
Cat	3.00	13.35	6.58	19.93
Nonhuman primate	5.45	20.9	10.3	31.2
Dog	10.31	30.7	16.5	47.2
Dog	22.7	67.6	36.4	104

Ventilation

A guideline of 10 to 15 fresh-air changes per hour has been used for secondary enclosures for many years. Although it is effective in many settings, the guideline does not consider the range of possible heat loads; the species, size, and number of animals involved; the type of bedding or frequency of cage changing; the room dimensions; or the efficiency of air distribution from the secondary to the primary enclosure. In some situations, such a flow rate might overventilate a secondary enclosure that contains few animals and waste energy or underventilate a secondary enclosure that contains many animals and allow heat and odor to accumulate.

The air-conditioning load and flow rate for an animal room should be determined by the following factors:

- Desired animal microenvironment (Besch 1975, 1980; ILAR 1996)
- Species of animal(s)
- Animal population
- Recommended ambient temperature (Table 1)
- Heat produced by motors on specialized animal housing units (e.g., laminar flow racks or HEPA-filtered air supply units for ventilated racks)
- Heat generated by the animals (Table 2)

Additional design factors include method of animal cage ventilation; operational use of a fume hood or a biological safety cabinet during procedures such as animal cage cleaning and animal examination; airborne contaminants (generated by animals, bedding, cage cleaning, and room cleaning); and institutional animal care standards (Besch 1980, ILAR 1996). It should be noted that the ambient conditions of the animal room might not reflect the actual conditions within a specific animal cage.

Animal Heat Production

Air-conditioning systems must remove the sensible and latent heat produced by laboratory animals. The literature concerning the metabolic heat production appears to be divergent, but new data are consistent. Current recommended values are given in Table 2. These values are based on experimental results and the following formula:

$$\mathrm{ATHG} = 2.5M$$

where

ATHG = average total heat gain, W per animal
M = metabolic rate of animal, W per animal = $3.5W^{0.75}$
W = mass of animal, kg

Conditions in animal rooms must be maintained constant. This may require year-round availability of refrigeration and, in some cases, dual/standby chillers and emergency electrical power for motors and control instrumentation. Storage of critical spare parts is one alternative to the installation of a standby refrigeration system.

Design Considerations

If the entire animal facility or extensive portions of it are permanently planned for species with similar requirements, the range of individual adjustments should be reduced. Each animal room or group of rooms serving a common purpose should have separate temperature and humidity controls.

The animal facility and human occupancy areas should be conditioned separately. The human areas may use a return air HVAC system and may be shut down on weekends for energy conservation. Separation prevents exposure of personnel to biological agents, allergens, and odors present in animal rooms.

Control of air pressure in animal housing and service areas is important to ensure directional airflow. For example, quarantine, isolation, soiled equipment, and biohazard areas should be kept under negative pressure, whereas clean equipment and pathogen-free animal housing areas and research animal laboratories should be kept under positive pressure (ILAR 1996).

Supply air outlets should not cause drafts on research animals. Efficient air distribution for animal rooms is essential; this may be accomplished effectively by supplying air through ceiling outlets and exhausting air at floor level (Hessler and Moreland 1984). Supply and exhaust systems should be sized to minimize noise.

A study by Neil and Larsen (1982) showed that predesign evaluation of a full-size mock-up of the animal room and its HVAC system was a cost-effective way to select a system that distributes air to all areas of the animal-holding room. Wier (1983) describes many typical design problems and their resolutions. Room air distribution should be evaluated using ASHRAE *Standard* 113 procedures to evaluate drafts and temperature gradients.

HVAC ductwork and utility penetrations must present a minimum number of cracks in animal rooms so that all wall and ceiling surfaces can be easily cleaned. Exposed ductwork is not generally recommended; however, if constructed of 316 stainless steel in a fashion to facilitate removal for cleaning, it can provide a cost-effective alternative. Joints around diffusers, grilles, and the like should be sealed. Exhaust air grilles with 25 mm washable or disposable filters are normally used to prevent animal hair and dander from entering the ductwork.

Noise from the HVAC system and sound transmission from nearby spaces should be evaluated. Sound control methods should be used required.

Multiple cubicles animal rooms enhance the operational flexibility of the animal room (i.e., housing multiple species in the same room, quarantine, and isolation). Each cubicle should be treated as if it were a separate animal room, with air exchange/balance, temperature, and humidity control.

CONTAINMENT LABORATORIES

With the initiation of biomedical research involving recombinant DNA technology, federal guidelines on laboratory safety were published that influence design teams, researchers, and others. Containment describes safe methods for managing hazardous chemicals and infectious agents in laboratories. The three elements of containment are laboratory operational practices and procedures, safety equipment, and facility design. Thus, the HVAC design engineer helps decide two of the three containment elements during the design phase.

In the United States, the U.S. Department of Health and Human Services (DHHS), Centers for Disease Control and Prevention (CDC), and National Institutes of Health (NIH) classify biological laboratories into four levels—Biosafety Levels 1 through 4—listed in DHHS (1993).

Biosafety Level 1

Biosafety Level 1 is suitable for work involving agents of no known hazard or of minimal potential hazard to laboratory personnel

and the environment. The laboratory is not required to be separated from the general traffic patterns in the building. Work may be conducted either on an open benchtop or in a chemical fume hood. Special containment equipment is neither required nor generally used. The laboratory can be cleaned easily and contains a sink for washing hands. The federal guidelines for these laboratories contain no specific HVAC requirements, and typical college laboratories are usually acceptable. Many colleges and research institutions require directional airflow from the corridor into the laboratory, chemical fume hoods, and approximately 3 to 4 air changes per hour of outside air. Directional airflow from the corridor into the laboratory helps to control odors.

Biosafety Level 2

Biosafety Level 2 is suitable for work involving agents of moderate potential hazard to personnel and the environment. DHHS (1993) contains lists that explain the levels of containment needed for various hazardous agents. Laboratory access is limited when certain work is in progress. The laboratory can be cleaned easily and contains a sink for washing hands. Biological safety cabinets (Class I or II) are used whenever

- Procedures with a high potential for creating infectious aerosols are conducted. These include centrifuging, grinding, blending, vigorous shaking or mixing, sonic disruption, opening containers of infectious materials, inoculating animals intranasally, and harvesting infected tissues or fluids from animals or eggs.
- High concentrations or large volumes of infectious agents are used. Federal guidelines for these laboratories contain minimum facility standards.

At this level of biohazard, most research institutions have a full-time safety officer (or safety committee) who establishes facility standards. The federal guidelines for Biosafety Level 2 contain no specific HVAC requirements; however, typical HVAC design criteria can include the following:

- 100% outside air systems
- 6 to 15 air changes per hour
- Directional airflow into the laboratory rooms
- Site-specified hood face velocity at fume hoods (many institutions specify 0.4 to 0.5 m/s)
- An assessment of research equipment heat load in a room
- Inclusion of biological safety cabinets

Most biomedical research laboratories are designed for Biosafety Level 2. However, the laboratory director must evaluate the risks and determine the correct containment level before design begins.

Biosafety Level 3

Biosafety Level 3 applies to facilities in which work is done with indigenous or exotic agents that may cause serious or potentially lethal disease as a result of exposure by inhalation. The Biosafety Level 3 laboratory uses a physical barrier of two sets of self-closing doors to separate the laboratory work area from areas with unrestricted personnel access. This barrier enhances biological containment to within the laboratory work area.

The ventilation system must be single-pass, nonrecirculating and configured to maintain the laboratory at a negative pressure relative to surrounding areas. Both audible alarms and visual gages are required to notify personnel if the laboratory pressure relationship changes from a negative condition. The designer may want to have these alarms reported to a constantly monitored location.

Gastight dampers are required in the supply and exhaust ductwork to allow decontamination of the laboratory. The ductwork between these dampers and the laboratory must also be gastight. All penetrations of the Biosafety Level 3 laboratory envelope must be sealed for containment and to facilitate gaseous decontamination of the work area.

All procedures involving the manipulation of infectious materials are conducted inside biological safety cabinets. The engineer must ensure that the connection of the cabinets to the exhaust system does not adversely affect the performance of the biological safety cabinets or the exhaust system. Refer to the section on Biological Safety Cabinets for further discussion.

The exhaust air from biological safety cabinets and/or the laboratory work area may require HEPA filtration. The need for filtration should be reviewed with the appropriate safety officers. If required, HEPA filters should be equipped with provisions for bag-in, bag-out filter handling systems and gastight isolation dampers for biological decontamination of the filters.

The engineer should review with the safety officer the need for special exhaust or filtration of exhaust from any scientific equipment located in the Biosafety Level 3 laboratory.

Biosafety Level 4

Biosafety Level 4 is required for work with dangerous and exotic agents that pose a high risk of aerosol-transmitted laboratory infections and life-threatening disease. The design of HVAC systems for these areas will have stringent requirements that must be determined by the biological safety officer.

SCALE-UP LABORATORIES

Scale-up laboratories are defined differently depending on the nature and volume of work being conducted. For laboratories performing recombinant DNA research, large-scale experiments involve 10 L or more. A chemical or biological laboratory is defined as scale-up when the principal holding vessels are glass or ceramic. When the vessels are constructed primarily of metals, the laboratory is considered a pilot plant, which this chapter does not currently address.

The amount of experimental materials present in scale-up laboratories is generally significantly greater than the amount found in the small-scale laboratory. The experimental equipment is also larger and therefore requires more space. The result is larger chemical fume hoods or reaction cubicles that may be of the walk-in type. Significantly higher laboratory airflow rates are needed to maintain the face velocity of the chemical fume hoods or reaction cubicles, although their size frequently presents problems of airflow uniformity over the entire face area. Walk-in hoods are sometimes entered during an experimental run, so provisions for breathing-quality air stations and other forms of personnel protection should be considered. Environmental containment or the ability to decontaminate the laboratory, the laboratory exhaust airstream, or other effluent may be needed in the event of an upset. Scale-up laboratories are frequently airflow intensive and at times may be in operation for sustained periods.

TEACHING LABORATORIES

Laboratories in academic settings can generally be classified as those used for instruction and those used for research. Research laboratories vary significantly depending on the work being performed; they generally fit into one of the categories of laboratories described previously.

The design requirements for teaching laboratories also vary based on their function. The designer should become familiar with the specific teaching program, so that a suitable hazard assessment can be made. For example, the requirements for the number and size of fume hoods vary greatly between undergraduate inorganic and graduate organic chemistry teaching laboratories.

Unique aspects of teaching laboratories include the need of the instructor to be in visual contact with the students at their work stations and to have ready access to the controls for the

fume hood operations and any safety shutoff devices and alarms. Frequently, students have not received extensive safety instruction, so easily understood controls and labeling are necessary. Because the teaching environment depends on verbal communication, sound from the building ventilation system is an important concern.

CLINICAL LABORATORIES

Clinical laboratories are found in hospitals and as stand-alone operations. The work in these laboratories generally consists of handling human specimens (blood, urine, etc.) and using chemical reagents for analysis. Some samples may be infectious; because it is impossible to know which samples may be contaminated, good work practices require that all be handled as biohazardous materials. The primary protection of the staff at clinical laboratories depends on the techniques and laboratory equipment (e.g., biological safety cabinets) used to control aerosols, spills, or other inadvertent releases of samples and reagents. People outside the laboratory must also be protected.

Additional protection can be provided by the building HVAC system with suitable exhaust, ventilation, and filtration. The HVAC engineer is responsible for providing an HVAC system that meets the biological and chemical safety requirements. The engineer should consult with appropriate senior staff and safety professionals to ascertain what potentially hazardous chemical or biohazardous conditions will be in the facility and then provide suitable engineering controls to minimize risks to the staff and the community. The use of biological safety cabinets, chemical fume hoods, and other specific exhaust systems should be considered by appropriate laboratory staff and the design engineer.

RADIOCHEMISTRY LABORATORIES

In the United States, laboratories located in Department of Energy (DOE) facilities are governed by DOE regulations. All other laboratories using radioactive materials are governed by the Nuclear Regulatory Commission (NRC), state, and local regulations. Other agencies may be responsible for the regulation of other toxic and carcinogenic materials present in the facility.

Laboratory containment equipment for nuclear processing facilities are treated as primary, secondary, or tertiary containment zones, depending on the level of radioactivity anticipated for the area and the materials to be handled. Chapter 25 has additional information on nuclear laboratories.

OPERATION AND MAINTENANCE

Due to long-term research studies, laboratories may need to maintain design performance conditions with no interruptions for long periods. Even when research needs are not so demanding, systems that maintain air balance, temperature, and humidity in laboratories must be highly reliable, with a minimal amount of downtime. The designer should work with operation and maintenance personnel as well as users early in the design of systems to gain their input and agreement.

System components must be of adequate quality to achieve reliable HVAC operation, and they should be reasonably accessible for maintenance. Laboratory work surfaces should be protected from possible leakage of coils, pipes, and humidifiers. Changeout of supply and exhaust filters should require minimum downtime.

Centralized monitoring of laboratory variables (e.g., pressure differentials, face velocity of fume hoods, supply flows, and exhaust flows) is useful for predictive maintenance of equipment and for ensuring safe conditions.

For their safety, laboratory users should be instructed in the proper use of laboratory fume hoods, safety cabinets, ventilated enclosures, and local ventilation devices. They should be trained to understand the operation of the devices and the indicators and alarms that show whether they are safe to operate. Users should request periodic testing of the devices to ensure that they and the connected ventilation systems are operating properly.

Personnel that know the nature of the contaminants in a particular laboratory should be responsible for decontamination of equipment and ductwork before they are turned over to maintenance personnel for work.

Maintenance personnel should be trained to keep laboratory systems in good operating order and should understand the critical safety requirements of those systems. Preventive maintenance of equipment and periodic checks of air balance should be scheduled. High-maintenance items should be placed outside the actual laboratory (in service corridors or interstitial space) to reduce disruption of laboratory operations and exposure of the maintenance staff to laboratory hazards. Maintenance personnel must be aware of and trained in procedures for maintaining good indoor air quality (IAQ) in laboratories. Many IAQ problems have been traced to poor maintenance due to poor accessibility (Woods et al. 1987).

ENERGY

Due to the nature of the functions they support, laboratory HVAC systems consume large amounts of energy. Efforts to reduce energy use must not compromise the safety standards established by safety officers. Typically, HVAC systems supporting laboratories and animal areas use 100% outside air and operate continuously. All HVAC systems serving laboratories can benefit from energy reduction techniques that are either an integral part of the original design or added later. Energy reduction techniques should be analyzed in terms of both appropriateness to the facility and economic payback.

The HVAC engineer must understand and respond to the scientific requirements of the facility. Research requirements typically include continuous control of temperature, humidity, relative static pressure, and air quality. Energy reduction systems must maintain the required environmental conditions during both occupied and unoccupied modes.

Energy Conservation

Energy can be conserved in laboratories by reducing the exhaust air requirements. For example, the exhaust air requirements for fume hoods can be reduced by closing part of the hood opening during operation, thereby reducing the airflow needed to obtain the desired capture velocities (an exception is bypass hoods, which require similar quantities of exhaust air whether open or fully closed). The sash styles that may be adjusted are described in the section on Laboratory Exhaust and Containment Devices.

Another way to reduce exhaust airflow is to use variable volume control of exhaust air through the fume hoods to reduce exhaust airflow when the fume hood sash is not fully open. A variation of this arrangement incorporates user-initiated selection of the fume hood airflow from a minimum flow rate to a maximum flow rate when the hood is in use. Any airflow control must be integrated with the laboratory control system, described in the section on Control, and must not jeopardize the safety and function of the laboratory.

A third energy conservation method uses night setback controls when the laboratory is unoccupied to reduce the exhaust volume to one-quarter to one-half the minimum required when the laboratory is occupied. Timing devices, sensors, manual override, or a combination of these can be used to set back the controls at night. If this strategy is a possibility, the safety and function of the laboratory must be considered, and appropriate safety officers should be consulted.

Energy Recovery

Energy can often be recovered economically from the exhaust airstream in laboratory buildings with large quantities of exhaust air. Many energy recovery systems are available, including rotary air-to-air energy exchangers or heat wheels, coil energy recovery loops (runaround cycle), twin tower enthalpy recovery loops, heat pipe heat exchangers, fixed-plate heat exchangers, thermosiphon heat exchangers, and direct evaporative cooling. Some of these technologies can be combined with indirect evaporative cooling for further energy recovery. See Chapter 44 of the 2000 *ASHRAE Handbook—Systems and Equipment* for more information.

Concerns about the use of energy recovery devices in laboratory HVAC systems include (1) the potential for cross-contamination of chemical and biological materials from the exhaust air to the intake airstream and (2) the potential for corrosion and fouling of the devices located in the exhaust airstream. NFPA *Standard* 45 specifically prohibits the use of latent heat recovery devices in fume hood exhaust systems.

Energy recovery is also possible for hydronic systems associated with HVAC. Rejected heat from centrifugal chillers can be used to produce low-temperature reheat water. Potential also exists in plumbing systems, where waste heat from washing operations can be recovered to heat makeup water.

COMMISSIONING

In addition to HVAC systems, electrical systems and chemical handling and storage areas must be commissioned. Training of technicians, scientists, and maintenance personnel is a critical aspect of the commissioning process. Users must understand the systems and their operation.

It should be determined early in the design process whether any laboratory systems must comply with Food and Drug Administration (FDA) regulations because these systems have additional design and commissioning requirements.

Commissioning is defined in Chapter 41, and the process is outlined in ASHRAE *Guideline* 1. Laboratory commissioning is more demanding than that described in ASHRAE *Guideline* 1 because areas must be considered that are not associated with the normal office complex. Requirements for commissioning should be clearly understood by all participants, including the contractors and the owner's personnel. Roles and responsibilities should be defined, and responsibilities for documenting results should be established.

Laboratory commissioning starts with the intended use of the laboratory and should include development of a commissioning plan, as outlined in ASHRAE *Guideline* 1. The validation of individual components should come first; after individual components are successfully validated, the entire system should be evaluated. This requires verification and documentation that the design meets applicable codes and standards and that it has been constructed in accordance with the design intent. Before general commissioning begins, the following data must be obtained:

- Complete set of the laboratory utility drawings
- Definition of the use of the laboratory and an understanding of the work being performed
- Equipment requirements
- All test results
- Understanding of the intent of the system operation

For HVAC system commissioning, the following should be verified and documented:

- Fume hood design face velocities have been met.
- Manufacturer's requirements for airflows for biological safety cabinets and laminar flow clean benches have been met.
- Exhaust system configuration, damper locations, and performance characteristics, including any required emission equipment, are correct.
- Control system operates as specified. Controls include fume hood alarm; miscellaneous safety alarm systems; fume hood and other exhaust airflow regulation; laboratory pressurization control system; laboratory temperature control system; and main ventilation unit controls for supply, exhaust, and heat recovery systems. Control system performance verification should include speed of response, accuracy, repeatability, turndown, and stability.
- Desired laboratory pressurization relationships are maintained throughout the laboratory, including entrances, adjoining areas, air locks, interior rooms, and hallways. Balancing terminal devices within 10% of design requirements will not provide adequate results. Additionally, internal pressure relationships can be affected by airflow around the building itself. See Chapter 15 of the 1997 *ASHRAE Handbook—Fundamentals* for more information.
- Fume hood containment performance is within specification. ASHRAE *Standard* 110 provides criteria for this evaluation.
- Dynamic response of the laboratory's control system is satisfactory. One method of testing the control system is to open and shut laboratory doors during fume hood performance testing.
- System fault tree and failure modes are as specified.
- Standby electrical power systems function properly.
- Design noise criterion) (NC levels of occupied spaces have been met.

ECONOMICS

In laboratories, HVAC systems make up a significant part (often 30 to 50%) of the overall construction budget. The design criteria and system requirements must be reconciled with the budget allotment for HVAC early in the planning stages and continually throughout the design stages to ensure that the project remains within budget.

Every project must be evaluated on both its technical features and its economics. The following common economic terms are discussed in Chapter 35 and defined here as follows:

Initial cost. Cost to design, install, and test an HVAC system such that it is fully operational and suitable for use.

Operating cost. Cost to operate a system (including energy, maintenance, and component replacements) such that the total system can reach the end of its normal useful life.

Life-cycle cost. Cost related to the total cost over the life of the HVAC system, including capital cost, considering the time value of money.

Mechanical and electrical costs related to HVAC systems are commonly assigned a depreciation life based on current tax policies. This depreciation life may be different from the projected functional life of the equipment, which is influenced by the quality of the system components and of the maintenance they receive. Some portions of the system, such as ductwork, could last the full life of the building. Other components, such as air-handling units, may have a useful life of 15 to 30 years, depending on their original quality and ongoing maintenance efforts. Estimated service life of equipment is listed in Chapter 35.

Engineering economics can be used to evaluate life-cycle costs of configuration (utility corridor versus interstitial space), systems, and major equipment. The user or owner makes a business decision concerning quality of the system and its ongoing operating costs. The HVAC engineer may be asked to provide an objective analysis of energy, maintenance, and construction costs, so that an appropriate life-cycle cost analysis can be made. Other considerations that may be appropriate include economic influences related to the long-term use of energy and governmental laws and regulations.

Many technical considerations and the great variety of equipment available influence the design of HVAC systems. Factors affecting design must be well understood to ensure appropriate comparisons between various systems and to determine the impact on either first or operating costs.

CHAPTER 14

ENGINE TEST FACILITIES

Engine Heat Release 14.1
Engine Exhaust 14.1
Internal Combustion Engine Test Cells 14.2
Test Cell Supply 14.2
Gas-Turbine Test Cells 14.3
Chassis Dynamometer Rooms 14.3
Ventilation 14.3
Combustion Air Supply 14.4
Cooling Water Systems 14.4
Noise 14.4

INDUSTRIAL testing of turbine and internal combustion engines is performed in enclosed test spaces to control noise and isolate the test for safety or security. These spaces are ventilated or conditioned to control the facility environment and fumes. Isolated engines are tested in test cells; engines situated inside automobiles are tested on chassis dynamometers. The ventilation and safety principals for test cells also apply when large open areas in the plant are used for production testing and emissions measurements.

Enclosed test cells are normally found in research or emissions test facilities. Test cells may require instruments to measure cooling system water flow and temperature; exhaust gas flow, temperature, and emission concentrations; fuel flow; power output; and combustion air volume and temperature. Changes in the temperature and humidity of the test cell affect these measurements. Accurate control of the testing environment is becoming more critical. For example, the U.S. Environmental Protection Agency requires tests to demonstrate control of automobile contaminants in both hot and cold environments.

Air conditioning and ventilation of test cells must (1) supply and exhaust proper quantities of air to remove heat and control temperature; (2) exhaust sufficient air at proper locations to prevent buildup of combustible vapors; (3) supply and modulate large quantities of air to meet changing conditions; (4) remove exhaust fumes; (5) supply combustion air; (6) prevent noise transmission through the system; and (7) provide for human comfort and safety during setup, testing, and tear-down procedures. Supply and exhaust systems for test cells may be unitary, central, or a combination of the two. Mechanical exhaust is necessary in all cases.

ENGINE HEAT RELEASE

The special air-conditioning requirements of an engine test facility stem from the burning of the fuel used to run the engine. The heat released by an engine divides into work done, exhaust, cooling water, and radiation. For internal combustion engines at full load, 10% of the total heat content of the fuel is radiated and convected into the room or test cell atmosphere and 90% is fairly evenly divided between the shaft output (work), exhaust gas heating, and heating of the jacket cooling water.

Air-cooled engines create a forced convection load on the test space equal to the jacket water heat that it replaces. For turbine engines, the exhaust gas carries double the heat of the internal combustion engine exhaust and there is no jacket water to heat. The engine manufacturer can provide a more precise analysis of the heat release characteristics at various speeds and power outputs.

Test facilities use dynamometers to determine the power being supplied to the engine shaft. The dynamometer converts the shaft work into heat that must be accounted for by a cooling system or as heat load into the space. Often the shaft work is converted into electricity through a generator and the electric power is dissipated by a resistance load bank. Inefficiencies of the various pieces of equipment add to the load of the space in which they are located.

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

Heat released into the jacket water must also be removed. If a closely connected radiator is used, the heat load is added to the room load. Many test facilities include a heat exchanger and a secondary cooling circuit transfers the heat to a cooling tower. Some engines require an oil cooler separate from the jacket water. Whichever system is used, the cooling water flow, temperature, and pressure is usually monitored as part of the test operation and heat from these sources need to be accommodated by the facility's air conditioning.

Exhaust systems present several challenges to the design of an engine test cell. Exhaust gases can exit the engine at 800°C or higher. Commonly the exhaust gas is augmented by inserting the exhaust pipe into a larger bore exhaust system (laboratory fixed system). The exhaust gas draws room air into the exhaust to both cool the gas and ventilate the test cell. Both the exhausted room air and combustion air must be supplied to the room from the HVAC or from outside.

Radiation and convection from the exhaust pipes, catalytic converter, muffler, etc. also add to the load. In most cases the test cell HVAC system should account for an engine that can fully load the dynamometer. It should have capacity control for operation at partial load and no load conditions.

Large gas turbine engines have unique noise and airflow requirements, and as such they usually are provided with dedicated test cells. Small gas turbines can often be tested in a regular engine test cell with minor modifications.

ENGINE EXHAUST

Engine exhaust systems remove combustible products, unburned fuel vapors, and water vapor. Flow loads and the operating pressure need to be established for the design of the supporting HVAC.

Flow loads are calculated based on the number of engines, the engine sizes and loads, and the use factors or diversity.

Operating pressure is the engine discharge pressure at the connection to the exhaust. Systems may operate at positive pressure using available engine tail-pipe pressure to force the flow of gas, or at negative pressure with mechanically induced flow.

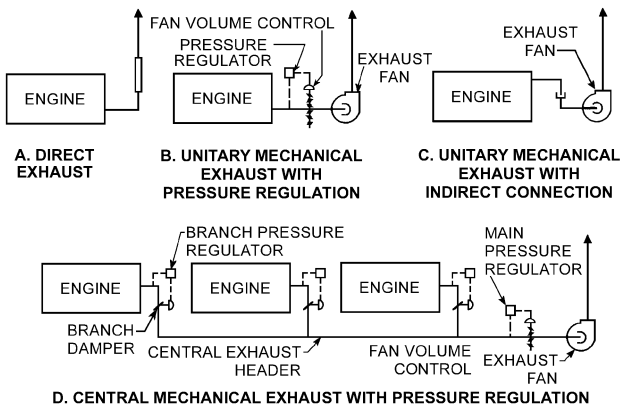

Fig. 1 Engine Exhaust Systems

The simplest way to induce engine exhaust from a test cell is to size the exhaust pipe to minimize variations in pressure on the engine and to connect it directly to the outside (Figure 1A). Exhausts directly connected to the outside are subject to wind currents and air pressure and can be hazardous due to the positive pressure in the system.

Mechanical engine exhausts are either unitary or central. A **unitary exhaust** (Figure 1B) serves only one test cell. It can be closely regulated to match the operation of the engine. A central exhaust (Figure 1D) serves multiple test cells with one or more exhaust fans and a duct system with branch connections to the individual test cells. Relief of a possible explosion in the ductwork should be considered.

Engine exhaust pressures fluctuate with changes in engine load and speed. Central exhausts should be designed so that load variations in individual test cells have a minimum effect on the system. Engine characteristics and diversity of operation determine the maximum airflow to be handled. Dampers and pressure regulators may be required to keep the pressures within test tolerances.

An indirect connection between the engine exhaust pipe and mechanical exhaust gas removal (Figure 1C) eliminate variation in back pressure and augment the exhaust gas flow by inducing room air into the exhaust stream. In this system the engine exhaust pipe terminates by being centered and inserted about 75 mm into the augmentation pipe, which is at least 25 mm larger in diameter. The induced room air is mixed with the exhaust gases yielding a much cooler exhaust flow. However, the potential for increased corrosion in a cooler exhaust must be considered when selecting the construction materials. The engine muffler should be located upstream of the augmentation connection to control noise. The indirect connection should be considered a potential point of ignition if the exhaust is fuel rich and the tail pipe reaches temperatures above 370°C.

Exhaust pipes and mufflers run very hot. A ventilated heat shield or a water jacketed pipe reduces this cell heat load and some exhausts are equipped with direct water injection. Thermal expansion, stress, and pressure fluctuations must also be considered in the design of the exhaust fan and ducting. The equipment must be adequately supported and anchored to relieve the thermal expansion.

Exhaust systems for chassis dynamometer installations must capture the high velocity exhaust from the tailpipe to prevent fume buildup in the room. An exhaust flow rate of 330 L/s has been used effectively for automobiles at a simulated speed of 100 km/h.

Engine exhaust should discharge through a stack extending above the roof to an elevation sufficient to allow the fumes to clear the building. Chapter 43, Building Air Intake and Exhaust Design, has further details about exhaust stacks. Codes or air emission standards may require that exhaust gases be cleaned prior to being discharged to atmosphere.

INTERNAL COMBUSTION ENGINE TEST CELLS

Test Cell Exhaust

Ventilation for test cells is based on exhaust requirements for (1) removal of heat generated by the engine, (2) emergency purging (removal of fumes after a fuel spill), and (3) continuous cell scavenging during nonoperating periods. Heat is transferred to the test cell by convection and radiation from all of the heated surfaces such as the engine and exhaust system. At a standard air density of $\rho = 1.2$ kg/m^3 and $c_p = 1.0$ kJ/(kg·K) the airflow is:

$$Q = \frac{q}{\rho c_p (t_e - t_s)} = \frac{q}{1.2(t_e - t_s)}$$

where

Q = airflow, m^3/s
q = engine heat release, kW
t_e = temperature of exhaust air, °C
t_s = temperature of supply air, °C

The constant (1.2) should be corrected for other temperatures and pressures.

Heat radiated from the engine, dynamometer, and exhaust piping warms the surrounding surfaces, which release the heat to the air by convection. The value for $(t_e - t_s)$ in the equation cannot be arbitrarily set when a portion of q is radiated heat. The previous section on Engine Heat Release discusses other factors required to determine the overall q.

Vapor Removal. The exhaust should remove vapors as quickly as possible. Emergency purging, often 50 L/s per square metre of floor area, should be controlled by a manual overriding switch for each test cell. In case of fire, provisions need to be made to shut down all equipment, close fire dampers at all openings, and shut off the fuel-flow solenoid valves.

Cell Scavenging. Exhaust air is the minimum amount of air required to keep combustible vapors from fuel leaks from accumulating. In general, 10 L/s per square metre of floor area is sufficient. Because gasoline vapors are heavier than air, exhaust grilles should be low even when an overhead duct is used. Exhausting close to the engine minimizes the convective heat that escapes into the cell.

In some installations, all air is exhausted through a floor grating surrounding the engine bed plate and into a cubicle or duct below. In this arrangement, slots in the ceiling over the engine supply a curtain of air to remove the heat. This scheme is particularly suitable for a central exhaust (Figure 2). Water sprays in the under-floor exhaust lessen the danger of fire or explosion in case of fuel spills.

Trenches and pits should be avoided in test cells. If they exist, as in most chassis dynamometer rooms, they should be mechanically exhausted at all times. Long trenches may require multiple exhaust takeoffs. The exhaust should sweep the entire area, leaving no dead air spaces. Because of fuel spills and vapor accumulation, suspended ceilings or basements should not be located directly below the engine test cell. If such spaces exist, they should be ventilated continuously and have no fuel lines running through them.

Table 1 lists exhaust quantities used in current practice; although the exhaust should be calculated for each test cell on the basis of heat to be removed, evaporation of possible fuel spills, and the minimum ventilation needed during downtime.

TEST CELL SUPPLY

The air supply to a test cell should be balanced to yield a slightly negative pressure. Test cell air should not be recirculated. Air taken from non-test areas can be used, provided good ventilation practices

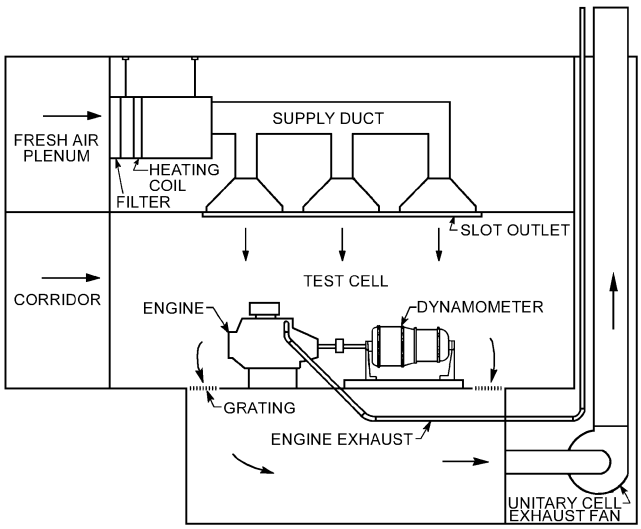

Fig. 2 Engine Test Cell Showing Direct Engine Exhaust—Unitary Ventilation System

Table 1 Exhaust Quantities for Test Cells

	Minimum Exhaust Rates per Square Metre of Floor Area	
	L/s	Air changes per h[a]
Engine testing—cell operating	50	60[b]
Cell idle	10	12
Trenches[c] and pits	50	—
Accessory testing	20	24
Control rooms and corridors	5	6

[a] Based on a cell height of 3m.
[b] For chassis dynamometer rooms, this quantity is usually set by test requirements.
[c] For large trenches, use 0.5 m/s across the cross-sectional area of the trench.

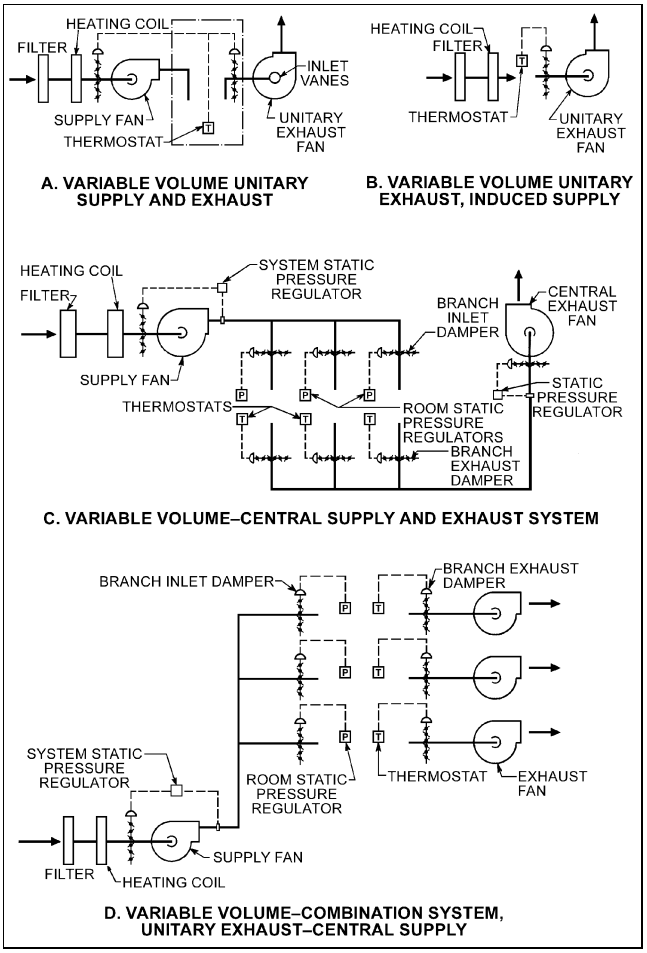

Fig. 3 Heat Removal Ventilation Systems

are followed; such as using air that is free of unacceptable contaminants and is sufficient for temperature control and can maintain the proper test cell pressure.

Ventilation air should keep the released heat from the engine away from the cell occupants. Slot outlets with automatic dampers to maintain a constant discharge velocity have been used with variable volume systems.

A variation of systems C and D in Figure 3 includes a separate air supply sized for the minimum (downtime) ventilation rate and for a cooling coil with room thermostat to regulate the coil to control the temperature in the cell. This system is useful in installations where much time is devoted to the setup and preparation of tests, or where constant temperature is required for complicated or sensitive instrumentation. Except for production and endurance testing, the actual engine operating time in test cells may be surprisingly low. The average test cell is used approximately 15 to 20% of the time.

Air should be filtered to remove particulates and insects. The degree of filtration is determined by the type of tests. Facilities in clean environments sometimes use unfiltered outdoor air.

Heating coils are needed to temper supply air if there is danger of freezing equipment or if low temperatures adversely affect tests.

GAS-TURBINE TEST CELLS

Large gas-turbine test cells must handle large quantities of air required by the turbine, attenuate the noise generated, and operate safely with respect to the large flow of fuel. Such cells are unitary and use the turbine to draw in the untreated air and exhaust it through noise attenuators.

Small gas turbine engines can generally be tested in a conventional test cell with relatively minor modifications. The test-cell ventilation air supply and exhausts are sized for the heat generated by the turbine as for a conventional engine. The combustion air supply for the turbine is considerable; it may be drawn from the cell, from outdoors, or through separate conditioning units that handle only combustion air.

Exhaust quantities are higher than from internal combustion engines and are usually ducted directly to the outdoors through muffling devices that provide little restriction to airflow. The exhaust air may be water cooled, as temperature may exceed 700°C.

CHASSIS DYNAMOMETER ROOMS

A chassis dynamometer (Figure 4) simulates road driving and acceleration conditions. The drive wheels of the vehicle rest on a large roll which drives the dynamometer. Air quantities, which are calibrated to correspond to the air velocity at a particular road speed, flow across the front of the vehicle for radiator cooling and to approximate the effects air speed on the body of the vehicle. Additional refinements may vary the air temperature within prescribed limits from 15 to 55°C, control relative humidity, and/or add shakers to simulate road conditions. Air is usually introduced through an area approximating the frontal area of the vehicle. A duct with a return grille at the rear of the vehicle may be lowered so that the air remains near the floor rather than cycling through a ceiling return air grille. The air is recirculated to the air-handling equipment above the ceiling.

Chassis dynamometers are also installed in:

- Cold rooms, where temperatures may be as low as −70°C
- Altitude chambers, where elevations up to 3700 m can be simulated
- Noise chambers for sound evaluation
- Electromagnetic cells for evaluation of electrical components
- Environmental chambers
- Full-sized wind tunnels with throat areas much larger than the cross sectional area of the vehicle. Combustion air is drawn directly from the room, but the engine exhaust must be installed in the wall that will preserve the low temperature and humidity.

A temperature soak space is often placed near chassis dynamometer rooms having a controlled temperature. This space is used to cool or heat those automobiles scheduled to enter the room. Generally, 18 to 24 h is required before the temperature of the vehicle stabilizes to the temperature of the room. The soak space and the temperature controlled room are often isolated from the rest of the facility, with entry and egress through an air lock.

VENTILATION

Constant-volume systems with variable supply temperatures can be used; however, variable-volume, variable-temperature systems are usually selected. Ventilation is generally controlled on the

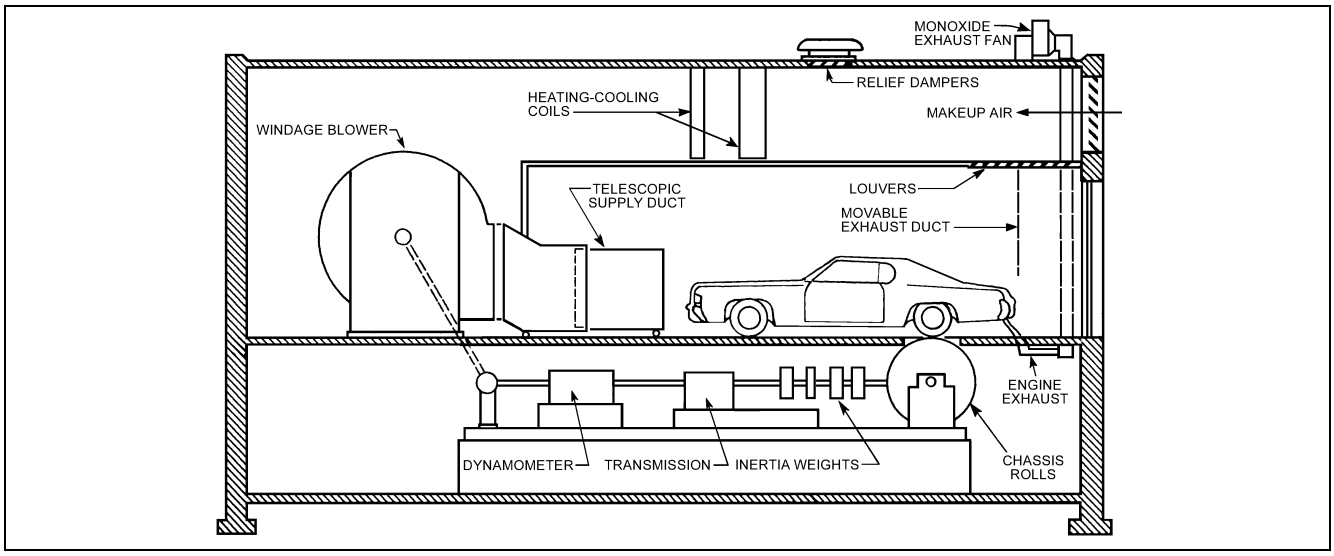

Fig. 4 Chassis Dynamometer Room

exhaust side (Figure 3). Unitary variable-volume systems (Figure 3A) use an individual exhaust fan and makeup air supply for each cell. Supply and exhaust fans are interlocked, and their operation is coordinated with the engine, usually by sensing the temperature of the cell. Some systems have exhaust only, with supply induced directly from outside (Figure 3B). The volume is varied by changing fan speed or damper position.

Ventilation with central supply fans, central exhaust fans, or both (Figure 3C) regulate air quantities by test cell temperature control of individual dampers or by two-position switches actuated by dynamometer operations. Air balance is maintained by static pressure regulation in the cell. Constant pressure in the supply duct is obtained by controlling the supply-fan inlet vanes, modulating dampers, or varying fan speed.

In systems with individual exhaust fans and central supply air, the exhaust is controlled by cell temperature or a two-position switch actuated by dynamometer operation. The central supply system is controlled by a static pressure device located in the cell to maintain room pressure (Figure 3D). Variable-volume exhaust airflow should not drop below minimum requirements. Exhaust requirements should override cell temperature requirements; thus reheat may be needed.

Ventilation should be interlocked with fire protection to shut down the supply to and exhaust from the cell in case of fire. Exhaust fans should be nonsparking, and makeup air should be tempered.

COMBUSTION AIR SUPPLY

Combustion air is usually drawn from the test cell or introduced directly from the outdoors. Separate units that only condition the combustion air can be used if combustion air must be closely regulated and conditioning of the entire test cell is impractical. These units filter, heat, and cool the supply air and regulate its humidity and pressure; they usually provide air directly to the engine air intake. Combustion air systems may be central units or portable packaged units.

COOLING WATER SYSTEMS

Dynamometers absorb and measure the useful output of an engine or its components. Two classes of dynamometers are the water-cooled induction type and the electrical type. In the water-cooled dynamometer the engine work is converted to heat, which is absorbed by circulating water. Electrical dynamometers convert engine work to electrical energy, which can be used or dissipated as heat in resistance grids or load banks. Grids should be located outdoors or adequately ventilated.

Heat loss from electric dynamometers is approximately 8% of the measured output, plus a constant load of about 5 kW for auxiliaries in the cell. Recirculating water absorbs heat from the engine jacket water, oil coolers, and water cooled dynamometers through circulating pumps, cooling towers, or atmospheric coolers and hot and cold well collecting tanks.

NOISE

Noise generated by internal combustion engines and gas turbines must be considered in the design of a test cell air-handling system. Part of the engine noise is discharged through the tail pipe. If possible, internal mufflers should be installed to attenuate this noise at its source. Any ventilation ducts or pipe trenches that penetrate the cells must be insulated against sound transmission to other areas or to the outdoors. Attenuation equivalent to that provided by the structure of the cell should be applied to the duct penetrations. Table 2 lists typical noise levels in test cells during engine operations.

Table 2 Typical Noise Levels in Test Cells

Type and Size of Engine	Sound Level 0.9 m from Engine, dBA			
	63 Hz	124 Hz	500 Hz	2000 Hz
Diesel				
Full load	105	107	98	99
Part load	70	84	56	49

CHAPTER 15

CLEAN SPACES

Terminology 15.1
Clean Spaces and Cleanroom Applications 15.2
Airborne Particles and Particle Control 15.2
Air Pattern Control 15.3
Testing Clean Air and Clean Spaces 15.4
Pharmaceutical and Biomanufacturing Clean Spaces 15.5
Start-Up and Qualification of Pharmaceutical Cleanrooms .. 15.8
Semiconductor Cleanrooms 15.9
High-Bay Cleanrooms 15.10
Environmental Systems 15.11
Energy Conservation in Cleanrooms 15.13
Noise and Vibration Control 15.13
Room Construction and Operation 15.13

DESIGN of clean spaces or cleanrooms encompasses much more than the traditional control of temperature and humidity. In clean space design, other factors may include control of particulate, microbial, electrostatic discharge (ESD), and gaseous contamination, airflow pattern control, pressurization, sound and vibration control, industrial engineering aspects, and manufacturing equipment layout. The objective of a good cleanroom design is to control these variables while maintaining reasonable installation and operating costs.

TERMINOLOGY

Acceptance criteria. The upper and lower limits of the room environment (critical parameters) if these limits are exceeded, the pharmaceutical product may be considered adulterated.

Air lock. A small room between two rooms of different air pressure, with interlocked doors to prevent loss of pressure in the higher pressure room.

As-built cleanroom. A cleanroom that is complete and ready for operation, with all services connected and functional, but without production equipment or personnel in the room.

Aseptic space. A space controlled such that bacterial growth is contained within acceptable limits. This is not a sterile space, in which absolutely no life exists.

At-rest cleanroom. A cleanroom that is complete with production equipment installed and operating, but without personnel in the room.

CFU (colony forming unit). A measure of bacteria present in a pharmaceutical processing room measured via sampling as part of performance qualification.

Challenge. An airborne dispersion of particles of known sizes and concentration used to test filter integrity and efficiency.

Cleanroom. A specially constructed enclosed area environmentally controlled with respect to particulate, temperature, humidity, air pressure, air pressure flow patterns, air motion, vibration, noise, viable organisms, and lighting.

Clean space. A defined area in which the concentration of particles and environmental conditions are controlled at or below specified limits.

Contamination. Any unwanted material, substance, or energy.

Conventional-flow cleanroom. A cleanroom with nonunidirectional or mixed airflow patterns and velocities.

Critical parameter. A room variable (such as temperature, humidity, air changes, room pressure, particulates, viable organisms, etc.) that, by law or by determination from pharmaceutical product development data, affects product strength, identity, safety, purity, or quality (SISPQ).

Critical surface. The surface of the work part to be protected from particulate contamination.

Design conditions. The environmental conditions for which the clean space is designed.

DOP. Dioctyl phthalate, an aerosol formerly used for testing efficiency and integrity of HEPA filters.

E.C. (or E.E.C. or EU) European Economic Community guidelines for GMP pharmaceutical manufacturing.

ESD. Electrostatic discharge.

Exfiltration. Leakage of air from a room through cracks in doors and pass throughs or through material transfer openings, etc., due to differences in space pressures.

First air. The air that issues directly from the HEPA filter before it passes over any work location.

GMP. Good manufacturing practice. As defined by CFR 21 (also, cGMP = current GMP).

High-efficiency particulate air (HEPA) filter. A filter with an efficiency in excess of 99.97% at 0.3 µm particle size.

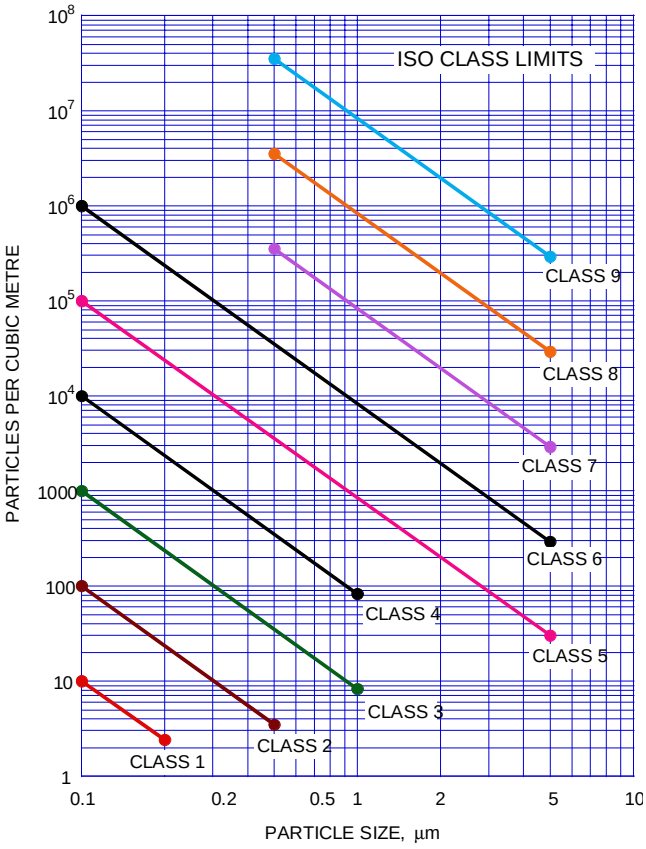

Fig. 1 ISO Air Cleanliness Class Limits
(Reproduced with permission from ISO/FDIS *Standard* 14644-1.)

The preparation of this chapter is assigned to TC 9.11, Clean Spaces.

Table 1 Selected Airborne Particulate Cleanliness Classes for Cleanrooms and Clean Zones

(Reproduced with permission from ISO/FDIS *Standard* 14644-1.)

ISO Class	Concentration Limits, Particles per Cubic Metre					
	0.1 µm	0.2 µm	0.3 µm	0.5 µm	1 µm	5 µm
1	10	2				
2	100	24	10	4		
3	1,000	237	102	35	8	
4	10 000	2 370	1 020	352	83	
5	10 000	23 700	10 200	3 520	832	29
6	1 000 000	237 000	102 000	35 200	8 320	293
7				352 000	83 200	2 930
8				3 520 000	832 000	29 300
9				35 200 000	8 320 000	293 000

Note: Values shown are the concentration limits for particles equal to and larger than the sizes shown. (Concentration limits are calculated in accordance with Section 3.2 of the standard.)

$$C_n = 10N(0.1/D)^{2.08}$$

where C_n = concentration limits, N = ISO class, and D = particle diameter.

IEST. Institute of Environmental Sciences and Technology.

Infiltration. The uncontrolled air that exfiltrates from spaces surrounding the cleaner space.

ISPE. International Society for Pharmaceutical Engineering.

ISO 14644-1. The international standard that specifies airborne particulate cleanliness classes in cleanrooms. Table 1 and Figure 1 summarize the classes of the ISO standard.

Laminar flow. See **Unidirectional flow**.

Leakage. See **Exfiltration**.

Makeup air. Air introduced to the air system for ventilation, pressurization, and replacement of exhaust air.

Minienvironment/Isolator. A barrier, enclosure, or glove box that isolates products from production workers and other contamination sources.

Monodispersed particles. An aerosol with a narrow band of particle sizes generally used for challenging and rating HEPA and UPLA air filters.

Nonunidirectional flow workstation. A workstation without uniform airflow patterns and velocities.

Operational cleanroom. A cleanroom in normal operation with all services functioning and with production equipment and personnel present and performing their normal work functions.

Oral product. A pharmaceutical product to be introduced into the patient by way of mouth. These products are usually not manufactured in aseptic spaces.

PAO. Polyalphaolefin, a substitute for DOP in the testing of HEPA filters.

Parenteral product. A pharmaceutical product to be injected into the patient. Parenterals are manufactured under aseptic conditions or are terminally sterilized to destroy bacteria and meet aseptic requirements.

Particle concentration. The number of individual particles per unit volume of air.

Particle size. The apparent maximum linear dimension of a particle in the plane of observation.

Polydispersed particles. An aerosol with a broad band of particle sizes generally used to leak test filters and filter framing systems.

Qualification. Formal commissioning and operating of a system through established installation, operational, and performance qualification procedures (with approvals).

Qualification protocol. A written description of activities necessary to qualify a pharmaceutical facility, with required approval signatures.

Room classification. Room air quality class (see Figure 1 and Table 1).

SISPQ. A pharmaceutical product's strength, identify, safety, purity, and quality.

SOP. Standard operating procedure.

Topical product. A pharmaceutical product to be applied to the skin or soft tissue in forms of liquid, cream, or ointment, which therefore needs not be aseptic. Sterile ophthalmic products, though, are usually manufactured aseptically.

ULPA (ultralow penetration air) filter. A filter with a minimum of 99.999% efficiency at 0.12 µm particle size.

Unidirectional flow. Formerly called laminar flow. Air flowing at constant and uniform velocity in the same direction.

Workstation. An open or enclosed work surface with direct air supply.

CLEAN SPACES AND CLEANROOM APPLICATIONS

The use of clean space environments in manufacturing, packaging, and research continues to grow as technology advances and the need for cleaner work environments increases. The following major industries use clean spaces for their products:

Pharmaceuticals. Preparation of pharmaceutical, biological, and medical products requires clean spaces to control viable (living) particles that would produce undesirable bacteria growth and other contaminants.

Electronics. The advances in semiconductor microelectronics continue to drive cleanroom design. Semiconductor facilities account for a significant percentage of all cleanrooms in operation in the United States, with most of the newer semiconductor cleanrooms being ISO Class 5 or cleaner.

Aerospace. Cleanrooms were first developed for aerospace applications to manufacture and assemble satellites, missiles, and aerospace electronics. Most applications involve clean spaces of large volumes with cleanliness levels of ISO Class 8 or cleaner.

Miscellaneous Applications. Cleanrooms are also used in aseptic food processing and packaging; manufacture of artificial limbs and joints; automotive paint booths; crystal; laser/optic industries; and advanced materials research.

Hospital operating rooms may be classified as cleanrooms, yet their primary function is to limit particular types of contamination rather than the quantity of particles present. Cleanrooms are used in patient isolation and surgery where risks of infection exist. For more information, see Chapter 7, Health Care Facilities.

AIRBORNE PARTICLES AND PARTICLE CONTROL

Airborne particles occur in nature as pollen, bacteria, miscellaneous living and dead organisms, and windblown dust and sea spray. Industry generates particles from combustion processes, chemical vapors, and friction in manufacturing equipment. People in the workspace are a prime source of particles in the form of skin flakes, hair, clothing lint, cosmetics, respiratory emissions, and bacteria from perspiration. These airborne particles vary in size from 0.001 µm to several hundred micrometres. Particles larger than 5 µm tend to settle quickly. With many manufacturing processes, these airborne particles are viewed as a source of contamination.

Particle Sources in Clean Spaces

In general, particle sources, with respect to the clean space, are grouped into two categories: external and internal.

External Sources. External sources are those particles that enter the clean space from the outside, normally via infiltration through doors, windows, and wall penetrations for pipes, ducts, etc. However, the largest external source is usually outside makeup air entering through the air conditioning.

In an operating cleanroom, external particle sources normally have little effect on overall cleanroom particle concentration because HEPA filters clean the supply air. However, the particle concentration in clean spaces at rest relates directly to ambient particle concentrations. External sources are controlled primarily by air filtration, room pressurization, and sealing of space penetrations.

Internal Sources. Particles in the clean space are generated by people, cleanroom surface shedding, process equipment, and the manufacturing process itself. Cleanroom personnel can be the largest source of internal particles. Workers may generate several thousand to several million particles per minute in a cleanroom. Personnel-generated particles are controlled with new cleanroom garments, proper gowning procedures, and airflow designed to continually shower the workers with clean air. As personnel work in the cleanroom, their movements may reentrain airborne particles from other sources. Other activities, such as writing, may also cause higher particle concentrations.

Particle concentrations in the cleanroom may be used to define cleanroom class, but actual particle deposition on the product is of greater concern. The sciences of aerosols, filter theory, and fluid motions are the primary sources of understanding of contamination control. Cleanroom designers may not be able to control or prevent internal particle generation completely, but they may anticipate internal sources and design control mechanisms and airflow patterns to limit their effect on the product.

Fibrous Air Filters

Proper air filtration prevents most externally generated particles from entering the cleanroom. Present technology for high-efficiency air filters centers around two types: high-efficiency particulate air (HEPA) filters and ultralow penetration air (ULPA) filters. HEPA and ULPA filters use glass fiber paper technology. Laminates and nonglass media for special applications have been developed. HEPA and ULPA filters are usually constructed in a deep pleated form with either aluminum, coated string, filter paper, or hot-melt adhesives as pleating separators. Filters may vary from 25 to 300 mm in depth; available media area increases with deeper filters and closer pleat spacing.

Theories and models verified by empirical data indicate that interception and diffusion are the dominant capture mechanisms for HEPA filters. Fibrous filters have their lowest removal efficiency at the most penetrating particle size (MPPS), which is determined by filter fiber diameter, volume fraction or packing density, and air velocity. For most HEPA filters, the MPPS is between 0.1 and 0.3 μm. Thus, HEPA and ULPA filters have rated efficiencies based on 0.3 μm and 0.12 μm particle sizes, respectively.

AIR PATTERN CONTROL

Air turbulence in the clean space is strongly influenced by air supply and return configurations, foot traffic, and process equipment layout. Selection of the air pattern configurations is the first step of good cleanroom design. User requirements for cleanliness level, process equipment layout, available space for installation of air pattern control equipment (i.e., air handlers, clean workstations, environmental control components, etc.), and project financial considerations all influence the final air pattern design selection. Financial aspects govern air pattern control design where operating and capital costs may limit the type and size of air-handling equipment that can be used.

Numerous air pattern configurations are in use, but in general they fall into two categories: unidirectional airflow (often mistakenly referred to as laminar flow) and nonunidirectional airflow (commonly called turbulent or mixed airflow).

Unidirectional airflow, though not truly laminar airflow, is characterized as air flowing in a single pass in a single direction through a cleanroom or clean zone with generally parallel streamlines. Ideally, the flow streamlines would be uninterrupted, and although personnel and equipment in the airstream do distort the streamlines, a state of constant velocity is approximated. Most particles that encounter an obstruction in a unidirectional airflow strike the obstruction and continue around it as the airstream reestablishes itself downstream of the obstruction.

Nonunidirectional airflow does not meet the definition of unidirectional airflow because it has either multiple-pass circulating characteristics or nonparallel flow.

Nonunidirectional Airflow

Variations of nonunidirectional airflow are based primarily on the location of supply air inlets and outlets and air filter locations. Some examples of unidirectional and nonunidirectional airflow systems are shown in Figures 2 and 3. Airflow is typically supplied to the space through supply diffusers containing HEPA filters (Figure 2) or through supply diffusers with HEPA filters located in the ductwork or air handIer (Figure 3). In a mixed-flow room, air is prefiltered in the supply and then HEPA-filtered at the workstations located in the clean space (see the left side of Figure 3).

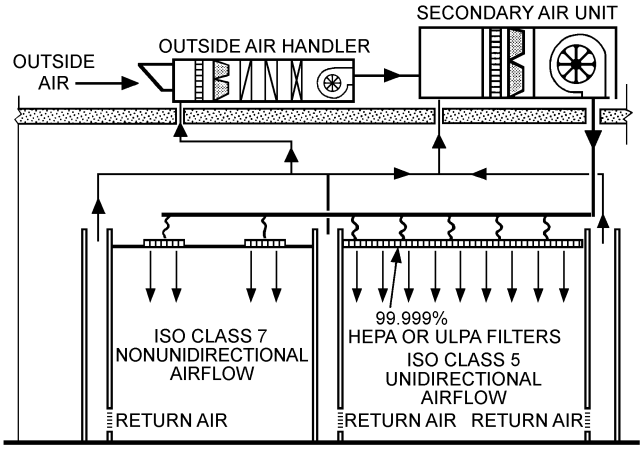

Fig. 2 ISO Class 7 Nonunidirectional Cleanroom with Ducted HEPA Filter Supply Elements and ISO Class 5 Unidirectional Cleanroom with Ducted HEPA or ULPA Filter Ceiling

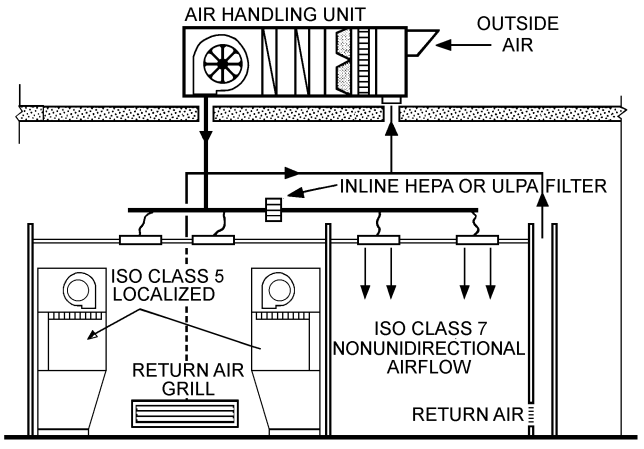

Fig. 3 ISO Class 7 Nonunidirectional Cleanroom with HEPA Filters Located in Supply Duct and ISO Class 5 Local Workstations

Nonunidirectional airflow may provide satisfactory contamination control results for cleanliness levels of Class M4.5 through Class M6.5. Attainment of desired cleanliness classes with designs similar to Figures 2 and 3 presupposes that the major space contamination is from makeup air and that contamination is removed in air-handler or ductwork filter housings or through HEPA filter supply devices. When internally generated particles are of primary concern, clean workstations are provided in the clean space.

Air turbulence is harmful for flow control, but air turbulence is needed to enhance the mixing of low and high particle room concentrations and produce a homogeneous particle concentration level acceptable to the process.

Unidirectional Airflow

Air patterns are optimized, and air turbulence is minimized in unidirectional airflow. In a **vertical laminar flow (VLF) room**, air is typically introduced through the ceiling HEPA or ULPA filters and returned through a raised access floor or at the base of sidewalls. Because air enters from the entire ceiling area, this configuration produces nominally parallel airflow. In a **horizontal flow cleanroom**, air enters one wall and returns on the opposite wall.

A **downflow cleanroom** has a ceiling with HEPA filters, but air flows from only a portion of the ceiling. In a cleanroom with a low class number the greater part of the ceiling requires HEPA filters. For an ISO Class 5 or better room, the entire ceiling usually requires HEPA filtration. Ideally, a grated or perforated floor serves as the air exhaust. This type of floor is inappropriate in pharmaceutical cleanrooms, which typically have solid floors and low-level wall returns.

In a downflow cleanroom, a uniform shower of air bathes the entire room in a downward flow of ultraclean air. Contamination generated in the space will not move laterally against the downward flow of air (it is swept down and out through the floor) or contribute to a buildup of contamination in the room.

Care must be taken in design, selection, and installation to seal a HEPA or ULPA filter ceiling. Properly sealed HEPA or ULPA filters installed in the ceiling can provide the cleanest air presently available in a workroom environment.

In a **horizontal flow cleanroom**, the supply wall consists entirely of HEPA or ULPA filters supplying air at approximately 0.45 m/s across the entire section of the room. The air then exits through the return wall at the opposite end of the room and recirculates. As with the downflow room, this design removes contamination generated in the space and minimizes cross-contamination perpendicular to the airflow. However, a major limitation to this design is that downstream air becomes contaminated. The air leaving the filter wall is the cleanest; it then becomes contaminated by the process as it flows past the first workstation. The process activities can be oriented to have the most critical operations at the clean end of the room, with the progressively less critical operations located toward the return air, or dirty end of the room.

U.S. *Federal Standard* 209E does not specify velocity requirements, so the actual velocity is as specified by the owner or the owner's agent. The 0.45 m/s velocity specified in an earlier standard (FS 209B) is still widely accepted in the cleanroom industry. Current research suggests lower velocities may be possible. Careful testing should be performed to ensure that required cleanliness levels are maintained. Other reduced air volume designs may use a mixture of high and low pressure drop HEPA filters, reduced coverage in high traffic areas, or lower velocities in personnel corridor areas.

Unidirectional airflow systems have a predictable airflow path that airborne particles tend to follow. Without good filtration practices, unidirectional airflow only indicates a predictable path for particles. However, superior cleanroom performance may be obtained with a good understanding of unidirectional airflow. This airflow remains parallel (or within 18° of parallel) to below the normal work surface height of 760 to 900 mm. However, this flow deteriorates when the air encounters obstacles such as process equipment and work benches, or if air has traveled excessive distances. Personnel movement also degrades the flow. The result is a cleanroom with areas of good unidirectional airflow and areas of turbulent airflow.

Turbulent zones have countercurrents of air with high velocities, reverse flow, or no flow at all (stagnancy). Countercurrents can produce stagnant zones where small particles may cluster and finally settle onto surfaces or product; countercurrents may also lift particles from contaminated surfaces. Once lifted, these particles may deposit on product surfaces.

Cleanroom mockups may help the designer avoid turbulent airflow zones and countercurrents. Smoke, neutral-buoyancy helium-filled soap bubbles, and nitrogen vapor fogs can make air streamlines visible within the cleanroom mockup.

Computer-Aided Flow Modeling

Computer models of particle trajectories transport mechanisms, and contamination propagation are commercially available. Flow analysis with computer models may compare flow fields associated with different process equipment, work benches, robots, and building structural design. Airflow analysis of flow patterns and air streamlines is performed by computational fluid dynamics for laminar and turbulent flow where incompressibility and uniform thermophysical properties are assumed. Design parameters may be modified to determine the effect of airflow on particle transport and flow streamlines; thus avoiding the cost of mock-ups.

Major features and benefits associated with most computer flow models are

1. Two- or three-dimensional modeling of simple cleanroom configurations, including people and equipment
2. Modeling of both laminar and turbulent airflows
3. Multiple air inlets and outlets of varying sizes and velocities
4. Allowances for varying boundary conditions associated with walls, floors, and ceilings
5. Aerodynamic effects of process equipment, work benches, and people
6. Prediction of specific airflow patterns, velocities, and temperature gradients of all or part of a cleanroom
7. Reduced cost associated with new cleanroom design verification
8. Graphical representation of flow streamlines and velocity vectors to assist in flow analysis (Figures 4 and 5)
9. Graphical representation of simulated particle trajectories and propagation (Figure 6)

Research has shown good correlation between flow modeling by computer and that done in simple mockups. However, computer flow modeling software should not be considered a panacea for cleanroom design.

TESTING CLEAN AIR AND CLEAN SPACES

Because early cleanrooms were largely for governmental use, testing procedures have been set by government standards. ISO *Standard* 14644-1 defines air cleanliness levels for clean spaces around the world. U.S. *Federal Standard* 209 is also widely accepted. However, aspects of cleanroom performance other than air cleanliness are no longer covered by FS 209E. Standardized testing methods and practices have been developed and published by the Institute of Environmental Sciences and Technology (IEST), the American Society for Testing and Materials (ASTM), and others.

Three basic test modes for cleanrooms are used to evaluate a facility properly: (1) as built, (2) at rest, and (3) operational. A cleanroom cannot be fully evaluated until it has performed under full occupancy, and the process to be performed in it is operational.

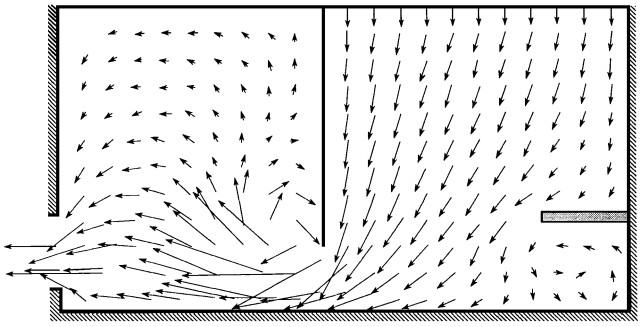

Fig. 4 Cleanroom Airflow Velocity Vectors Generated by Computer Simulation

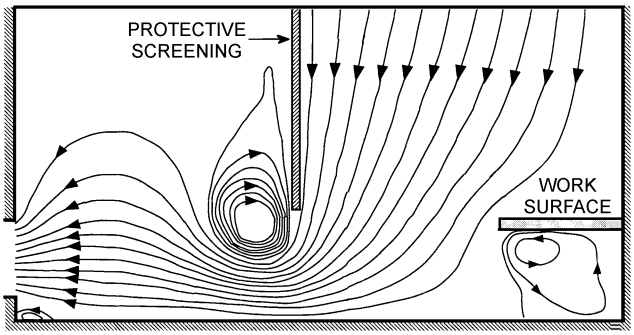

Fig. 5 Computer Modeling of Cleanroom Airflow Streamlines

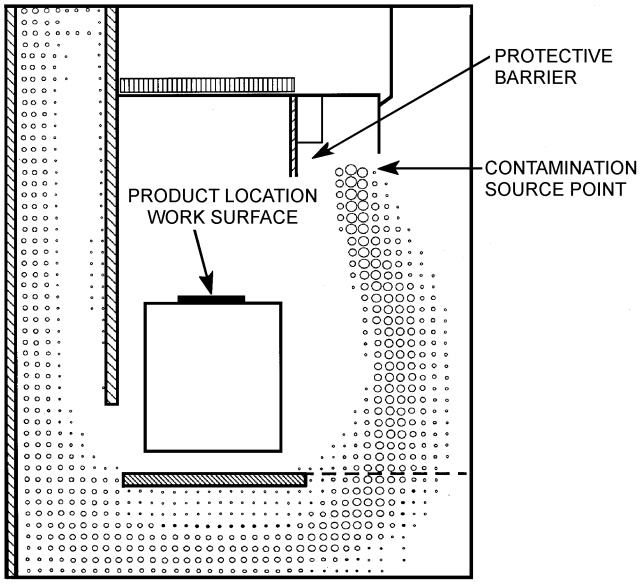

Fig. 6 Computer Simulation of Particle Propagation in a Cleanroom

Thus, the techniques for conducting initial performance tests and operational monitoring must be similar.

Sources of contamination, as previously described, are both external and internal for both laminar and nonlaminar flow cleanrooms. The primary air loop is the major source of external contamination. Discrete particle counters using laser or light-scattering principles may be used to detect particles of 0.01 to 5 µm. For particles 5 µm and larger, microscopic counting can be used, with the particles collected on a membrane filter through which a sample of air has been drawn.

HEPA filters in unidirectional flow and ISO Class 5 ceilings should be tested for pinhole leaks at the following places: the filter media, the sealant between the media and the filter frame, the filter frame gasket, and the filter bank supporting frames. The area between the wall or ceiling and the frame should also be tested. A pinhole leak at the filter bank can be extremely critical, since the leakage rate varies inversely as the square of the pressure drop across the hole. (The industry term "pinhole" used to describe the leak site is a misnomer. The size is almost never that of a hole formed by a pin, but is actually many times smaller.)

The testing procedure of the IEST (1993) describes 12 tests for cleanrooms. Which tests are applicable to each specific cleanroom project must be determined.

PHARMACEUTICAL AND BIOMANUFACTURING CLEAN SPACES

Facilities for the manufacture of pharmaceutical products require careful assessment of many entities including HVAC, controls, room finishes, process equipment, room operations, and utilities. Flow of equipment, personnel, and product must also be considered. It is important to involve the designers, operators, commissioning staff quality control, maintenance, constructors, and the production representative during the conceptual stage of design. Critical variables for room environment and types of controls vary greatly with the clean space's intended purpose. It is particularly important to determine critical parameters with quality assurance to set limits for temperature, humidity, room pressure, and other control requirements.

In the United States, regulatory requirements and specification documents such as the *Code of Federal Regulations* 210 and 211, ISPE Guides, and National Fire Protection Association (NFPA) standards are available. These documents describe good manufacturing practice (GMP). The goal of GMP is to achieve a proper and repeatable method of producing sterile products free from microbial and particle contaminants.

The Commission of the European Communities (CEC) adopted the European Union (EU) *Guide to Good Manufacturing Practice for Medicinal Products* in 1992. Much of the regulation is based on the United Kingdom's *Guide to Good Pharmaceutical Manufacturing Practice*. The designer needs to verify which GMP documents apply to the facility and which are advisory.

In the United States, the one factor that makes pharmaceutical processing suites most different from clean spaces for other purposes (e.g., electronic and aerospace) is the requirement to pass U.S. Food and Drug Administration (FDA) inspection for product licensing. It is important to include the FDA's regulatory arms, the Center for Biologics Evaluation and Research (CBER) or the Center for Drug Evaluation and Research (CDER) for design early in the concept design process.

In addition, early in the design process, a qualification plan (QP) must be considered. Functional requirement specifications (FRS), critical parameters and acceptance criteria, installation qualification (IQ), operational qualification (OQ), and performance qualification (PQ) in the cleanroom suites are all requirements for process validation. lQ, OQ, and PQ protocols, in part, set the acceptance criteria and control limits for critical parameters such as temperature, humidity, room pressurization, air change rates, and operating particle counts (or air classifications). These protocols must receive defined approvals in compliance with the owner's guidelines. The qualification plan must also address standard operating procedures (SOPs), preventive maintenance (PM), and operator and maintenance personnel training.

Biomanufacturing and pharmaceutical aseptic clean spaces are typically arranged in suites, with clearly defined operations in each

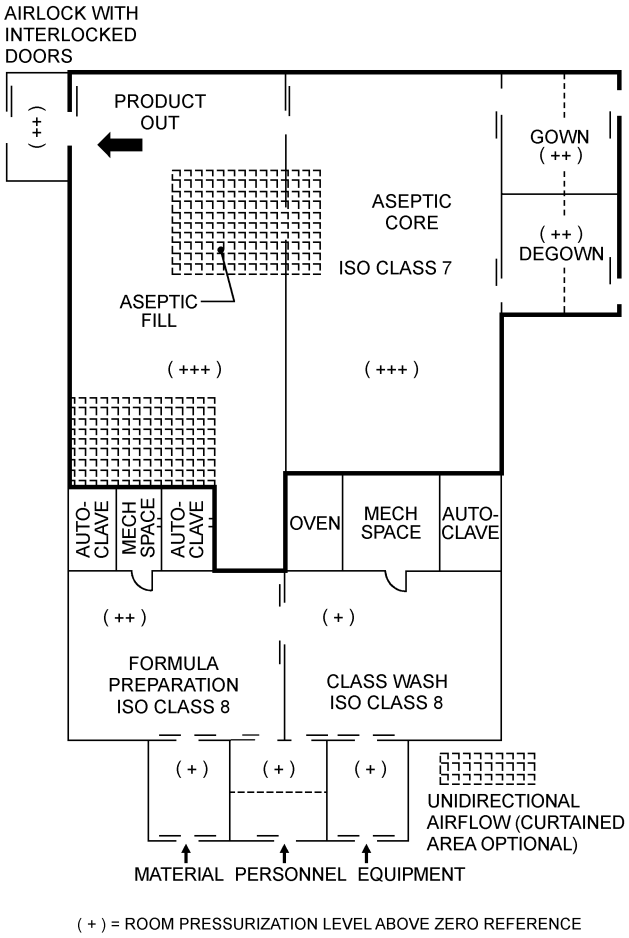

Fig. 7 Typical Aseptic Suite

suite. For example, common convention positions an aseptic core (ISO Class 5) filling area in the innermost room, which is at the highest pressure surrounded by areas of descending pressure and increasing particulate classes and bacterial levels (see Figure 7).

In aseptic processing facilities, the highest quality area is intentionally placed within the lower quality areas and separated by room air classification and air pressure differences via air locks. A commonly used pressure difference is 12 to 15 Pa between air classifications, with the higher quality room having the higher pressure. Lower pressure differences may be acceptable if they are proven effective. A pressure differential is generally accepted as good manufacturing practice to inhibit particles from entering a clean suite.

Where product containment is an issue (e.g., pathogens or toxic materials), the suite requires a lower pressure than the adjacent rooms, but it may still require a higher air quality. In this case, the air lock may be designed to maintain one pressure level higher than the adjacent room, and also higher than the contained suite (Figure 8). Biological containment requirements are addressed by the U.S. National Institutes of Health where potentially hazardous organisms are grouped in biosafety levels BL-1 to BL-4.

Design Concerns for Pharmaceutical Cleanrooms

The owner and designer must define the maximum range of variable value (**acceptance criterion**) for each critical parameter. In that range, the product's safety, identity, strength, purity, and quality will not be affected. The owner should define **action alarm** points at the limits of acceptance criteria, such that product exposed to conditions outside these action limits may have been adulterated. The designer should select tighter (but achievable) target design values

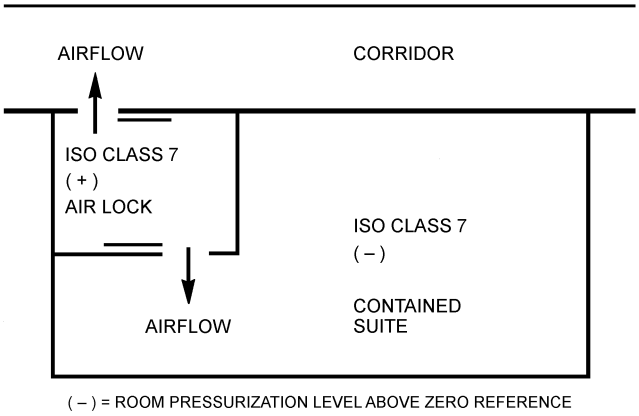

Fig. 8 Contained Suite Arrangement

for critical parameters (in the range of acceptance criteria) and for non-critical parameters.

Facilities manufacturing penicillin or similar antibiotics (such as cephalosporins) must be physically isolated from other manufacturing areas and served by their own HVAC system. Certain other products may require similar separation.

Facilities manufacturing aseptic/sterile products derived from chemical synthesis may have different requirements than those manufacturing biological or biotechnological products. The owner must define the inspecting agency's requirements.

The United States Pharmacopoeia (USP) limits the temperatures to which finished pharmaceutical products may be exposed to 15 to 25°C. The production facility may need tighter limits than these, based on the owner's observed product data. Personnel comfort will be a factor in design. Personnel can perspire in their protective overgarments and cause particulate and microbial counts to increase, so lower temperatures and tighter temperature control may be necessary.

Relative humidity may be critical to the product's integrity. Some products are processed or packaged cold and need low room dew point to prevent condensation on equipment and vials. Certain products are hygroscopic and require lower humidity than a condensing coil can provide; desiccant dehumidification should be considered. Humidification is usually needed for personnel comfort but not usually for product needs. It may also be needed where dust might present an explosion hazard or where low humidity may hinder the handling of dry materials. Clean steam (free of chemicals and other additives) is preferred for humidification because it is free of bacteria, but the humidification system should be free of amines or other contaminants if room air might contact the product.

Although airborne particles and viable organisms may be minimized by dilution (high air changes) and by supplying high-quality HVAC air, the most effective control is to minimize the release of these contaminants within the room. Personnel and machinery are the most common sources of contamination, and can be isolated from the product by gowning, masks, and isolation barriers. A careful study of the manner in which each room will operate should reveal the most probable sources of contaminants and will help the HVAC designer determine dilution air quantities and locate air supply outlets and returns. Avoid duct liners and silencers in supply air ductwork where contaminants can collect and bacteria can grow. Ensure special attention is paid to cleaning and degreasing of metal sheeting and air ductwork before installation.

Airborne particulate and microbe levels in aseptic processing areas are limited by government regulations, with lower limits for the more critical operations rooms. European and U.S. FDA particulate limits are for the room in operation, but may also define limits for the room at rest.

Facilities meeting U.S. GMPs must meet particulate levels with manufacturing underway (the exception being aseptic powder processing, where airborne particulate levels at powder filling heads will exceed limits. These rooms are tested with production running but no product present). GMPs suggest a minimum of 20 air changes per hour for rooms with an air particulate classification, with exposed sterile product under a unidirectional flow hood or inside a ISO Class 5 barrier enclosure. The U.S. GMPs currently require only two classes: ISO Class 5 for sterile product exposure, and ISO Class 8 for adjoining spaces. However, common practice places exposed products in a ISO Class 5 unidirectional flow zone inside a ISO Class 7 room. Facilities designed for European Community regulations require a minimum of 20 air changes per hour in every room for which particulate levels must be controlled (i.e., where aseptic product or equipment is handled). Where isolation barriers and containment or spot exhaust are not practical, airborne contaminants may be minimized by increased room air changes. There are no minimum air change requirements for facilities manufacturing nonaseptic products.

Note that once product is stoppered and capped in containers, the need for particulate control and minimal air changes is reduced or eliminated, depending on the degree of protection provided by product packaging. The owner should determine the necessary critical environmental parameters and acceptance criteria for each room and processing step.

Return openings for room HVAC should be located at low levels on the walls, to promote a downward flow of air from supply to return, sweeping contaminants to the floor and away from the product. In larger rooms, internal return air columns may be necessary. Perforated floors are discouraged due to cleanability problems.

Aseptic facilities usually require pinhole-scanned (integrity-tested) HEPA filters on supply air (not ULPA). Many operations install HEPA filters in the supply air to nonaseptic production facilities to minimize cross-contamination from other manufacturing areas served by the HVAC. To increase the life of terminal HEPA filters in aseptic facilities, and to minimize the need to rebalance the supply system due to differential loading of terminal HEPA filters, many designers install a high-capacity HEPA bank downstream of the supply air fan, with constant volume control to compensate for primary filter pressure changes and any dehumidifier airflow. The final HEPA filter is usually in a sealed gel frame or composed of a one-piece lay-in design that can be caulked to the ceiling frame, maintaining the integrity of the room envelope. Standard supply air diffusers are not recommended for a classified room since they are difficult to clean.

Aseptic product must be protected by pressurizing the room in which it is exposed, to 15 Pa above the next lower cleanliness room classification. To keep pressure differential from dropping to zero when a door is opened, air locks are recommended between rooms of different air pressure, especially at the entrance to the aseptic production room itself. Room pressure is a function of airflow resistance through cracks, openings, and permeable surfaces in the room shell. Consider all potential openings, slots, and door leakage that can affect the amount of air needed to pressurize the space. Because net room airflow and room pressure are closely related, outdoor or makeup air requirements are often dictated by room pressures rather than by the number of occupants. The HVAC should be able to handle more makeup air than needed for commissioning, because door seals can deteriorate over time.

ISO Class 2 Unidirectional hoods are basically banks of HEPA filters, integrity tested to be pinhole-free. Since it is difficult to maintain unidirectional flow for long distances or over large areas, the hood should be located as closely as possible to product exposure sites (the work surface). Hood-face velocity is usually 0.45 m/s ±20%; velocity requirements differ somewhat from the FDA's. The user should specify velocity and uniformity requirements. A unidirectional hood usually has clear sidewalls (curtains) to promote downward airflow and prevent entrainment of room particles into the hood's zone of protection. Curtains should extend below the product exposure site and be designed to prevent accidental disruption of airflow patterns by personnel. Many production facilities prefer rigid curtains to facilitate cleaning and sanitization.

Hood fan heat may become a problem, forcing the designer to overcool the room from which the hood draws its air or to provide sensible cooling air directly into the hood's circulating system.

Barrier Technology

Cleanrooms designed to meet ISO Class 5 or better require considerable equipment, space, and maintenance. Operating this equipment is an expensive commitment. Furthermore, cleanrooms typically require gowned operators to be inside to manipulate the product and adjust the machinery. Since the operator generates a large portion of particulate and contamination, it would be better to place the operator outside the controlled environment. With the operator removed from the controlled space, its volume can be reduced leading to substantially reduced capital and operating cost, hence the increasing popularity of barrier technology or isolators.

Each isolator is designed to fit a specific application and is customized for its tasks. Applications vary widely depending on product, process equipment, and throughput volume. Sterile barriers are typically positive pressure envelopes around the filling equipment with a multiple of glove ports for operator access, constructed of polished stainless steel with clear rigid view ports.

"Mouse holes" permit passage of vials in and out of the unit. Special transfer ports are used for stoppers and tools. Important design concerns include accessibility, ergonomics, interference with mating equipment, decontamination or sterilization procedures, access to service equipment, filter change, filter certification, process validation, and environmental control.

Extra attention must be paid to product filling, vial, and stopper protection; access to the barrier for sterilized stoppers; interface to the vial sterilization (depyrogenation) device; sterilizing of product path including pumps and tubing; and airflow patterns inside the barrier, especially at critical points. If hydrogen peroxide is to be used as a surface sterilant, care must be taken to assure good circulation and adequate concentration inside the barrier, as well as removal of residual vapor in the required time frame.

Other barrier applications offer operator protection while maintaining a sterile internal environment. These tend to be total containment isolators with totally contained product transfer ports. This system maintains all internal surfaces sealed from the external environment or operator exposure. Because of potential chamber leaks, its internal pressure may be kept negative with respect to the ambient space via exhaust fans, posing an additional potential risk to the product that must be addressed with the owner.

Nonsterile powder control may incorporate more passive barrier designs such as a downflow sample weighing hood. This arrangement takes advantage of unidirectional airflow to wash particles down and away from the operator's breathing zone. Low-wall air returns positioned at the back of the cubicle capture the dust. An arrangement of roughing and final filters permits the air to return to the air handlers and back to the work zone through the ceiling. Product compounds involving noxious or solvent vapors require a once-through air design. Barrier technology, by the nature of its design, affords the opportunity for installation in environments that might require no special control or particulate classification. Since isolators and containment chambers are still relatively new to the pharmaceutical industry, installations for sterile product must be in a controlled ambient room condition of ISO Class 8.

Maintainability

A facility that considers maintainability in its design is much more reliable and should have fewer operational and regulatory

concerns. Such maintainability concerns as accessibility, frequency of maintenance, and spare parts should be considered. Many pharmaceutical facilities have been designed such that routine maintenance can be performed from outside the facility, the exception being unidirectional and terminal HEPA filters, which must be tested twice a year. Quality of materials is important to reliability, especially where failure can compromise a critical parameter. Consider how much exposure and risk to product and personnel is required during maintenance activities (i.e., how to clean the inside of a glove box contaminated by a toxic product). Beside cleanable room surfaces that must be sanitized, consider if and how HVAC equipment may be sanitized using the owner's procedures. Determine if ductwork must be internally cleaned, and how.

Controls, Monitors, Alarms

Room pressure may be maintained by a passive (statically balanced) HVAC if there are few airflow variables. For example, an HVAC of a few pressurized rooms may be statically balanced if there is a method of maintaining supply airflow volume to compensate for filter loading to assure minimum room air changes. More complex designs may require active room pressure control, usually by controlling exhaust or return air volume in a control loop that senses and controls room pressure, not airflow differentials. Pressure controls should not overreact to doors opening and closing, since it is virtually impossible to pressurize a room to 12 Pa with a room door standing open. Some time delay is usually advisable in pressure controls and pressure alarms to allow time for doors to close. Duration of the time delay can be determined by observing actual processes, but should be as short as possible.

If room humidity must be maintained to tolerances tighter than the broad range that normal comfort cooling can maintain, active relative humidity control should be considered. If a desiccant dehumidifier is needed, operation of the unit over its range of flow must not adversely affect the ability of the HVAC to deliver a constant air supply volume to the facility.

Monitor and alarm critical parameters to prove they are under control. Log alarm data and parameter values during excursions. Logging may range from a local recorder to DDC disk data storage with controlled access. Software source code should be traceable, with changes to software under the owner's control after qualification is complete. Commercial HVAC graphic programming software is usually acceptable, but verify this with regulatory agencies before detailed design begins. Also, keep complete calibration records for sensors, alarms, and recorders of critical parameter data.

Noise Concerns

Noise from the HVAC can be a common problem because fans must overcome the pressure drop of additional air filtration. The amount of noise generated must be reduced rather than adding duct silencers, which may harbor bacteria and are difficult to clean. Separate supply and return fans running at lower tip speeds instead of a single-fan air handler can reduce the noise. HVAC noise may not be an issue if production equipment is considerably noisier.

Nonaseptic Products

Nonaseptic pharmaceutical facilities (such as topical and oral products) are similar in design to those described for aseptic product manufacturing, but with fewer critical components to be qualified. However, critical parameters such as room humidity may become more important while airborne particulate counts do not apply in the United States. If the product is potent, barrier isolation may still be advisable. Room differential pressures or airflow directions, and air changes are usually critical in that they are needed to control cross-contamination of products, but no regulatory minimum pressure or air change values apply.

START-UP AND QUALIFICATION OF PHARMACEUTICAL CLEANROOMS

Qualification of HVAC for Aseptic Pharmaceutical Manufacturing

Qualification of the pharmaceutical cleanroom HVAC is part of the overall commissioning of the building and its equipment, except that documentation is more rigorous. The qualification covers the equipment affecting critical parameters and their control. Other groups in the manufacturing company, such as the safety or environmental groups may also require similar commissioning documentation for their areas of concern. The most important objective in meeting the requirements of the approving agency is to (1) state what procedures will be followed and then verify that it was done, and (2) show that product is protected and room acceptance criteria are met.

Qualification Plan and Acceptance Criteria

Early in the design, the owner and designer should discuss who will be responsible for as-built drawings, setting up maintenance files, and training. They should create a qualification plan for the HVAC, which includes (1) a functional description of what the systems will do; (2) maps of room pressures, airflow diagrams, and cleanliness zones served by each air handler; (3) a list of critical components to be qualified including the computer controlling the HVAC; (4) a list of owner's procedures that must be followed for the qualification of equipment and systems that affect critical variables; (5) a list of qualification procedures (IQ/OQ/PQ protocols) that must be written especially for the project; and (6) a list of needed commissioning equipment.

The approval procedure should also be defined in the QP. It is important to be able to measure and document the critical variables of a system (such as room pressure), but it is also important to document the performance of components that affect that critical variables (i.e., room pressure sensors, temperature sensors, airflow volume monitor, etc.) for GMP as well as business records. Documentation helps ensure that replacement parts (such as motors) can be specified, purchased, and installed to satisfy critical variables.

It is integral to determine what the critical components are (including instruments), the performance of which could affect critical parameters, and the undetected failure of which could lead to adulteration of the product. This may be accomplished by a joint effort between the HVAC engineer, owner, and a qualified protocol writer. If performance data are in the qualification records, replacement parts of different manufacture can be installed without major change control approvals, as long as they meet performance requirements. Owner approvals for the qualification plan should be obtained while proceeding with detailed design.

Qualification is the successful completion of the following activities for critical components and systems. The designer should understand the requirements for owner's approval of each protocol (usually, the owner approves the blank protocol form and the subsequently executed protocol).

The installation qualification (IQ) protocol is a record of construction inspection to verify compliance with contract documents, including completion of punchlist work, for critical components. It may include material test reports, receipt verification forms, shop inspection reports, motor rotation tests, and contractor-furnished testing and balancing. This record also includes calibration records for instrumentation used in commissioning and for installed instrumentation (such as sensors, recorders, transmitters, controllers, and actuators) traceable to National Institute of Standards and Technology (NIST) instruments.

Control software should be bench tested, and preliminary (starting) tuning parameters should be entered. Control loops should be dry-loop checked to verify that installation is correct. Equipment

and instruments should be tagged and wiring labeled. Commissioning documentation must attest the completion of these activities. This includes as-built drawings and installation-operation-maintenance (lOM) manuals from the contractors and vendors.

The operational qualification (OQ) protocol documents the start-up that includes critical components. This includes individual performance testing of control loops under full operating pressure performed in a logical order (i.e., fan control before room pressure control). The commissioning agent must produce verification that operating parameters are within acceptance criteria.

The HVAC may be challenged under extremes of design load (where possible) to verify operation of alarms and recorders, to determine (and correct, if significant) weak points, and to verify control and door interlocks. Based on observations, informal alert values of critical parameters, which might signify abnormal operation, may be considered. Although product would not be adulterated at these parameter values, the owner's staff could assess an alarm and react to it before further deviations from normal operation were experienced.

Documented smoke tests will verify space pressure and airflow in critical rooms or inside containment hoods, and show airflow patterns and directions around critical parts of production equipment. Many smoke tests have been documented on videotape, especially when room pressure differentials are lower than acceptance criteria require and cannot be corrected.

Files should include an updated description of the HVAC, which describes how it operates, schematics, airflow diagrams, and room pressure maps that accompany it. Copies should be readily accessible and properly filed. Operating personnel should be familiar with the data shown in these GMP records and be able to explain it to an agency inspector.

Other Documents. GMP documents should also include test reports for HEPA filters (efficiency or pinhole-scan integrity tests) at final operating velocities. If the filter installer performed the tests, the data should have been part of the IQ package.

Documents should verify that instruments display, track, and store critical parameters and action alarms. (Consider recording data by exception and routine documentation of data at minimal regular frequency.)

Systems and equipment should be entered into the owner's maintenance program, with rough drafts of new maintenance procedures (final drafts should reflect commissioning experience).

Records should attest to the completion of these activities, including final as-built and air and water balance reports.

Performance qualification (PQ) is proof that the entire HVAC performs as intended under actual production conditions. PQ is the beginning of the ongoing verification that the system meets the acceptance criteria of the product (often called validation). This includes documentation of

- Maintenance record keeping and final operating and maintenance procedures in place, with recommended frequency of maintenance. The owner may also want a procedure for periodic challenge of the controls and alarms
- Logs of critical parameters that prove the system maintains acceptance criteria over a prescribed time
- Training records of operators and maintenance personnel
- Final loop tuning parameters

After acceptance of PQ, the owner's change control procedure should limit further modifications to critical components (as shown on IQ and OQ forms) that affect the product. Although much of the building's HVAC equipment should not need qualification, records for the entire facility should be kept and problems corrected before they become significant. Records of the corrections should also be maintained.

Once the system is operational, pharmaceutical product trial lots are run in the facility (process validation) and the owner should regularly monitor viable (microbial) and nonviable particles in the room.

SEMICONDUCTOR CLEANROOMS

Since the middle 1990s, most microelectronic facilities manufacturing semiconductors have required a cleanroom providing ISO Class 5 and cleaner. State-of-the-art cleanroom technology has been driven by the decreasing size of microelectronics circuitry and larger wafer sizes. A deposited particle having a diameter of 10% of the circuit width may cause a circuit to fail. With circuit line widths approaching 0.1 μm, particles of 0.01 μm are of concern. Many of today's facilities are designed to meet as-built air cleanliness of less than 30 particles 0.1 μm and larger per cubic metre of air.

Semiconductor Cleanroom Configuration

Semiconductor cleanrooms today are of two major configurations: the clean tunnel or the open-bay design. The **clean tunnel** is composed of narrow modular cleanrooms that may be completely isolated from each other. Fully HEPA or ULPA filtered pressurized plenums, ducted HEPA or ULPA filters, or individual fan modules are used in clean tunnel installations. Production equipment may be located within the tunnel or installed through the wall where a lower cleanliness level (nominally ISO Class 7 or cleaner) service chase is adjacent to the clean tunnel. The service chase is used in conjunction with either sidewall return or a raised floor. A basement return may also be-used with a raised floor.

The primary advantage of the tunnel is reduced HEPA or ULPA filter coverage and ease of expanding additional tunnel modules into unfiltered areas. The tunnel is typically between 2.5 and 4.3 m wide. If the tunnel is narrower, production equipment cannot be placed on both sides. If it is wider, the flow becomes too turbulent and tends to break toward the walls before it leaves the work plane. Figure 9 is a clean tunnel element.

The tunnel design also has the drawback of restricting new equipment layouts. Cleanroom flexibility is very valuable to semiconductor manufacturing logistics. As processes change and new equipment is installed, the clean tunnel may restrict equipment location to the point that a new module must be added. The tunnel approach may complicate the movement of product from one type of equipment to another.

The **open-bay design** involves large (up to 10 000 m^2) open-construction cleanroom layouts. Interior walls may be placed wherever manufacturing logistics dictate, thus providing maximum equipment layout flexibility. Replacement of process equipment with newer equipment is an ongoing process for most wafer fabrication facilities where support services must be designed to handle different process equipment layouts and even changes in process

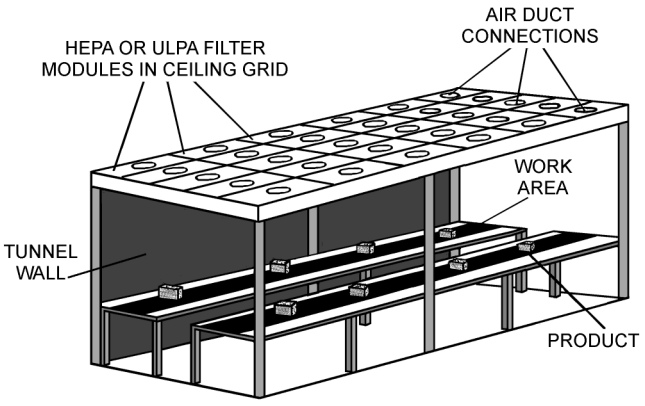

Fig. 9 Elements of a Clean Tunnel

function. Many times a manufacturer may completely redo the equipment layout if a new product is being made.

In the open-bay design, pressurized plenum or ducted filter modules are used, but pressurized plenums are becoming more common. When the pressurized plenum is used, either one large plenum with multiple supply fans or small adjacent plenums may be configured. Small plenums provide the ability to shut down areas of the cleanroom without disturbing other clean areas. Small plenums may also include one or more supply fans.

Major semiconductor facilities, with total manufacturing areas of 3000 m^2 and larger, may incorporate both open-bay and tunnel design configurations. Flexibility to allow equipment layout revisions warrants the open-bay design. Process equipment suitable for through-the-wall installation, such as diffusion furnaces, may use the tunnel design or open bay, whereas process equipment such as lithographic steppers and coaters must be located entirely under laminar flow conditions; thus, open-bay designs are more suitable. The decisions on which method to use, tunnel or open bay, should be discussed among the cleanroom designer, production personnel, and the contamination control specialist.

Many semiconductor facilities contain separate cleanrooms for process equipment ingress into the main factory These ingress areas are staged levels of cleanliness. For instance, the equipment receiving area may be ISO Class 8 for equipment uncrating while the next stage may be ISO Class 7 for preliminary equipment setup and inspection. The final stage, where equipment is cleaned and final installation preparations are made prior to the fabrication entrance, is ISO Class 6. In some cases, these staged cleanrooms must have adequate clear heights to allow forklifting of equipment subassemblies.

Airflow in Semiconductor Cleanrooms

Current semiconductor industry cleanrooms use **vertical unidirectional airflow**, which produces a uniform shower of clean air throughout the entire cleanroom. Particles are swept from personnel and process equipment, with contaminated air leaving at the floor level; this produces clean air for all space above the work surface. In contrast, horizontal airflow produces decreasing cleanliness downstream from the air inlet.

In vertical unidirectional airflow with cleanliness ISO Classes 3, 4, and 5, the cleanroom ceiling area consists of HEPA or ULPA filters set in a nominal grid size of 1200 mm by 2400 mm. HEPA or ULPA filters are set into a T-bar-style grid with gasketed or caulked seals for many ISO Class 5 systems; Class 3 and Class 4 systems often use either low-vapor pressure petrolatum fluid or silicone dielectric gel to seal the HEPA or ULPA filters into a channel-shaped ceiling grid. Whether T-bar or channel-shaped grids are used, the HEPA or ULPA filters normally cover 85 to 95% of the ceiling area, with the remainder of the ceiling area composed of gridwork, lighting, and fire protection sprinkler panels.

HEPA or ULPA filters in vertical unidirectional airflow designs are installed (1) with a pressurized plenum above the filters, (2) through individually ducted filters, or (3) with individually fan-powered filter modules. A system with a plenum must provide even pressurization to maintain uniform airflow through each filter. Ducted HVAC typically has higher static pressure loss from the ducting and balance dampers. Higher maintenance costs may also be incurred due to the balance method involved with ducted HVAC.

Individual fan-powered filter modules use fans with a power rating of less than 1 kW (usually forward-curved fans) that provide airflow through one filter assembly. This method allows airflow to be varied throughout the cleanroom and requires less space for mechanical components. The disadvantages of this method are the large number of fans involved, low fan and motor efficiencies due to the small sizes, potentially higher fan noises, and higher maintenance costs.

When through-the-floor return grating is used, a basement return is normally included to provide a more uniform return as well as floor space for "dirty" production support equipment.

Sidewall returns are an alternative to through-the-floor returns; however, airflow may not be uniform throughout the work area. As previously stated, these returns are most applicable for cleanrooms with double sidewall returns and widths less than 4.3 m.

Adequate prefiltration is an economical way to increase ULPA filter life. Prefilters are located in the recirculation airflow, either in the return basement or in the air handler. The prefilters should be located in the recirculated air to allow replacement without disrupting production.

Air Ionization. In addition to cleanroom particle control with fiber filters, air ionization is sometimes used to control particle attraction to product surfaces by eliminating electrostatic discharge and static charge buildup. However, the emitter tip material must be selected to prevent deposit of particles on the product.

HIGH-BAY CLEANROOMS

High-bay cleanrooms are those facilities with ceiling heights between 12 and 36 m. They are used primarily in the aerospace industry for the production and testing of missiles, launch vehicles, rocket engineers, communication and observation satellites, and jet aircraft assembly, painting, and cleaning operations. Crystal-pulling areas in semiconductor labs also use high-bay designs.

Most high-bay cleanrooms are designed to meet Class 7, Class 8 or an unofficial Class 8.5 called out in some U.S. Air Force and U.S. Navy specifications. If Class 6 or 5 is specified, the end user must be made to understand the tremendous economic impact this will have on the project costs.

Downflow and Horizontal Flow Designs

Downflow. In this design, air is delivered in a unidirectional (or simulated unidirectional) flow pattern from the ceiling and returned through floor return openings or low sidewall returns. The objective is to shower the object from above so that all particulate matter is flushed to the returns. The supply air terminals may be HEPA filter diffusers or high-volume air diffusers. Downflow rooms allow space flexibility because more than one device may be worked on in the room at the same air cleanliness level.

The disadvantage of downflow high-bay cleanrooms is the relative difficulty of balancing the airflow. High-bay cleanrooms typically have concrete floors that may include some trenches to return some of the air that is not taken in at low sidewall returns. Special care must be taken to ensure clean air at the object because the laminar flow pattern of the air disintegrates. At the low velocities associated with unidirectional design, pathways may be created toward the returns, causing the clean air to miss the object. Any activity in the cleanroom that generates even a small amount of heat produce updrafts in the downward-flowing supply air.

Horizontal Flow. Horizontal flow designs are always unidirectional with the cleanest air always available to wash the object in the room. Properly designed horizontal rooms are easier to balance than vertical flow rooms because the volumes of supply and return air may be controlled at different horizontal levels in the room.

The principal disadvantage of horizontal flow high-bay rooms is that they provide clean air for only one object, or at best, several objects, as long as they are in the same plane exposed to the supply air. Once past the object, the air cleanliness degrades to the extent the process generates that particles.

Downflow designs are most widely used, but certain projects such as the Space Telescope use horizontal high-bay cleanrooms.

Air-Handling

Due to the large volume of air in a high-bay cleanroom, a central recirculating fan system is commonly used with minimum heating

and cooling capability. A separate injection air handler provides heating, cooling, and makeup air. The injection system must include volumetric controls to ensure proper building pressure.

Equipment and Filter Access

Air-handling equipment and prefilters should be accessible from outside the cleanroom. Adequate provision must be made for filter change-out if air is distributed to the cleanroom with HEPA filters at the room entry. In horizontal cleanrooms, access should be from the upstream (pressure) side, and service scaffolds should be incorporated at least every 2.4 m in height of the filter bank. Downflow ceiling filters in T-bar ceilings or gel-seal ceilings must be accessed from below using an OSHA-approved gantry crane with full mobility across the ceiling. Prefilters in the main air supply should be placed in built-up frames with both upstream and downstream access. A HEPA filter bank remote from the room air distribution system should be installed in a built-up bank with a gel or clamp seal. Access doors must then be installed upstream and downstream for certification, scanning, and qualification testing.

Prefilter Selection

In any high-bay cleanroom class (except Class 8.5), air will pass through a final HEPA filter before entering the room, and these final filters must be protected by prefilters. HEPA filters in recirculating air should be protected with 85% rated bag or rigid media filters with no other prefilters present than required. Makeup air should include minimum 85% ASHRAE filters on the fan inlet and minimum 95% DOP filters on the fan discharge. This design cleans the makeup air sufficiency so that it is no longer a variable, regardless of the particle count of the outside air.

ENVIRONMENTAL SYSTEMS

Cooling Loads and Cooling Methods

Two major internal heat load components in cleanroom facilities are process equipment and fans. Because most cleanrooms are located entirely within conditioned space, traditional heat sources of infiltration, fenestration, and heat conductance from adjoining spaces are typically less than 2 to 3% of the total load. Some cleanrooms have been built with windows to the outside, usually for daylight awareness, and a corridor separating the cleanroom window from the exterior window.

The major cooling sources designed to remove cleanroom heat and maintain environmental conditions are makeup air units, primary and secondary air units, and the process equipment cooling system. Some process heat, typically heat from electronic sources in process equipment computers and controllers, may be removed by the process exhaust.

Fan energy is a very large heat source in ISO Class 4 or better cleanrooms. Recirculated room airflow rates of 0.45 m/s, which equals 500 plus air changes per hour, are typical for ISO Class 4 or better cleanrooms.

Latent loads are primarily associated with makeup air dehumidification. A low dry-bulb leaving air temperature (2 to 7°C), associated with dehumidified makeup air, supplements sensible cooling. Supplemental cooling by makeup air may account for as much as 900 W/m^2 of cleanroom.

Process cooling water (PCW) is used in process equipment heat exchangers, performing either simple heat transfer to cool internal heat sources, or process specific heat transfer, in which the PCW contributes to the process reaction.

The diversity of the manufacturing heat sources, that is, the portion of the total heat that is transferred to each cooling medium, should be well understood. When bulkhead or through-the wall equipment is used, the equipment heat loss to support chases versus to the production area will affect the cooling design when the support chase is served by a different cooling system than the production area.

Makeup Air

The control of makeup air and cleanroom exhaust affects cleanroom pressurization, humidity, and room cleanliness. The flow requirements of makeup air are dictated by the amount required to replace process exhaust and by air volumes for pressurization. Makeup air volumes can be much greater than the total process exhaust volume in order to provide adequate pressurization and safe ventilation.

Makeup air is frequently introduced into the primary air path on the suction side of the primary fan(s). Makeup volumes are adjusted with zone dampers and makeup fan controls using speed controllers, inlet vanes, etc. Opposed-blade dampers should have low leak characteristics and minimum hysteresis.

Makeup air should be filtered prior to injection into the cleanroom because it is the primary source of external particles in the cleanroom. If the makeup air is injected upstream of the cleanroom ceiling ULPA or HEPA filters, minimum 95% efficient filters (ASHRAE *Standard* 52.1) should be used to avoid high dust loading and reduced life of HEPA filters.

In addition, 30% efficient prefilters followed by 85% filters may be used to prolong the life of the 95% filter. When makeup air is injected downstream of the main HEPA filter, additional HEPA filtering of the makeup air should be added in with the previously mentioned prefilters. In addition to particle filtering, many makeup air handlers require filters to remove chemical contaminants present in the outside air. These contaminants include salts and pollutants from industries and automobiles. Chemical filtration may be accomplished with absorbers such as activated carbon or potassium permanganate impregnated with activated alumina or zeolite.

Process Exhaust

Process exhausts for semiconductor facilities handle acid, solvent, toxic, pyrophoric (self-igniting) fumes, and process heat exhaust. Process exhaust should be dedicated for each fume category, dedicated by process area, or based on the chemical nature of the fume and its compatibility with exhaust duct material. Typically, process exhausts are segregated into corrosive fumes, which are ducted through plastic or fiberglass reinforced plastic (FRP) ducts, and flammable (normally from solvents) gases and heat exhaust, which are ducted in metal ducts. Care must be taken to ensure that gases cannot combine into hazardous compounds that can ignite or explode within the ductwork. Segregated heat exhausts are sometimes installed to recover heat, or hot uncontaminated air that may be exhausted into the suction side of the primary air path.

Required process exhaust volumes vary from 5 L/s per square metre of cleanroom for photolithographic process areas, to 50 L/s per square metre for wet etch, diffusion, and implant process areas. When specific process layouts have not been designated prior to exhaust design, an average of 25 L/s per square metre is normally acceptable for fan and abatement equipment sizing. Fume exhaust ductwork should be sized at low velocities (5 m/s) to allow for future needs.

For many airborne substances, the American Conference of Governmental Industrial Hygienists (ACGIH) has established requirements to avoid excessive worker exposure. The U.S. Occupational Safety and Health Administration (OSHA) has set specific standards for the allowable concentration of airborne substances. These limits are based on working experience, laboratory research, and medical data; and they are subject to constant revision. When limits are to be determined, the *Industrial Ventilation: A Manual of Recommended Practices* (ACGIH 1998) may be referred to.

Fire Safety for the Exhaust

The Uniform Building Code (UBC) designates semiconductor fabrication facilities as Group H, Division 6, occupancies. The H-6 occupancy class should be reviewed even if the local jurisdiction does not use the UBC because it is currently the only major code in the United States specially written for the semiconductor industry and, hence, can be considered usual practice. This review is particularly helpful if the local jurisdiction has few semiconductor facilities.

Article 51 in the *Uniform Fire Code* (UFC) addresses the specific requirements for process exhaust relating to fire safety and minimum exhaust standards. UFC Article 80, Hazardous Materials, is relevant to many semiconductor cleanroom projects due to the large quantities of hazardous materials stored in these areas. Areas covered include ventilation and exhaust standards for production and storage areas, control requirements, use of gas detectors, redundancy and emergency power, and duct fire protection.

Temperature and Humidity

Precise temperature control is required in most semiconductor cleanrooms. Specific chemical processes may change under different temperatures, or masking alignment errors may occur due to product dimensional changes as a result of the coefficient of expansion. Temperature tolerances of ±0.5 K are common, and precision of 0.05 to 0.3 K is likely in wafer or mask writing process areas. Wafer reticle writing by electron beam technology requires ±0.05 K while photolithographic projection printers require ±0.3 K tolerance. Specific process temperature control zones must be small enough to counteract the large air volume inertia in vertical laminar flow cleanrooms. Internal environmental controls, which allow for room tolerances of ±0.5 K and larger temperature control zones, are used in many process areas.

Within temperature zones of the typical semiconductor factory, latent heat loads are normally small enough to be offset by incoming makeup air. Sensible temperature is controlled with either (1) cooling coils in the primary air stream, or (2) unitary sensible cooling units that bypass primary air through the sensible air handler and blend conditioned air with unconditioned primary air.

In most cleanrooms of ISO Class 6 or better, production personnel wear full coverage protective smocks that require a cleanroom temperature of 20°C or less. If full-coverage smocks are not used, a lower temperature set point is recommended for comfort. Process temperature set points may be higher as long as product tolerances are maintained.

Semiconductor humidity levels vary from 30 to 50% rh. Humidity control and precision are functions of process requirements, prevention of condensation on cold surfaces within the cleanroom, and control of static electric forces. Humidity tolerances vary from 0.5 to 5% rh, primarily dictated by process requirements. Photolithographic areas have the more precise standards and lower set points. Photoresists are chemicals used in photolithography, and their exposure timing can be affected by varying relative humidity. Negative resists typically require low (35 to 45%) relative humidity. Positive resists tend to be more stable, so the relative humidity can go up to 50% rh where there is less of a static electricity problem.

Independent makeup units should control the dew point in places where direct-expansion refrigeration, chilled water/glycol cooling coils, or chemical dehumidification are used. Chemical dehumidification is rarely used in semiconductor facilities due to the high maintenance cost and the potential for chemical contamination in the cleanroom. While an operating cleanroom generally does not require reheat, systems are typically designed to provide heat to the space when new cleanrooms are being built and no production equipment has been installed.

Makeup air is humidified by steam humidifiers or atomizing equipment. Steam humidifiers are most commonly used. Care should be taken to avoid the potential release of water treatment chemicals. Stainless-steel unitary packaged boilers with high-purity water and stainless-steel piping have also been used. Water sprayers, located in the cleanroom return, use air-operated water jet sprayers. Evaporative coolers have been used, taking advantage of the sensible cooling effect in dry climates.

Pressurization

Pressurization of semiconductor cleanrooms is another method of contamination control, providing resistance to infiltration of external sources of contaminants. Outside particulate contaminates enter the cleanroom by infiltration through doors, cracks, passthroughs, and other process-related penetrations for pipes, ducts, etc. Positive pressure in the cleanroom (as referenced to any less clean space) ensures that air flows from the cleanest space to the less clean space. Positive differential pressure in the cleanroom inhibits the entrance of unfiltered external particulate contamination.

A differential pressure of 15 kPa is a widely used standard. The cleanest cleanroom should maintain the highest pressure, with pressure decreasing corresponding to decreasing cleanliness.

Pressure within the cleanroom is principally established by the balance between process exhaust, leakage, makeup air volumes, and the supply and return air volumes. Process equipment vendors and industrial hygienists dictate process exhaust requirements, and they cannot be changed without safety risks. Cleanroom supply air volumes are also set by contamination control specialists. Control of makeup air and return air volumes are the primary means for pressure control. Pressure differences should be kept as low as possible while still creating the proper flow direction. Large pressure differences can create eddy currents at wall openings and cause vibration problems.

Static or active control methods are normally used in cleanroom pressure control. One method is used in lieu of the other based upon pressure control tolerance. Pressure control precision is typically ±2 to ±8 Pa; the owner's contamination control specialist specifies the degree of precision required. Many semiconductor processes where cleanroom pressure affects the process itself (e.g., glass deposition with saline gas) require process chamber pressure precision of ±600 mPa.

Static pressure control methods are suited for unchanging cleanroom environments, where the primary pressure control parameters (process exhaust and supply air volumes) either do not change or change slowly over weeks or months at a time. Static controls provide initial room pressure, and monthly or quarterly maintenance adjusts makeup and return volumes if the pressure level has changed. Static systems may include differential pressure gages for visual monitoring by maintenance personnel.

Active systems provide closed-loop control where pressure control is critical. Standard controls normally cannot maintain the differential pressure when doors without an air lock are opened. Active systems should be carefully evaluated as to their need, however.

Air locks may also be used to segregate pressures in the factory, but typically, air locks are used between uncontrolled personnel corridors, entrance foyers, and the protective-clothing (smocks) gowning area. Air locks may also be used between the gowning room and the main wafer fabrication area and for process equipment staging areas prior to ingress into the wafer fabrication area. Within the main portion of the factory, air locks are rarely used because they restrict personnel access, evacuation routes, and traffic control.

Sizing and Redundancy

The design of environmental HVAC must consider future requirements of the factory. Semiconductor products can become obsolete in as little as two years, and process equipment may be replaced as new product designs dictate. As new processes are added or old ones deleted (e.g., wet etch versus dry etch) the function of one

cleanroom may change from high-humidity requirements to low humidity, or the heat load many increase or decrease. Thus, the cleanroom designer must design for flexibility and growth. Unless specific process equipment layouts are available, maximum cooling capability should be provided in all process areas at the time of installation, or space should be provided for future installations.

Because cleanroom space relative humidity must be held to close tolerances, and humidity excursions cannot be tolerated, the latent load removal should be based on high ambient dew points and not on the high mean coincident dry-bulb/wet-bulb data.

In addition to proper equipment sizing, redundancy is also desirable when economics dictate it. Many semiconductor wafer facilities operate 24 hours per day, seven days per week, and shut down only during holidays and scheduled nonwork times. Mechanical and electrical redundancy is required if the loss of such equipment would shut down critical and expensive manufacturing processes. For example, process exhaust fans must operate continuously for safety reasons, while particularly hazardous exhaust should have two fans, both running. The majority of the process equipment is computer-controlled with interlocks to provide safety for personnel and products. Electrical redundancy or uninterrupted power supplies may be necessary to prevent costly downtime during power outages. Decisions regarding redundancy should be based on life-cycle economics.

ENERGY CONSERVATION IN CLEANROOMS

The major operating costs associated with a cleanroom include conditioning of makeup air, air movement in the cleanroom, and process exhaust. Environmental control, contamination control, and process equipment electrical loads can be as much as 3 kW/m^2. Besides process equipment electrical loads, most energy is used for cooling, air movement, and process liquid transport (i.e., deionized water and process cooling water pumping). A life-cycle cost analysis should determine the extent of energy reductions.

Fan Energy. Because flow rates in typical semiconductor facilities are 90 to 100 times greater than in conventional HVAC, and still very high in other cleanrooms, the fan system should be closely examined for ways to conserve energy. Static pressures and total airflow requirements should be designed to reduce operating costs. The fan energy required to move recirculation air may be decreased by reducing the air volume or static pressure. Energy conservation operating modes should be verified during qualification of the system. If these modes are not part of the original design, the control procedure must be changed and the operational change validated.

Air volumes may be lowered by decreasing HEPA or ULPA filter coverage or by reducing the cleanroom average air velocity. When air volumes are reduced, each square metre of reduced HEPA coverage saves 250 to 500 W/m^2 in fan energy and the same amount in cooling load. Reducing room average velocity from 0.45 to 0.40 m/s saves 50 W/m^2 in fan energy and the same amount in cooling energy. If the amount of air supplied to the cleanroom cannot be lowered, reductions in static pressure can produce significant savings. With good fan selection and transport design, up to 150 W/m^2 can be saved per 250 Pa reduction in static pressure. Installing low pressure drop HEPA filters, pressurized plenums in lieu of ducted filters, and proper fan inlets and outlets, may reduce static pressure. Many cleanrooms operate for only one shift. Air volume may be reduced during nonworking hours by using two-speed motors, variable-frequency drives, inverters, inlet vanes, and variable-pitch fans or, in multifan systems, by using only some of the fans.

Additional energy may be saved by installing high-efficiency motors on fans instead of standard-efficiency motors. Good fan selection also influences energy cost. The choice of forward-curved centrifugal fans versus backward-inclined, airfoil, or vaneaxial fans affects efficiency. The number of fans used in a pressurized plenum design influences redundancy as well as total energy use. The fan size changes power requirements as well. Different options should be investigated.

Makeup and Exhaust Energy. As stated previously, process exhaust requirements in the typical semiconductor facility vary from 5 to 50 L/s per square metre. Makeup air requirements vary correspondingly, with an added amount for leakage and pressurization. The energy required to supply the conditioned makeup air can be quite large. The type of equipment installed normally determines the quantity of exhaust in a given facility. Heat recovery has been used effectively in process exhaust. When heat recovery is used, the heat exchanger material must be selected carefully due to the potentially corrosive atmosphere. Also, heat recovery equipment has the potential to cross-contaminating products in pharmaceutical facilities.

Makeup air cannot normally be reduced without decreasing the process exhaust. Due to safety and contamination control requirements, process exhaust may be difficult to reduce. Therefore, the costs of conditioning the makeup air should be investigated. Conventional HVAC methods, such as use of high-efficiency chillers, good equipment selection, and precise control design can also save energy. One energy-saving method uses multiple-temperature chillers to bring outdoor air temperature for large facilities to a desired dew point in steps.

NOISE AND VIBRATION CONTROL

Noise is difficult to control. Noise generated by contamination control equipment requires particular attention, although production equipment noise may be more significant than HVAC noise. Prior to the start of the design, the noise and vibration criteria should be established. Chapter 46 provides more complete information on sound control.

In normal applications of microelectronics contamination control, equipment vibration displacement levels need not be dampened below 0.5 μm in the 1 to 50 Hz range. However, electron microscopes and other ultrasensitive microelectronics cleanroom instruments may require smaller deflections in different frequency ranges. Photolithographic areas may prohibit floor deflections greater than 0.075 μm. As a general rule, the displacement should not exceed one-tenth the line width.

For highly critical areas, vaneaxial fans may be considered. These fans generate less noise in the lower frequencies, and they may be dynamically balanced to displacements of less than 4 μm, which decreases the likelihood of transmitting vibration to sensitive areas in electronics cleanrooms.

ROOM CONSTRUCTION AND OPERATION

Control of particulate contamination from sources other than the supply air depends on the classification of the space, the type of system, and the operation involved. Typical details that may vary with the room class include the following:

Construction Finishes

- **General.** Smooth, monolithic, cleanable, and chip-resistant, with minimum seams, joints, and no crevices or moldings
- **Floors.** Sheet vinyl, epoxy, or polyester coating with wall base carried-up, or raised floor (where approved) with and without perforations using the above materials
- **Walls.** Plastic, epoxy-coated drywall, baked enamel, polyester, or porcelain with minimum projections
- **Ceilings.** Plaster covered with plastic, epoxy, or polyester coating or with plastic-finished clipped acoustical tiles (no tiles in pharmaceutical cleanrooms) when entire ceiling is not fully HEPA or ULPA filtered
- **Lights.** Teardrop-shaped single lamp fixtures mounted between filters, or flush-mounted and sealed

- **Service penetrations.** All penetrations for pipes, ducts, conduit runs, etc. fully sealed or gasketed
- **Appurtenances.** All doors, vision panels, switches, clocks, etc. either flush-mounted or sloped tops
- **Windows.** All windows flush with wall; no ledges on cleanest side

Personnel and Garments

- Hands and face cleaned before entering area
- Lotions and soap containing lanolin to lessen the emission of skin particles
- No cosmetics and skin medications
- No smoking and eating
- Lint-free smocks, coveralls, gloves, head covers, and shoe covers

Materials and Equipment

- Equipment and materials are cleaned before entry.
- Nonshedding paper and ballpoint pens are used. Pencils and erasers are not permitted.
- Work parts are handled with gloved hands, finger cots, tweezers, and other methods to avoid transfer of skin oils and particles.
- Sterile pharmaceutical product containers must be handled with sterilized tools only.

Particulate Producing Operations

- Electronics grinding, welding, and soldering operations are shielded and exhausted.
- Nonshedding containers and pallets are used for transfer and storage of materials.

Entries

- Air locks and pass-throughs maintain pressure differentials and reduce contamination.

CHAPTER 16

DATA PROCESSING AND ELECTRONIC OFFICE AREAS

Design Criteria 16.1
Cooling Loads 16.2
Air-Conditioning Systems 16.2
Supply Air Distribution 16.4
Return Air 16.5
Direct-Cooled Computer Equipment 16.5
Air-Conditioning Components 16.5
Instrumentation 16.6
Fire Protection 16.6
Energy Conservation and Heat Recovery 16.6

DATA PROCESSING and electronic office areas contain computers, electronic equipment, and peripheral equipment needed for data processing functions. Computer equipment has expanded beyond the traditional computer room to become an integral part of the entire office environment.

Computers and electronic equipment generate heat and gaseous contaminants; such equipment usually contains components vulnerable to temperature and humidity variations, dust and other air impurities, and static electrical discharge. Exposure to conditions deviating from prescribed limits can cause improper operation or complete shutdown of equipment and may substantially reduce equipment useful life expectancy (Weschler and Shields 1991). Loss of equipment function or data can cause significant, sometimes irreparable, damage to organizations that depend on it.

Ancillary spaces for computer-related activities or for storage of computer components and materials may require environmental conditions comparable to those where the computers are housed, although tolerances may be wider and the degree of criticality is usually much lower. Other ancillary areas housing such auxiliary equipment as engine generators, motor generators, uninterruptible power supplies (UPSs), and transformers have less stringent air-conditioning and ventilating requirements than do computer areas, but the continuing satisfactory operation of this equipment is vital to the proper functioning of the computer system.

DESIGN CRITERIA

Computer Rooms

Data processing spaces that house mainframe computers, computer personnel, and associated equipment require air conditioning to maintain proper environmental conditions for both the equipment and personnel. Computer room environments should be maintained within established limits and not be subjected to rapid changes.

Table 1 Typical Computer Room Design Conditions

Condition	Recommended Level
Temperature control range[a]	22ºC ± 1ºC
Relative humidity control range[a]	50 ± 5%
Filtration quality[b]	45%, min. 20%

[a]These conditions are typical of those recommended by most computer equipment manufacturers.
[b]From ASHRAE *Standard* 52.1 dust-spot efficiency test.

Table 2 Design Conditions for Air Supply Direct to Computer Equipment

Condition	Recommended Level
Temperature	As required for heat dissipation
Relative humidity[a]	Maximum 65%
Filtration quality[b]	45% minimum

[a] Some manufacturers permit up to 80% rh.
[b] As per dust spot efficiency test in ASHRAE *Standard* 52.1.

The environmental conditions required by computer equipment vary, depending on the manufacturer and the type of equipment supported. Table 1 lists conditions recommended for most computer rooms. Most computer manufacturers recommend that the computer equipment draw conditioned air from the room. Some equipment may require direct cooling using conditioned air, chilled water, or refrigerant. Criteria for air-cooled computers may differ from those cooled by room air in that this air must remove computer equipment heat adequately and preclude the possibility of condensation of moisture within the equipment (see Table 2).

Because of the large amount of heat released in data processing areas, designs should minimize new energy use for cooling, humidification, and dehumidification.

Room Environmental Requirements

The distribution of air in the room and/or the response of controls may not match the nonuniform heat distribution of the equipment. Modern computer equipment is controlled to minimize energy input, which results in a much wider variation in power consumption and heat release than for older equipment.

High relative humidity may cause improper feeding of paper, corrosion, and, in extreme cases, condensation on cold surfaces of direct-cooled equipment. Low relative humidity, combined with other factors, may result in static discharge, which can destroy or adversely affect the operation of data processing and electronic equipment. Volatile organic compounds can plate onto critical surfaces like disk drives, causing the head to crash, and onto printed circuit boards where dust and static electricity can induce stray currents in very low voltage applications.

Before it is introduced into the computer room, outdoor air should be treated and preconditioned to remove dust, salts, and corrosive gases. Dust can adversely affect the operation of data processing equipment, so high-quality filtration and proper filter maintenance are essential. Corrosive gases can quickly destroy the thin metal films and conductors used in printed circuit boards, and corrosion can cause high resistance at terminal connection points.

Computer room air conditioning must provide adequate outdoor air (1) to dilute internally generated contaminants and (2) to maintain the room under positive pressure relative to surrounding spaces. The need to maintain positive pressure to keep contaminants out of the room is usually a controlling design criterion. An outdoor air quantity of 6 to 8 air changes per day usually satisfies contaminant dilution requirements (Weschler and Shields 1991). Although most computer rooms have few occupants, ventilation for human occupancy should be provided in accordance with ASHRAE *Standard* 62. Where outdoor air is diluted with recirculated air from the computer room or adjacent areas, higher ventilation rates are required.

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

The air-conditioning equipment for computer spaces should be served by electrically isolated power sources to prevent electrical noise from adversely affecting computer equipment operation and reliability. Equipment located in computer spaces should be independently supported and isolated to prevent vibration transmission to the computer equipment. Computer equipment manufacturers should be consulted regarding computer equipment sound tolerance and specific requirements for vibration isolation.

Temperature, humidity, and filtration requirements for the equipment are within the comfort range for room occupants, but drafts and cold surfaces must be minimized in occupied areas. Some manufacturers have established criteria for allowable rates of environmental change to prevent shock to the computer equipment. These can usually be satisfied by high-quality, commercially available controls with control ranges of ± 0.5 K and ± 5% rh. The manufacturer's requirements should be reviewed and fulfilled to ensure that the system will function properly during normal operation and during periods of start-up and shutdown. Computer equipment usually tolerates a somewhat wider range of environmental conditions when idle, but it may be desirable to operate the air conditioning to keep the room within those limits and minimize thermal shock to the equipment.

Because computer technology is continually changing, computer equipment in a given space will be changed and/or rearranged during the life of an air-conditioning system. The system must be sufficiently flexible to permit rearrangement of components and expansion without requiring rebuilding. In the typical installation, it should be possible to modify the system without extensive air-conditioning shutdowns. In critical applications, it should be possible to modify the system without shutdown.

Isolation of Computer Spaces

Computer equipment spaces are usually isolated for security and environmental control. To maintain proper relative humidity in computer rooms in otherwise unhumidified spaces, vapor retarders sufficient to restrain moisture migration during the maximum expected vapor pressure differences between the computer room and surrounding areas should be installed around the entire envelope. Cable and pipe entrances should be sealed and caulked with a vapor-retarding material. Door jambs should fit tightly. In exterior walls in colder climates, windows should be double- or triple-glazed and door seals are required.

Ancillary Spaces Environment

Storage spaces for products such as paper and tapes generally require conditions similar to those in the computer room.

Electrical power supply and conditioning equipment can tolerate more variation in temperature and humidity than computer equipment. Equipment in this category includes motor generators, UPSs, batteries, voltage regulators, and transformers. Ventilation to remove heat from the equipment is normally sufficient. Manufacturers' data should be checked to determine the amount of heat release and the design conditions for satisfactory operation.

Battery rooms for UPSs require ventilation to remove hydrogen and to control the space temperature. The optimum space temperature is 25°C. Temperatures maintained higher or lower reduce the ability of batteries to hold a charge. Hydrogen accumulation may be no greater than 3% by volume, and the ventilation should be designed to prevent pockets of concentration, particularly at the ceiling.

Engine generators used for primary or emergency power require large amounts of ventilation when running. This equipment is easier to start if a low ambient temperature is avoided.

COOLING LOADS

The major heat source in a computer room is the equipment. This heat tends to be highly concentrated, nonuniformly distributed, and increasingly variable. Computer components that generate large quantities of heat are normally constructed with internal fans and passages to convey cooling air, usually drawn from the space, through the machine. Heat gain from lights should be no greater than that in good-quality office space; occupancy loads will be low to moderate. Heat gains through the structure depend on the location and construction of the room. Transmission heat gain to the space should be carefully evaluated and provided for in the design. Vapor retarder analyses should be performed where humidity-controlled spaces contain windows on outside walls.

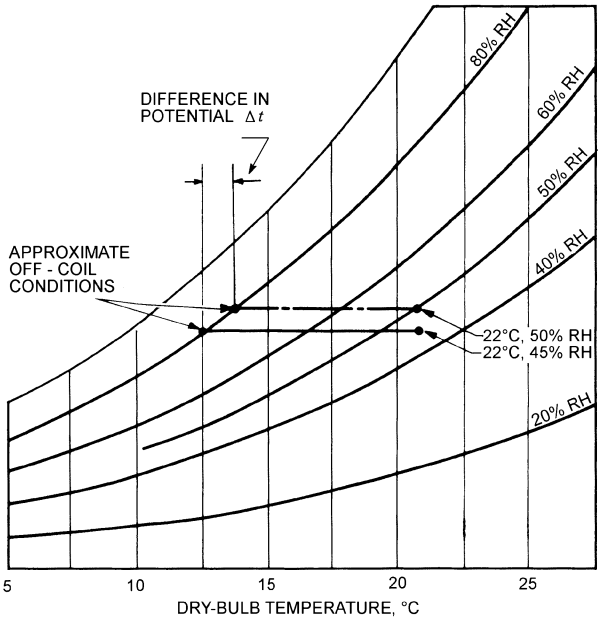

Fig. 1 Potential Effect of Room Design Conditions on Design Supply Air Quantity

Information on computer equipment heat release should be obtained from the specific computer manufacturers. In general, systems should be sized without a reduction for diversity, unless the computer manufacturer or experience with a similar installation recommends it.

Heat generated in computer rooms is almost entirely sensible. For this reason and because of the low room design temperatures, air supply quantity per unit of cooling load will be greater than for most comfort applications. Figure 1 shows that choosing room design at 22°C, 45% rh can reduce air supply quantity by approximately 15% compared to a slightly more humid room design of 22°C, 50% rh. A sensible heat ratio between 0.9 and 1.0 is common for computer room applications.

AIR-CONDITIONING SYSTEMS

It may be desirable for air-handling systems for data processing areas to be independent of other systems in the building, although cross-connection with other systems may be desirable for backup. Redundant air-handling equipment is frequently used, normally with automatic operation. The air-handling facilities should provide ventilation air, air filtration, cooling and dehumidification, humidification, and heating.

The refrigeration systems should be independent of other systems and may be required year-round, depending on design approach.

Computer rooms are being successfully conditioned with a wide variety of systems, including packaged precision air-conditioning units and central station air-handling systems. Air-handling and refrigeration equipment may be located either inside or outside computer rooms.

Precision Air-Conditioning Units

Precision air-conditioning units should be specifically designed for computer room applications and built to and tested in accordance with the requirements of ASHRAE *Standard* 127. Precision air-conditioning units are available with chilled water or multiple refrigerant compressors with separate refrigeration circuits; air filters; humidifiers; reheat; and integrated control systems with remote monitoring panels and interfaces. These units may also be equipped with dry coolers and propylene glycol precooling coils to permit water-side economizer operation where weather conditions make this strategy economical.

Self-contained air conditioners are usually located within the computer room but may also be remotely located and ducted to the conditioned space. If they are remote, their temperature and humidity controls should be in the conditioned space. Locating the air conditioner close to the load improves system flexibility to accommodate the changing load patterns common in computer rooms. Location in the computer room is practical because remote units may not have security protection beyond standard building maintenance. Where security is an issue, special attention should be paid to protecting the refrigerant condensing equipment for remote units.

In systems using precision air-conditioning units, it may be advantageous to introduce outdoor air through a dedicated system serving all data processing areas. Redundancy can be achieved with multiple units so that the loss of one or more units has less impact on overall system performance. Expansion of an existing data processing facility is often easier with precision air-conditioning units than with central station systems.

A set point of 22°C with constant volume precision air-conditioning units generally permits equipment to remain at an acceptable temperature within the established range for satisfactory operation. This low control set-point temperature provides a cushion for short-term peak load temperature rise without adversely affecting computer operation. Compared to constant volume units, variable volume equipment can be sized to provide excess capacity but will operate at discharge temperatures appropriate for optimum humidity control, minimize operational fan power requirements, provide superior control over space temperature, and reduce the need for reheat.

When chilled water precision air-conditioning units are used, the reliability of the remote refrigeration system must be considered. This system generally must be capable of operating 24 h per day, and provisions must be made for a year-round supply of chilled water. Chilled water precision air-conditioning units do not contain refrigeration equipment; and they generally require less servicing, can be more efficient, and more readily support heat recovery strategies than direct-expansion equipment.

Central Station Air-Handling Units

Central station supply systems must be designed to accommodate expanding loads in the computer areas. These systems must include filters, humidification, dehumidification, and controls. Central station supply systems have a larger capacity than precision air-conditioning units and offer significantly greater opportunities for energy conservation. Systems that use direct evaporative humidification with mechanical cooling and variable volume control allow the use of outdoor air for free cooling without a humidification energy penalty (see Chapter 50, Evaporative Cooling Applications). Waste heat from computer equipment can be used to provide the heat of vaporization.

By using discharge air temperature as a method of dew-point control, variable volume ventilation from air-handling equipment, using evaporative equipment with a saturation effectiveness of 90% or higher, can provide effective humidity control without humidity sensing or active control. Figure 2 illustrates a central station unit

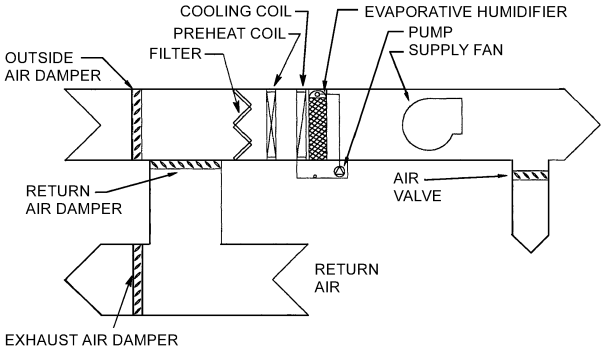

Fig. 2 Constant Temperature/Dew-Point Air-Handling Unit

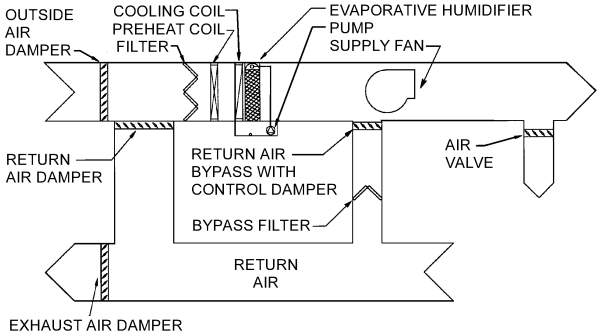

Fig. 3 Air-Handling Unit with Return Air Bypass

configuration that provides air at a constant temperature and dew point. As this cool air is provided at rates to maintain space temperature design conditions, space relative humidity becomes a direct function of space temperature, eliminating the need for expensive and unreliable humidity controls. Efficiency is increased by the evaporative process, which can use waste heat from the computers to provide the necessary heat of vaporization for humidification.

Because data processing areas have an extremely high sensible heat ratio, variable volume becomes a viable strategy, further reducing energy use. The evaporative process eliminates the need for refrigeration at temperatures below the supply air temperature of the system and reduces the need for refrigeration for significant periods of time when outside air conditions permit an evaporative cooling benefit. Stable, less-than-saturated air conditions can be achieved by bypassing system return air around the evaporative process to warm and dehumidify the supply air (see Figure 3).

Central station air-handling equipment should be arranged for convenient servicing and maintenance. Flexibility and redundancy can be achieved by using variable volume distribution, oversizing, cross-connecting multiple systems, or providing standby equipment. No floor space in the computer room is required, and sources of water and refrigeration may be eliminated from the computer room. Virtually all servicing and maintenance operations are performed in areas devoted specifically to air-conditioning equipment. System security issues, however, must be addressed.

Central systems serving computer rooms may serve other building functions if designed to provide continuous, year-round operation and to meet the cooling and humidification requirements. Central systems are superior to precision air-conditioning units for the electronic office area where overall environmental requirements may approach those of the computer room. Care should be taken to exercise redundant equipment frequently to prevent conditions that enhance the growth of mold and mildew in filters, insulated unit enclosures, and outdoor air pathways where spores and food sources for microbial growth may accumulate.

SUPPLY AIR DISTRIBUTION

To minimize room temperature gradients, supply air distribution should closely match load distribution. Distribution systems should be sufficiently flexible to accommodate changes in the location and magnitude of the heat gains with minimum change in the basic distribution system. Air distribution system materials should ensure a clean air supply. Duct or plenum material that may erode must be avoided. Access for cleaning is desirable.

Zoning

Computer rooms should be adequately zoned to maintain temperatures within the design criteria and to minimize temperature variations due to load fluctuations. Individual control for each major zone is desirable. The controlling thermostat must be located where it will sense the average conditions in the area it serves. In larger areas, temperature variations within a single room may occur, and subzoning of spaces may be desirable.

Underfloor Plenum Supply

To facilitate the interconnection of equipment components by electric cables, data processing equipment is usually set above a false floor, which affords a flat walking surface over the space where the connecting cables are installed. This space can be used as an air distribution channel, either as a plenum or, less often, to accommodate ducts.

Figure 4 shows a typical set up with underfloor plenum air supply. Air is distributed to the room through perforated panels or registers set or built into floor panels around the room, especially in the vicinity of computer equipment with high heat release. Airflow can be controlled by the size, location, and quantity of floor registers and perforated floor panels. These systems have the flexibility to accommodate relocation of computer equipment and future additional heat loads. All air should flow through openings in the underfloor cavity unless direct flow to a computer unit is desired. The potential adverse effect of direct air supply on the computer equipment (i.e., condensation within the machine) is serious enough to discourage its use unless the manufacturer requires it. Most openings between the underfloor space and the equipment usually exist to accommodate cables; collars are available that fit the cable and seal the opening.

Floor panels can be similar in appearance to, and interchangeable with, conventional computer room floor panels. The free area of floor panels may vary significantly between manufacturers. Because they are completely flush with the floor, perforated floor panels are suitable for installation in normal traffic aisles. With moderate airflows, panels located fairly close to equipment can produce a high degree of mixing near the point of discharge and will better prevent drafts and injection of unmixed conditioned air into computers than floor registers. Figure 5 shows typical floor panel air performance.

Floor-mounted registers allow volume adjustment and are capable of longer throws and better directional control than perforated floor outlets. Floor registers, however, should be located outside traffic areas. Some are not flush-mounted, and almost all tend to be draftier for nearby personnel than perforated floor panels with lower induction ratios.

Sufficient clearance to permit airflow must exist beneath a raised plenum floor: 300 mm of clearance is desirable, and 250 mm is the usual minimum. In applications where cabling is extensive and/or air quantities are especially high, additional floor clearance may be required. The supply air connections into an underfloor cavity should be designed to minimize air turbulence. Where possible, the supply to the cavity should be central to the area served, and abrupt changes in direction should be avoided. Piping, cable, and conduit should not be permitted to interfere with supply airflow.

Where multiple zones are served from an underfloor plenum, dividing baffles may be omitted because air will follow the path of least resistance. Dividing baffles required to meet fire codes can impede the modification of computer systems having cabling interconnections between zones because any cable change may entail penetration of a zone baffle.

Plenums should be airtight, thoroughly cleaned, and smoothly finished to prevent entrainment of foreign materials in the airstream. The use and method of construction of plenums may be restricted by local codes or fire underwriter regulations. Surfaces in underfloor plenums (e.g., water, chilled water, brine, or refrigerant piping) may require insulation and a vapor retarder if surface temperatures are low enough to cause condensation. If this is the case, water detectors should be installed to protect computers and underfloor wiring.

Ceiling and Ceiling Plenum Supply

Overhead supply through ceiling diffusers, shown in Figure 6, may be suitable for computer rooms. Ceiling and ceiling plenum supply systems can satisfy equipment and personnel comfort requirements, but they are generally not as flexible as underfloor plenum supply systems. This arrangement is compatible with both central station and packaged unitary equipment.

Distribution of air can be regulated by selective placement of acoustical pads on the perforated panels of a metal panel ceiling or by placement of active perforated sections in a lay-in acoustical tile plenum ceiling. Where precise distribution is essential, active ceiling diffusers or air supply zones may be equipped with air valves. Ceiling plenums, if properly constructed and cleaned, are more likely to remain clean than underfloor plenums.

Ceiling plenums must be sufficiently deep to permit airflow without turbulence; the required depth depends on air quantities. Best conditions may be achieved by using distribution ductwork,

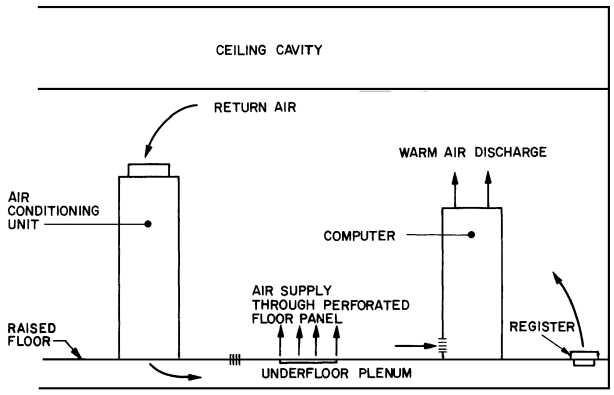

Fig. 4 Typical Underfloor Distribution

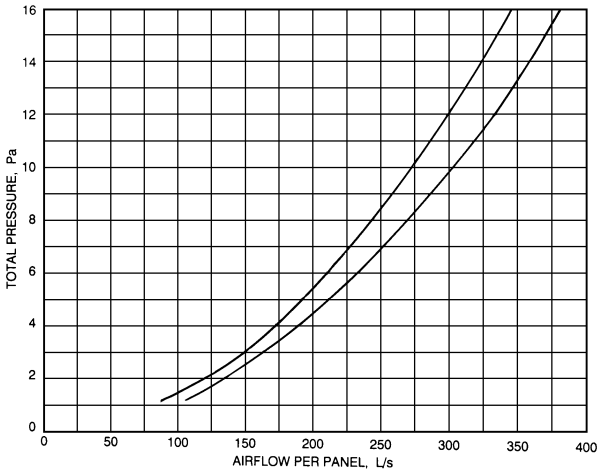

Fig. 5 Floor Panel Air Performance

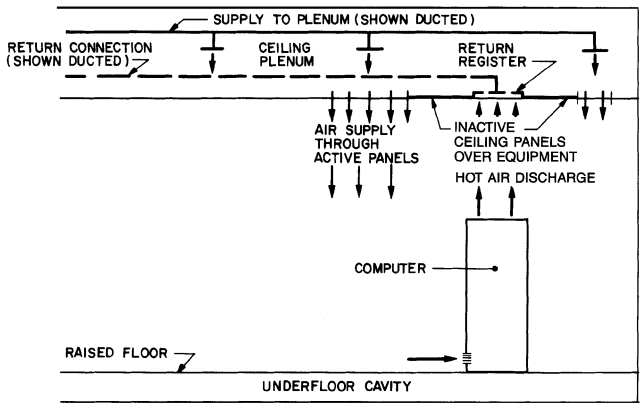

Fig. 6 Typical Ceiling Plenum Distribution

with the air discharged into the space through air valves or adjustable outlets above the ceiling. Overhead supply systems should be limited to applications where air supply concentrations are low or the need for flexibility is small. Where loads are high, aspirating diffusers may cause drafts, especially if the ceilings are low. It can be difficult to relocate rigidly ducted outlets in a facility that must remain in continuous operation.

RETURN AIR

The use of ceiling plenum returns is a common and effective strategy. Inlets should be located above equipment having high heat dissipation to take advantage of the thermal plume created above the equipment. Ceiling plenum returns can capture a portion of the heat from the computers and the lights directly in the return airstream, allowing a reduced air circulation rate. Ceiling plenum returns enhance the flexibility of the space to support future modifications of the computer installation.

DIRECT-COOLED COMPUTER EQUIPMENT

The majority of cooling in direct-cooled equipment is still accomplished with space air. Some computer equipment requires direct cooling to maintain the equipment environment within the limits established by the manufacturer. Heat released to the space from this equipment is usually equal to or greater than that for similar air-cooled computer systems. Generally, a closed system circulates distilled water or refrigerant through passages in the computer to cool it. Manufacturers normally supply the cooling system as part of the computer equipment.

Chilled water may be provided by either a small chiller matched in capacity to the computer equipment or a branch of the chilled water system serving the air-handling units. Design and installation of chilled water or refrigerant piping, and selection of the operating temperatures, should minimize the potential for leaks and condensation, especially within the computer room, while satisfying the requirements of the systems served. Chilled water systems for water-cooled computer equipment must be designed (1) to provide water at a temperature within the manufacturer's tolerances and (2) to be capable of operating year-round, 24 h per day.

AIR-CONDITIONING COMPONENTS

Controls

A well-planned control system must coordinate the performance of the temperature and humidity equipment. Controls for central station air-handling equipment may be included in a project-specific control system. Space temperature and humidity sensors should be carefully located to sample room conditions accurately.

Where multiple packaged units are provided, integration of control systems and regular calibration of controls is necessary to prevent individual units from working against each other. Errors in control system calibration, differences in unit set points, and sensor drift can cause multiple-unit installations to simultaneously heat and cool, and/or humidify and dehumidify, wasting a significant amount of energy.

Refrigeration

Refrigeration systems should be designed to match the anticipated cooling load, should be capable of expansion, and may be required to provide year-round, continuous operation. A separate refrigeration facility for the data processing area may be desirable where system requirements differ from those provided for other building and process systems and/or where emergency power requirements preclude combined systems. The system must provide the reliability and redundancy required to match the facility's needs. System operation, servicing, and maintenance should not interfere with facility operation. If required, the refrigeration system should be operable with emergency power. Fulfillment of these requirements may necessitate multiple units or cross-connections with other reliable systems. If the installation is especially critical, it may be necessary to install up to 100% standby capacity to meet the minimum requirements in the event of equipment failure.

Humidification

Many types of humidifiers may be used to serve data processing areas, including steam-generating (remote or local), pan types (with immersion elements or infrared lamps), and evaporative types (wetted pad and ultrasonic). Ultrasonic devices should use deionized water to prevent the formation of abrasive dusts from the crystallization of dissolved solids in the water. The humidifier must be responsive to control, maintainable, and free of moisture carryover. See Chapter 20 of the 2000 *ASHRAE Handbook—Systems and Equipment* for more information on humidifiers.

When an air-side economizer is used in the cooling of computer areas, evaporative humidification should be considered due to its ability to use waste heat energy to meet humidification requirements. Water-side economizers are economically feasible in some climates but do not have the energy efficiency potential of air-side approaches and may not provide adequate dilution ventilation.

Chilled Water Distribution Systems

Chilled water distribution systems should be designed to the same standards of quality, reliability, and flexibility as other computer room support systems. Where growth is likely, the chilled water system should be designed for expansion or the addition of new equipment without extensive shutdown. Figure 7 illustrates a looped chilled water system with sectional valves and multiple valved branch connections. The branches could serve air handlers or water-cooled computer equipment. The valves permit modifications or repairs without complete shutdown.

Where chilled water serves packaged equipment within the computer room, chilled water temperatures should be selected to satisfy the space sensible cooling loads while minimizing the risk of excessive condensation. Because computer room loads are primarily sensible, chilled water should be relatively warm. Water temperatures as high as 9°C are still slightly below the dew point of a 22°C, 45% rh room and several degrees below that of a 22°C, 50% rh room.

Chilled water and glycol piping must be pressure-tested, fully insulated, and protected with an effective vapor retarder. The test pressure should be applied in increments to all sections of pipe in the computer area. Drip pans piped to an effective drain should be placed below any valves or other components within the computer room that cannot be satisfactorily insulated. A good-quality strainer

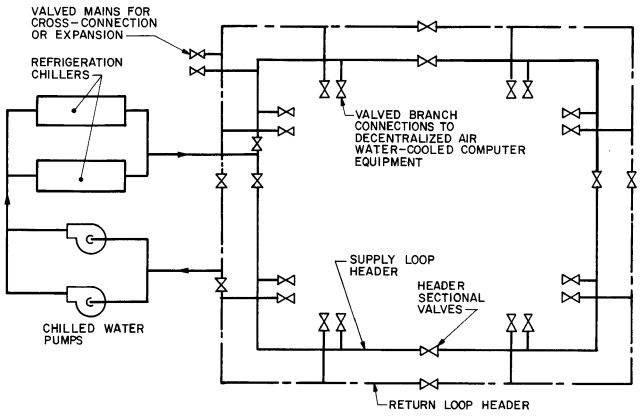

Fig. 7 Chilled Water Loop Distribution

should be installed in the inlet to local cooling equipment to prevent control valve and heat exchanger passages from clogging.

If cross-connections with other systems are made, possible effects on the computer room system of the introduction of dirt, scale, or other impurities must be addressed.

Redundancy

System reliability is so vital that the potential cost of system failure may justify redundant systems, capacity, and/or components. The designer should identify potential points of failure that could cause the system to interrupt critical data processing applications and should provide redundant or backup systems.

It may be desirable to cross-connect refrigeration equipment for backup, as suggested for air-handling equipment. Redundant refrigeration may be required; the extent of the redundancy depends on the importance of the computer installation. In many cases, standby power for the computer room air-conditioning system is justified.

Any complication to the basic conditioning system that might impair its reliability or otherwise adversely affect performance should be carefully considered before incorporation of heat recovery into the design. Potential monetary loss from system malfunction or unscheduled shutdown may outweigh savings from increased operating efficiency.

INSTRUMENTATION

Because computer equipment malfunctions may be caused by or attributed to improper regulation of the computer room thermal environment, it may be desirable to keep permanent records of the space temperature and humidity. If air is supplied directly to computer equipment, these records can be correlated with equipment function.

Alarms should be provided to signal when temperature or humidity limits are violated. With water-cooled computers, records should be kept of the entering and exiting water temperature and pressure. Indicating thermometers and pressure gages should be placed throughout the system so that operators can tell at a glance when unusual conditions prevail. Properly maintained and accurate gages for air-handling equipment filters can help prevent loss of system capacity and maintain correct computer room conditions. Sensing devices to indicate leaks or the presence of water in the computer room underfloor cavity are desirable in spaces served by precision air-conditioning units, especially if brine or chilled water distribution piping is installed within a computer room. Low points in drip pans installed beneath piping should also be monitored.

All monitoring and alarm devices should provide local indication. Monitoring devices many be interfaced with an integrated control or remote monitoring system that permits indications of system malfunctions to be transmitted to a remote location to initiate critical and maintenance alarms.

FIRE PROTECTION

Fire protection for the air-conditioning system should be integrated with fire protection for the computer room and for the whole facility. Applicable codes must be complied with, and the owner's insurers must be consulted. Automatic extinguishing systems afford the highest degree of protection. Fire underwriters often recommend an automatic sprinkler system. If a sprinkler system is used, a preaction, dry type should be used. Local annunciation of alarm points should be provided, and multiple stages of alarm and sprinkler system initiation should be used to prevent accidental discharge of sprinklers.

Sensing devices should be placed in the occupied space, the supply- and return-air passages, and the underfloor cavity (if it contains electric cables but is not used as an air supply plenum). These devices should provide early warning of combustion products, even if no smoke is visible and temperatures are at or near normal levels, to permit active measures to be taken to prevent damage or unscheduled shutdown of computer systems. All fire protection systems should provide for either manual or automatic shutdown of computer power, depending on the importance of the system and on the potential effect of an unwarranted shutdown (NFPA *Standard* 70).

Exhaust systems may be provided to ventilate computer rooms in the event of a fire suppression system discharge. Location of the exhaust pickup point below a supply plenum floor promotes quick purging of the space.

ENERGY CONSERVATION AND HEAT RECOVERY

Energy Conservation

Dramatic reductions in energy use can be achieved with conservation strategies. Where secondary uses for recovered heat do not exist or justify the use of heat recovery, central station air-conditioning systems using outdoor air for free cooling, variable volume ventilation, and evaporative cooling/humidification strategies offer significant opportunities for reducing energy use and improving air quality over precision air-conditioning systems. A dew-point control strategy can eliminate the need for troublesome humidity sensing devices and provide precise humidity control.

These same strategies may be employed to provide efficient and cost-effective solutions on a larger scale within the electronic office and other support environments.

Heat Recovery

If a use for recovered energy exists, computer rooms are good candidates for heat recovery because of their large year-round loads. Heat rejected during condensing can be used for space heating, domestic water heating, or other process heat. If the heat removed by the conditioning system can be efficiently transferred and applied elsewhere in the facility, some operational cost saving may be realized.

CHAPTER 17

PRINTING PLANTS

Design Criteria 17.1
Control of Paper Moisture Content 17.2
Platemaking 17.2
Relief Printing 17.3
Lithography 17.3
Rotogravure 17.4
Other Plant Functions 17.4

THIS chapter outlines air-conditioning requirements for key printing operations. Air conditioning of printing plants can provide controlled, uniform air moisture content and temperature in working spaces. Paper, the principal material used in printing, is hygroscopic and very sensitive to variations in the humidity of the surrounding air. Printing problems caused by paper expansion and contraction can be avoided by controlling the moisture content throughout the manufacture and printing of the paper.

DESIGN CRITERIA

The following are three basic printing methods:

- **Relief printing (letterpress).** Ink is applied to a raised surface.
- **Lithography.** The inked surface is neither in relief nor recessed.
- **Gravure (intaglio printing).** The inked areas are recessed below the surface.

Figure 1 shows the general work flow through a printing plant. The operation begins at the publisher and ends with the finished printed product and paper waste. Paper waste, which may be as much as 20% of the total paper used, affects the profitability of a printing operation. Proper air conditioning can help reduce the amount of paper wasted.

In sheetfed printing, individual sheets are fed through a press from a stack or load of sheets and collected after printing. In webfed rotary printing, a continuous web of paper is fed through the press from a roll. The printed material is cut, folded, and delivered from the press as signatures, which form the sections of a book.

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

Sheetfed printing is a slow process in which the ink is essentially dry as the sheets are delivered from the press. **Offsetting**, the transference of an image from one sheet to another, is prevented by applying a powder or starch to separate each sheet as it is delivered from the press. Starches present a housekeeping problem: the particles (30 to 40 μm in size) tend to fly off, eventually settling on any horizontal surface.

If both temperature and relative humidity are maintained within normal human comfort limits, they have little to do with web breaks or the runnability of paper in a webfed press. At extremely low humidity, static electricity causes the paper to cling to the rollers, creating undue stress on the web, particularly with high-speed presses. Static electricity is also a hazard when flammable solvent inks are used.

Special Considerations

Various areas in printing plants require special attention to processing and heat loads.

Engraving and platemaking departments must have very clean air—not as clean as that for industrial clean rooms, but cleaner than that for offices. Engraving and photographic areas may also have special ventilation needs because of the chemicals used. Nitric acid fumes from powderless etching require careful duct material selection. Composing rooms, which contain computer equipment, can be treated the same as similar office areas. The excessive dust from cutting in the stitching and binding operations must be controlled. Stereotype departments have very high heat loads.

In pressrooms, air distribution must not cause the web to flutter or force contaminants or heat (which normally would be removed by roof vents) down to the occupied level. Air should be introduced immediately above the occupied zone wherever possible to

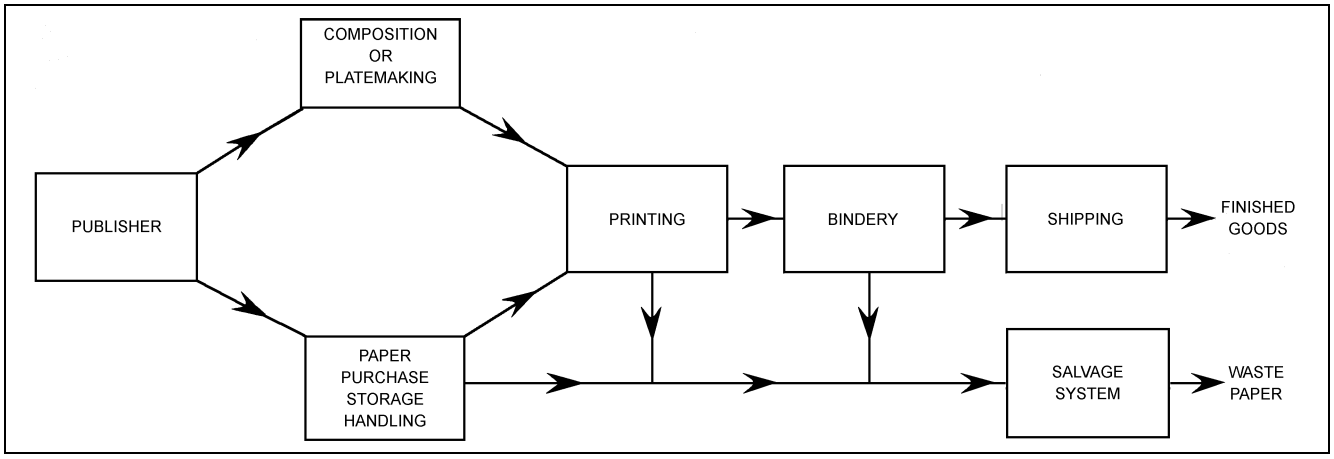

Fig. 1 Work Flow Through a Printing Plant

minimize total flow and encourage stratification. High air exchange rates may be required where solvent- or oil-based inks are used, due to the large quantity of organic solvent vapors that may be released from nonpoint sources. Exhaust emissions from dryer systems may contain substantial concentrations of solvent vapors, which must be captured and recovered or incinerated to satisfy local air pollution requirements. Where these measures are required, efforts should be made to maximize point source capture of vapors to minimize the size, cost, and energy requirements for vapor recovery/incineration equipment. Such efforts also minimize the impact of these requirements on general ventilation systems.

Conventional air-conditioning and air-handling equipment, particularly rooftop equipment, may be unable to handle the high outside air requirements of pressroom applications effectively. Stratified ventilation may be used in high-bay installations to reduce total system airflow and air-conditioning requirements. Pressrooms using oil- or solvent-based inks should be provided with a minimum of 2.5 L/(s·m^2) of outside air to ensure adequate dilution of internally generated volatile organic compounds. Ventilation of storage areas should be about 0.5 air changes per hour; bindery ventilation should be about 1 air change per hour. Storage areas with materials piled high may need roof-mounted smoke- and heat-venting devices.

In a bindery, loads of loose signatures are stacked near equipment, which makes it difficult to supply air to occupants without scattering the signatures. One solution is to run the main ducts at the ceiling with many supply branches dropped to within 2.5 to 3 m of the floor. Conventional adjustable blow diffusers, often the linear type, are used.

CONTROL OF PAPER MOISTURE CONTENT

Controlling the moisture content and temperature of paper is important in all printing, particularly multicolor lithography. Paper should be received at the printing plant in moisture-proof wrappers, which are not broken or removed until the paper is brought to the pressroom temperature. When exposed to room temperature, paper at temperatures substantially below the room temperature rapidly absorbs moisture from the air, causing distortion. Figure 2 shows the time required to temperature-condition wrapped paper. Printers usually order paper with a moisture content approximately in equilibrium with the relative humidity maintained in their pressrooms. Papermakers find it difficult to supply paper in equilibrium with a relative humidity higher than 50%.

Digital hygrometers can be used to check the hygroscopic condition of paper relative to the surrounding air. The probes contain a moisture-sensitive element that measures the electrical conductivity of the paper. Intact mill wrappings and the tightness of the roll normally protect a paper roll for about six months. If the wrapper is damaged, moisture will usually penetrate no more than 3 mm.

PLATEMAKING

Humidity and temperature control are important considerations when making lithographic and collotype plates, photoengravings, and gravure plates and cylinders. If the moisture content and temperature of the plates increase, the coatings increase in light sensitivity, which necessitates adjustments in the light intensity or the length of exposure to give uniformity.

If platemaking rooms are maintained at constant dry-bulb temperature and relative humidity, plates can be produced at known control conditions. As soon as it is dry, a bichromated colloid coating starts to age and harden at a rate that varies with the atmospheric conditions, so exposures made a few hours apart may be quite different. The rate of aging and hardening can be estimated more accurately when the space is air conditioned. Exposure can then be reduced progressively to maintain uniformity. An optimum relative humidity of 45% or less substantially increases the useful life of bichromated

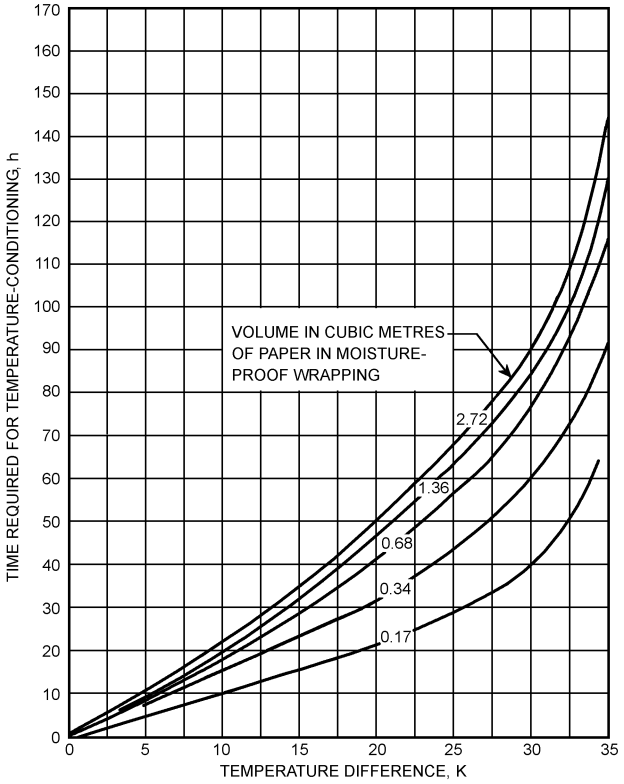

Fig. 2 Temperature-Conditioning Chart for Paper

colloid coatings; the relative humidity control should be within 2%. A dry-bulb temperature of 24 to 27°C maintained within 1 K is good practice. The ventilation air requirements of the plate room should be investigated. A plant with a large production of deep-etch plates should consider locating this operation outside the conditioned area.

Exhausts for platemaking operations consist primarily of lateral or downdraft systems at each operation. Because of their bulkiness or mass, plates or cylinders are generally conveyed by overhead rail to the workstation, where they are lowered into the tank for plating, etching, or grinding. Exhaust ducts must be below or to one side of the working area, so lateral exhausts are generally used for open-surface tanks.

Exhaust quantities vary, depending on the nature of the solution and shape of the tank, but they should provide exhaust in accordance with the recommendations of *Industrial Ventilation* by the American Conference of Governmental Industrial Hygienists (ACGIH 1998) for a minimum control velocity of 0.25 m/s at the side of the tank opposite the exhaust intake. Tanks should be covered to minimize exhaust air quantities and increase efficiency. Excessive air turbulence above open tanks should be avoided. Because of the nature of the exhaust, ducts should be acid-resistant and liquid-tight to prevent moisture condensation.

Webfed offset operations and related departments are similar to webfed letterpress operations, without the heat loads created in the composing room and stereotype departments. Special attention should be given to air cleanliness and ventilation in platemaking to avoid flaws in the plates due to chemical fumes and dust.

A rotogravure plant can be hazardous because highly volatile solvents are used. Equipment must be explosion-proof, and air-handling equipment must be spark-proof. Clean air must be supplied at controlled temperature and relative humidity.

Reclamation or destruction systems are used to prevent photosensitive hydrocarbons from being exhausted into the atmosphere. Some reclamation systems use activated carbon for continuous processing. Incineration or catalytic converters may be used to produce

rapid oxidation to eliminate pollutants. The amount of solvents reclaimed may exceed that added to the ink.

RELIEF PRINTING

In relief printing (letterpress), rollers apply ink only to the raised surface of a printing plate. Pressure is then applied to transfer the ink from the raised surface directly to the paper. Only the raised surface touches the paper to transfer the desired image.

Air conditioning in newspaper pressrooms and other webfed letterpress printing areas minimizes problems caused by static electricity, ink mist, and expansion or contraction of the paper during printing. A wide range of operating conditions is satisfactory. The temperature should be selected for operator comfort.

At web speeds of 5 to 10 m/s, it is not necessary to control the relative humidity because inks are dried with heat. In some types of printing, moisture is applied to the web, and the web is passed over chill rolls to further set the ink.

Webfed letterpress ink is heat-set, made with high-boiling, slow-evaporating synthetic resins and petroleum oils dissolved or dispersed in a hydrocarbon solvent. The solvent must have a narrow boiling range with a low volatility at room temperatures and a fast evaporating rate at elevated temperatures. The solvent is vaporized in the printing press dryers at temperatures from 120 to 200°C, leaving the resins and oils on the paper. Webfed letterpress inks are dried after all colors are applied to the web.

The inks are dried by passing the web through dryers at speeds of 5 to 10 m/s. There are several types of dryers: open-flame gas cup, flame impingement, high-velocity hot air, and steam drum.

Exhaust quantities through a press dryer vary from about 3300 to 7000 L/s at standard conditions, depending on the type of dryer used and the speed of the press. Exhaust temperatures range from 120 to 200°C.

Solvent-containing exhaust is heated to 700°C in an air pollution control device to incinerate the effluent. A catalyst can be used to reduce the temperature required for combustion to 540°C, but it requires periodic inspection and rejuvenation. Heat recovery reduces the fuel required for incineration and can be used to heat pressroom makeup air.

LITHOGRAPHY

Lithography uses a grease-treated printing image receptive to ink, on a surface that is neither raised nor depressed. Both grease and ink repel water. Water is applied to all areas of the plate, except the printing image. Ink is then applied only to the printing image and transferred to the paper in the printing process. In multicolor printing operations, the image may be printed up to four times on the same sheet of paper in different colors. Registration of images is critical to final color quality.

Offset printing transfers the image first to a rubber blanket and then to the paper. Sheetfed and web offset printing are similar to letterpress printing. The inks used are similar to those used in letterpress printing but contain water-resistant vehicles and pigment. In web offset and gravure printing, the relative humidity in the pressroom should be maintained constant, and the temperature should be selected for comfort or, at least, to avoid heat stress. It is important to maintain steady conditions to ensure the dimensional stability of the paper onto which the images are printed.

The pressroom for sheet multicolor offset printing has more exacting humidity requirements than other printing processes. The paper must remain flat with constant dimensions during multicolor printing, in which the paper may make six or more passes through the press over a period of a week or more. If the paper does not have the right moisture content at the start, or if there are significant changes in atmospheric humidity during the process, the paper will not retain its dimensions and flatness, and misregistering will result. In many cases of color printing, a register accuracy of 100 μm is required. Figure 3 shows the close control of the air relative humidity that is necessary to achieve this register accuracy. The data shown in this figure are for composite lithographic paper.

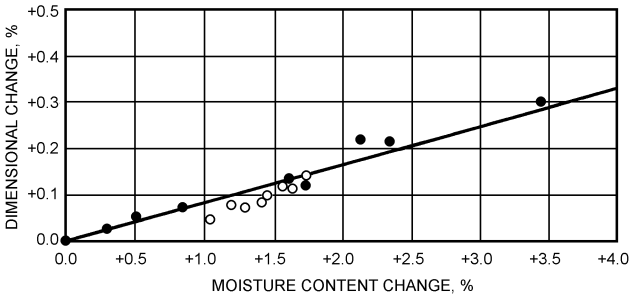

Fig. 3 Effects of Variation in Moisture Content on Dimensions of Printing Papers
(Weber and Snyder 1934)

Maintaining constant moisture content of the paper is complicated because paper picks up moisture from the moist offset blanket during printing—0.1 to 0.3% for each impression. When two or more printings are made in close register work, the paper at the start of the printing process should have a moisture content in equilibrium with air at 5 to 8% rh above the pressroom air. At this condition, the moisture evaporated from the paper into the air nearly balances the moisture added by the press. In obtaining register, it is important to keep the sheet flat and free from wavy or tight edges. To do this, the relative humidity balance of the paper should be slightly above that of the pressroom atmosphere. This balance is not as critical in four-color roll-feed presses because the press moisture does not penetrate the paper quickly enough between colors to affect sheet dimensions or cause sheet distortion.

Recommended Environment

The Graphic Arts Technical Foundation recommends ideal conditions in a lithographic pressroom of 24 to 27°C dry-bulb temperature and 43 to 47% rh, controlled to ±1 K dry-bulb temperature and ±2% rh (Reed 1970). Comfort and economy of operation influence the choice of temperature. The effect of relative humidity variations on register can be estimated for offset paper from Figure 3. Closer relative humidity control of the pressroom air is required for multicolor printing of 1930 mm sheets than for 560 mm sheets with the same register accuracy. Closer control is needed for multicolor printing, where the sheet makes two or more trips through the press, than for one-color printing.

Ink drying is affected by temperature and humidity, so uniform results are difficult to obtain without controlling the atmospheric conditions. Printing inks must dry rapidly to prevent offsetting and smearing. High relative humidity and high moisture content in paper tend to prevent ink penetration, so more ink remains on the surface than can be quickly oxidized. This affects drying time, intensity of color, and uniformity of ink on the surface. Relative humidity below 60% is favorable for drying at a comfortable temperature. Higher relative humidity may cause severe paper distortion and significant damage to the final product.

The air conditioning for the pressroom of a lithographic plant should control air temperature and relative humidity, filter the air, supply ventilation air, and distribute the air without pronounced drafts around the presses. The use of antioffset sprays to set the ink creates an additional air-filtering load from the pressroom. Drafts and high airflow over the presses lead to excessive drying of the ink and water, which causes scumming or other problems.

The operating procedures of the pressroom should be analyzed to determine the heat removal load. The lighting load is high and constant throughout the day. The temperature of the paper brought into

the pressroom and the length of time it is in the room should be considered to determine the sensible load from the paper. Figure 2 shows the time required for wrapped paper to reach room temperature. The press motors usually generate a large portion of the internal sensible heat gain.

Readings should be taken to obtain the running power load of the larger multicolor presses. The moisture content of the paper fed to the press and the relative humidity of the air must be considered when computing the internal latent heat gain. Paper is used that is in equilibrium with air at a relative humidity somewhat higher than that of the pressroom, so the paper gives up moisture to the space as it absorbs moisture during printing. If the moisture transfer is in balance, the water used in the printing process should be included in the internal moisture load. It is preferable to determine the water evaporation from the presses by testing.

Air Conditioning

Precise multicolor offset lithography printing requires either refrigeration with provision for separate humidity control, or sorption dehumidifying equipment for independent humidity control with provision for cooling. The need for humidity control in the pressroom may be determined by calculating the dimensional change of the paper for each percent of change in relative humidity and checking this with the required register for the printing process.

Air conditioning of the photographic department is usually considered next in importance to that of the pressroom. Most of the work in offset lithography is done on film. Air conditioning controls cleanliness and comfort and maintains the size of the film for register work.

Air conditioning is important in the stripping department, both for comfort and for maintaining size and register. Curling of the film and flats, as well as shrinkage or stretch of materials, can be minimized by maintaining constant relative humidity. This is particularly important for close-register color work. The photographic area, stripping room, and platemaking area usually are maintained at the same conditions as the pressroom.

Dryers used for web offset printing are the same type as for webfed letterpress. Drying is not as complex because less ink is applied and presses run at lower speeds—4 to 9 m/s.

ROTOGRAVURE

Rotogravure printing uses a cylinder with minute inkwells etched in the surface to form the printing image. Ink is applied to the cylinder, filling the wells. Excess ink is then removed from the cylinder surface by doctor blades, leaving only the ink in the wells. The image is then transferred to the paper as it passes between the printing cylinder and an impression cylinder.

In sheetfed gravure printing (as in offset printing), expansion, contraction, and distortion should be prevented to obtain correct register. The paper need not be in equilibrium with air at a relative humidity higher than that of the pressroom, because no moisture is added to the paper in the printing process. Humidity and temperature control should be exacting, like in offset printing. The relative humidity should be 45 to 50%, controlled to within ±2%, with a comfort temperature controlled to within ±1 K.

Gravure printing ink dries principally by evaporating the solvent in the ink, leaving a solid film of pigment and resin. The solvent is a low-boiling hydrocarbon, and evaporation takes place rapidly, even without the use of heat. The solvents have closed-cup flash points from −5 to 27°C and are classified as Group I or special hazard liquids by local code and insurance company standards. As a result, in areas adjacent to gravure press equipment and solvent and ink storage areas, electrical equipment must be Class I, Division 1 or 2, as described by the *National Electrical Code* (NFPA *Standard* 70), and ventilation requirements (both supply and exhaust) are stringent. Ventilation should be designed for high reliability, with sensors to detect unsafe pollutant concentrations and then to initiate alarm or safety shutdown when necessary.

Rotogravure printing units operate in tandem, each superimposing print over that from the preceding unit. Press speeds range from 6 to 12 m/s. Each unit is equipped with its own dryer to prevent subsequent smearing or smudging.

A typical drying system consists of four dryers connected to an exhaust fan. Each dryer is equipped with fans to recirculate 2500 to 4000 L/s (at standard conditions) through a steam or hot water coil and then through jet nozzles. The hot air (55°C) impinges on the web and drives off the solvent-laden vapors from the ink. It is normal to exhaust half of this air. The system should be designed and adjusted to prevent solvent vapor concentration from exceeding 25% of its lower flammable limit (Marsailes 1970). If this is not possible, constant lower-flammable-limit (LFL) monitoring, concentration control, and safety shutdown capability should be included.

In exhaust design for a particular process, solvent vapor should be captured from the printing unit where paper enters and exits the dryer, from the fountain and sump area, and from the printed paper, which continues to release solvent vapor as it passes from one printing unit to another. Details of the process, such as ink and paper characteristics and rate of use, are required to determine exhaust quantities.

When dilution-type ventilation is used, exhaust of 500 to 700 L/s (at standard conditions) at the floor is often provided between each unit. The makeup air units are adjusted to supply slightly less air to the pressroom than that exhausted in order to keep the pressroom negative with respect to the surrounding areas.

OTHER PLANT FUNCTIONS

Flexography

Flexography uses rubber raised printing plates and functions much like a letterpress. Flexography is used principally in the packaging industry to print labels and also to print on smooth surfaces, such as plastics and glass.

Collotype Printing

Collotype or photogelatin printing is a sheetfed printing process related to lithography. The printing surface is bichromated gelatin with varying affinity for ink and moisture, depending on the degree of light exposure received. There is no mechanical dampening as in lithography, and the necessary moisture in the gelatin printing surface is maintained by operating the press in an atmosphere of high relative humidity, usually about 85%. Since the tonal values printed are very sensitive to changes in the moisture content of the gelatin, the relative humidity should be maintained within ±2%.

Because tonal values are also very sensitive to changes in ink viscosity, temperature must be closely maintained; 27 ± 2°C is recommended. Collotype presses are usually partitioned off from the main plant, which is kept at a lower relative humidity, and the paper is exposed to high relative humidity only while it is being printed.

Salvage

Salvage systems remove paper trim and shredded paper waste from production areas, and carry airborne shavings to a cyclone or baghouse collector, where they are baled for recycling. Air quantities required are 2.5 to 2.8 m^3 per kilogram of paper trim, and the transport velocity in the ductwork is 23 to 25 m/s (Marsailes 1970). Humidification may be provided to prevent the buildup of a static charge and consequent system blockage.

Air Filtration

Ventilation and air-conditioning systems for printing plants commonly use automatic moving-curtain dry-media filters with renewable media having a mass arrestance of 80 to 90% (ASHRAE *Standard* 52.1).

In sheetfed pressrooms, a high-performance final filter is used to filter starch particles, which require about 85% ASHRAE dust-spot efficiency. In film processing areas, which require relatively dust-free conditions, high-efficiency air filters are installed, with 90 to 95% ASHRAE dust-spot efficiency.

A different type of filtration problem in printing is **ink mist** or **ink fly**, which is common in newspaper pressrooms and in heatset letterpress or offset pressrooms. Minute droplets of ink (5 to 10 μm) are dispersed by ink rollers rotating in opposite directions. The cloud of ink droplets is electrostatically charged. Suppressors, charged to repel the ink back to the ink roller, are used to control ink mist. Additional control is provided by automatic moving curtain filters.

Binding and Shipping

Some printed materials must be bound. Two methods of binding are perfect binding and stitching. In **perfect binding**, sections of a book (signatures) are gathered, ruffed, glued, and trimmed. The glued edge is flat. Large books are easily bound by this type of binding. Low-pressure compressed air and a vacuum are usually required to operate a perfect binder, and paper shavings are removed by a trimmer. The use of heated glue necessitates an exhaust system if the fumes are toxic.

In **stitching**, sections of a book are collected and stitched (stapled) together. Each signature is opened individually and laid over a moving chain. Careful handling of the paper is important. This has the same basic air requirements as perfect binding.

Mailing areas of a printing plant wrap, label, and ship the manufactured goods. Operation of the wrapper machine can be affected by low humidity. In winter, humidification of the bindery and mailing area to about 40 to 50% rh may be necessary to prevent static buildup.

CHAPTER 18

TEXTILE PROCESSING PLANTS

Fiber Making 18.1
Yarn Making 18.1
Fabric Making 18.3
Air-Conditioning Design 18.4
Energy Conservation 18.6

THIS chapter covers (1) basic processes for making fiber, yarn, and fabric; (2) various types of air-conditioning systems used in textile manufacturing plants; (3) relevant health considerations; and (4) energy conservation procedures.

Most textile manufacturing processes may be put into one of three general classifications: synthetic fiber making, yarn making, or fabric making. Synthetic fiber manufacturing is divided into staple processing, tow-to-top conversion, and continuous fiber processing; yarn making is divided into spinning and twisting; and fabric making is divided into weaving and knitting. Although these processes vary, their descriptions reveal the principles on which air-conditioning design is based.

FIBER MAKING

Processes preceding fiber extrusion have diverse ventilating and air-conditioning requirements based on principles similar to those that apply to chemical plants.

Synthetic fibers are extruded from metallic spinnerets and solidified as continuous parallel filaments. This process, called **continuous spinning**, differs from the mechanical spinning of fibers or tow into yarn, which is generally referred to as **spinning**.

Synthetic fibers may be formed by melt-spinning, dry-spinning, or wet-spinning. Melt-spun fibers are solidified by cooling the molten polymer; dry-spun fibers by evaporating a solvent, leaving the polymer in fiber form; and wet-spun fibers by hardening the extruded filaments in a liquid bath. The selection of a spinning method is affected by economic and chemical considerations. Generally, nylons, polyesters, and glass fibers are melt-spun, acetates dry-spun, rayons and aramids wet-spun, and acrylics dry- or wet-spun.

For melt-spun and dry-spun fibers, the filaments of each spinneret are usually drawn through a long vertical tube called a **chimney** or **quench stack**, within which solidification occurs. For wet-spun fibers, the spinneret is suspended in a chemical bath where coagulation of the fibers takes place. Wet-spinning is followed by washing, applying a finish, and drying.

Synthetic continuous fibers are extruded as a heavy denier tow for cutting into short lengths called staple or somewhat longer lengths for tow-to-top conversion, or they are extruded as light denier filaments for processing as continuous fibers. An oil is then applied to lubricate, give antistatic properties, and control fiber cohesion. The extruded filaments are usually drawn (stretched) both to align the molecules along the axis of the fiber and to improve the crystalline structure of the molecules, thereby increasing the fiber's strength and resistance to stretching.

Heat applied to the fiber when drawing heavy denier or high-strength synthetics releases a troublesome oil mist. In addition, the mechanical work of drawing generates a high localized heat load. If the draw is accompanied by twist, it is called **draw-twist**; if not, it is called **draw-wind**. After draw-twisting, continuous fibers may be given additional twist or may be sent directly to warping.

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

When tow is cut to make staple, the short fibers are allowed to assume random orientation. The staple, alone or in a blend, is then usually processed as described in the section on Cotton System. However, tow-to-top conversion, a more efficient process, has become more popular. The longer tow is broken or cut to maintain parallel orientation. Most of the steps of the cotton system are bypassed; the parallel fibers are ready for blending and mechanical spinning into yarn.

In the manufacture of glass fiber yarn, light denier multifilaments are formed by attenuating molten glass through platinum bushings at high temperatures and speeds. The filaments are then drawn together while being cooled with a water spray, and a chemical size is applied to protect the fiber. This is all accomplished in a single process prior to winding the fiber for further processing.

YARN MAKING

The fiber length determines whether spinning or twisting must be used. Spun yarns are produced by loosely gathering synthetic staple, natural fibers, or blends into rope-like form; drawing them out to increase fiber parallelism, if required; and then twisting. Twisted (continuous filament) yarns are made by twisting long monofilaments or multifilaments. Ply yarns are made in a similar manner from spun or twisted yarns.

The principles of mechanical spinning are applied in three different systems: cotton, woolen, and worsted. The cotton system is used for all cotton, most synthetic staple, and many blends. Woolen and worsted systems are used to spin most wool yarns, some wool blends, and synthetic fibers such as acrylics.

Cotton System

The cotton system was originally developed for spinning cotton yarn, but now its basic machinery is used to spin all varieties of staple, including wool, polyester, and blends. Most of the steps from raw materials to fabrics, along with the ranges of frequently used humidities, are outlined in Figure 1.

Opening, Blending, and Picking. The compressed tufts are partly opened, most foreign matter and some short fibers are removed, and the mass is put in an organized form. Some blending is desired to average the irregularities between bales or to mix different kinds of fiber. Synthetic staple, which is cleaner and more uniform, usually requires less preparation. The product of the picker is pneumatically conveyed to the feed rolls of the card.

Carding. This process lengthens the lap into a thin web, which is gathered into a rope-like form called a **sliver**. Further opening and fiber separation follows, as well as partial removal of short fiber and trash. The sliver is laid in an ascending spiral in cans of various diameters.

For heavy, low-count (length per unit of mass) yarns of average or lower quality, the card sliver goes directly to drawing. For lighter, high-count yarns requiring fineness, smoothness, and strength, the card sliver must first be combed.

Lapping. In sliver lapping, several slivers are placed side by side and drafted. In ribbon lapping, the resulting ribbons are laid one on

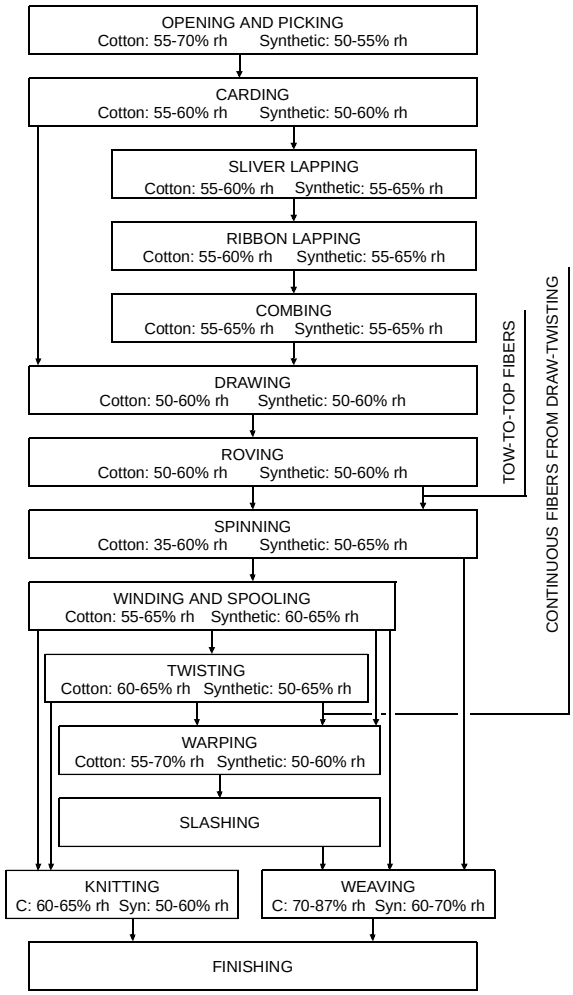

Fig. 1 Textile Process Flowchart and Ranges of Humidity

another and drafted again. The doubling and redoubling averages out sliver irregularities; drafting improves fiber parallelism. Some recent processes lap only once before combing.

Combing. After lapping, the fibers are combed with fine metal teeth to substantially remove all fibers below a predetermined length, to remove any remaining foreign matter, and to improve fiber arrangement. The combed lap is then attenuated by drawing rolls and again condensed into a single sliver.

Drawing. Drawing follows either carding or combing and improves uniformity and fiber parallelism by doubling and drafting several individual slivers into a single composite strand. Doubling averages the thick and thin portions; drafting further attenuates the mass and improves parallelism.

Roving. Roving continues the processes of drafting and paralleling until the strand is a size suitable for spinning. A slight twist is inserted, and the strand is wound on large bobbins used for the next roving step or for spinning.

Spinning. Mechanical spinning simultaneously applies draft and twist. The packages (any form into or on which one or more ends can be wound) of roving are creeled at the top of the frame. The unwinding strand passes progressively through gear-driven drafting rolls, a yarn guide, the C-shaped traveler, and then to the bobbin. The vertical traverse of the ring causes the yarn to be placed in predetermined layers.

The difference in peripheral speed between the back and front rolls determines the draft. Twist is determined by the rate of front roll feed, spindle speed, and drag, which is related to the traveler mass.

The space between the nip or bite of the rolls is adjustable and must be slightly greater than the longest fiber. The speeds of front and back rolls are independently adjustable. Cotton spindles normally run at 8000 to 9000 rpm but may exceed 14 000 rpm. In ring twisting, drawing rolls are omitted, and a few spindles run as high as 18 000 rpm.

Open-end or turbine spinning combines drawing, roving, lapping, and spinning. Staple fibers are fragmented as they are drawn from a sliver and fed into a small, fast-spinning centrifugal device. In this device, the fibers are oriented and discharged as yarn; twist is imparted by the rotating turbine. This system is faster, quieter, and less dusty than ring spinning.

Spinning is the final step in the cotton system; the feature that distinguishes it from twisting is the application of draft. The amount and point of draft application accounts for many of the subtle differences that require different humidities for apparently identical processes.

Atmospheric Conditions. From carding to roving, the loosely bound fibers are vulnerable to static electricity. In most instances, static can be adequately suppressed with humidity, which should not be so high as to cause other problems. In other instances, it is necessary to suppress electrostatic properties with antistatic agents. Wherever draft is applied, constant humidity is needed to maintain optimum frictional uniformity between adjacent fibers and, hence, cross-sectional uniformity.

Woolen and Worsted Systems

The woolen system generally makes coarser yarns, while the worsted system makes finer ones of a somewhat harder twist. Both may be used for lighter blends of wool, as well as for synthetic fibers with the characteristics of wool. The machinery used in both systems applies the same principles of draft and twist but differs greatly in detail and is more complex than that used for cotton.

Compared to cotton, wool fibers are dirtier, greasier, and more irregular. They are scoured to remove grease and are then usually reimpregnated with controlled amounts of oil to make them less hydrophilic and to provide better interfiber behavior. Wool fibers are scaly and curly, so they are more cohesive and require different treatment. Wool, in contrast to cotton and synthetic fibers, requires higher humidities in the processes prior to and including spinning than it does in the processes that follow. Approximate humidities are presented in Table 1.

Table 1 Recommended Humidities for Wool Processing at 24 to 27°C

Departments	Humidity, %
Raw wool storage	50 to 55
Mixing and blending	65 to 70
Carding—worsted	60 to 70
—woolen	60 to 75
Combing, worsted	65 to 75
Drawing, worsted—Bradford system	50 to 60
—French system	65 to 70
Spinning—Bradford worsted	50 to 55
—French (mule)	75 to 85
—woolen (mule)	65 to 75
Winding and spooling	55 to 60
Warping, worsted	50 to 55
Weaving, woolen, and worsted	50 to 60
Perching or clothroom	55 to 60

Twisting Filaments and Yarns

Twisting was originally applied to silk filaments; several filaments were doubled and then twisted to improve strength, uniformity, and elasticity. Essentially the same process is used today, but it is now extended to spun yarns, as well as to single or multiple filaments of synthetic fibers. Twisting is widely used in the manufacture of sewing thread, twine, tire cord, tufting yarn, rug yarn, ply yarn, some knitting yarns, etc.

Twisting and doubling is done on a **down-** or **ring-twister**, which draws in two or more ends from packages on an elevated creel, twists them together, and winds them into a package. Except for the omission of drafting, down-twisters are similar to conventional ring-spinning frames.

When yarns are to be twisted without doubling, an **up-twister** is used. Up-twisters are primarily used for throwing synthetic monofilaments and multifilaments to add to or vary elasticity, light reflection, and abrasion resistance. As with spinning, yarn characteristics are controlled by making the twist hard or soft, right (S) or left (Z). Quality is determined largely by the uniformity of twist, which, in turn, depends primarily on the tension and stability of the atmospheric conditions (Figure 1 and Table 1). As the frame may be double- or triple-decked, twisting requires concentrations of power. The frames are otherwise similar to those used in spinning, and they present the same air distribution problems. In twisting, lint is not a serious problem.

FABRIC MAKING

Preparatory Processes

When spinning or twisting is complete, the yarn may be prepared for weaving or knitting by processes that include winding, spooling, creeling, beaming, slashing, sizing, and dyeing. These processes have two purposes: (1) to transfer the yarn from the type of package dictated by the preceding process to a type suitable for the next and (2) to impregnate some of the yarn with sizes, gums, or other chemicals that may not be left in the final product.

Filling Yarn. Filling yarn is wound on quills for use in a loom shuttle. It is sometimes predyed and must be put into a form suitable for package or skein dyeing before it is quilled. If the filling is of relatively hard twist, it may be put through a twist-setting or conditioning operation in which internal stresses are relieved by applying heat, moisture, or both.

Warp Yarn. Warp yarn is impregnated with a transient coating of size or starch that strengthens the yarn's resistance to the chafing it will receive in the loom. The yarn is first rewound onto a cone or other large package from which it will unwind speedily and smoothly. The second step is warping, which rewinds a multiplicity of ends in parallel arrangement on large spools, called **warp or section beams**. In the third step, slashing, the threads pass progressively through the sizing solution, through squeeze rolls, and then around cans, around steam-heated drying cylinders, or through an air-drying chamber. A thousand kilograms or more may be wound on a single loom beam.

Knitting Yarn. If hard-spun, knitting yarn must be twist-set to minimize kinking. Filament yarns must be sized to reduce stripbacks and improve other running qualities. Both must be put in the form of cones or other suitable packages.

Uniform tension is of great importance in maintaining uniform package density. Yarns tend to hang up when unwound from a hard package or slough off from a soft one, and both tendencies are aggravated by spottiness. The processes that require air conditioning, along with recommended relative humidities, are presented in Figure 1 and Table 1.

Weaving

In the simplest form of weaving, harnesses raise or depress alternate warp threads to form an opening called a **shed**. A shuttle containing a quill is kicked through the opening, trailing a thread of filling behind it. The lay and the reed then beat the thread firmly into one apex of the shed and up to the fell of the previously woven cloth. Each shuttle passage forms a pick. These actions are repeated at frequencies up to five per second.

Each warp thread usually passes through a drop-wire that is released by a thread break and automatically stops the loom. Another automatic mechanism inserts a new quill in the shuttle as the previous one is emptied, without stopping the loom. Other mechanisms are actuated by filling breaks, improper shuttle boxing, and the like, which stop the loom until it is manually restarted. Each cycle may leave a stop mark sufficient to cause an imperfection that may not be apparent until the fabric is dyed.

Beyond this basic machine and pattern are many complex variations in harness and shuttle control, which result in intricate and novel weaving effects. The most complex loom is the **jacquard**, with which individual warp threads may be separately controlled. Other variations appear in looms for such products as narrow fabrics, carpets, and pile fabrics. In the **Sulzer weaving machine**, a special filling carrier replaces the conventional shuttle. In the rapier, a flat, spring-like tape uncoils from each side and meets in the middle to transfer the grasp on the filling. In the **water jet loom**, a tiny jet of high-pressure water carries the filling through the shed of the warp. Other looms transport the filling with compressed air.

High humidity increases the abrasion resistance of the warp. Weave rooms require 80 to 85% humidity or higher for cotton and up to 70% humidity for synthetic fibers. Many looms run faster when room humidity and temperature are precisely controlled.

In the weave room, power distribution is uniform, with an average concentration somewhat lower than in spinning. The rough treatment of fibers liberates many minute particles of both fiber and size, thereby creating considerable amounts of airborne dust. Due to high humidity, air changes average from four to eight per hour. Special provisions must be made for maintaining conditions during production shutdown periods, usually at a lower relative humidity.

Knitting

Typical products are seamless articles knitted on circular machines (e.g., undershirts, socks, and hosiery) and those knitted flat (e.g., full-fashioned hosiery, tricot, milanese, and warp fabrics).

Knitted fabric is generated by forming millions of interlocking loops. In its simplest form, a single end is fed to needles that are actuated in sequence. In more complex constructions, hundreds of ends may be fed to groups of elements that function more or less in parallel.

Knitting yarns may be either single strand or multi-filament and must be of uniform high quality and free from neps or knots. These yarns, particularly the multifilament type, are usually treated with special sizes to provide lubrication and to keep broken filaments from stripping back.

The need for precise control of yarn tension, through controlled temperature and relative humidity, increases with the fineness of the product. For example, in finer gages of full-fashioned hosiery, a 1 K change in temperature is the limit, and a 10% change in humidity may change in the length of a stocking by 75 mm. For knitting, desirable room conditions are approximately 24°C dry-bulb and 45 to 65% rh.

Dyeing and Finishing

Finishing, which is the final readying of a mill product for its particular market, ranges from cleaning to imparting special characteristics. The specific operations involved vary considerably, depending on the type of fiber, yarn, or fabric, and the end product usage. Operations are usually done in separate plants.

Inspection is the only finishing operation to which air conditioning is regularly applied, although most of the others require

ventilation. Finishing operations that use wet processes usually keep their solutions at high temperatures and require special ventilation to prevent destructive condensation and fog. Spot cooling of workers may be necessary for large releases of sensible, latent, or radiant heat.

AIR-CONDITIONING DESIGN

Air washers are especially important in textile manufacturing and may be either conventional low-velocity or high-velocity units in built-up systems. Unitary high-velocity equipment using rotating eliminators, although no longer common, is still found in some plants.

Contamination of air washers by airborne oils often dictates the separation of air washers and process chillers by heat exchangers, usually of the plate or frame type.

Integrated Systems

Many mills use a refined air washer system that combines the air-conditioning system and the collector system (see the section on Collector Systems) into an integrated unit. The air handled by the collector system fans and any air required to make up total return air are delivered back to the air-conditioning apparatus through a central duct. The quantity of air returned by individual yarn-processing machine cleaning systems must not exceed the air-conditioning supply air quantity. The air discharged by these individual suction systems is carried by return air ducts directly to the air-conditioning system. Before entering the duct, some of the cleaning system air passes over the yarn-processing machine drive motor and through a special enclosure to capture heat losses from the motor.

When integrated systems occasionally exceed the supply air requirements of the area served, the surplus air must be reintroduced after filtering.

Individual suction cleaning systems that can be integrated with air conditioning are available for cards, drawing frames, lap winders, combers, roving frames, spinning frames, spoolers, and warpers. The following advantages result from this integration:

1. With a constant air supply, the best uniform air distribution can be maintained year-round.
2. Downward airflow can be controlled; crosscurrents in the room are minimized or eliminated; drift or fly from one process to another is minimized or eliminated. Room partitioning between systems serving different types of manufacturing processes further enhances the value of this integration by controlling room air pattern year-round.
3. Heat losses of the yarn-processing frame motor and any portion of the processing frame heat captured in the duct, as well as the heat of the collector system equipment, cannot affect room conditions; hot spots in motor alleys are eliminated, and although this heat goes into the refrigeration load, it does not enter the room. As a result, the supply air quantity can be reduced.
4. Uniform conditions in the room improve production; conditioned air is drawn directly to the work areas on the machines, minimizing or eliminating wet or dry spots.
5. Maximum cleaning use is made of the air being moved. A guide for cleaning air requirements follows:

Pickers	1200 to 1900 L/s per picker
Cards	300 to 700 L/s per card
Spinning	2 to 4 L/s per spindle
Spooling	19 L/s per spool

Collector Systems

A collector system is a waste-capturing device that uses many orifices operating at high suction pressures. Each piece of production machinery is equipped with suction orifices at all points of major lint generation. The captured waste is generally collected in a fan and filter unit located either on each machine or centrally to accept waste from a group of machines.

A collector in the production area may discharge waste-filtered air either back into the production area or into a return duct to the air-conditioning system. It then enters the air washer or is relieved through dampers to the outdoors.

Figure 2 shows a mechanical spinning room with air-conditioning and collector systems combined into an integrated unit. In this case, the collector system returns all of its air to the air-conditioning system. If supply air from the air-conditioning system exceeds the maximum that can be handled by the collector system, additional air should be returned by other means.

Figure 2 also shows return air entering the air-conditioning system through damper T, passing through air washer H, and being delivered by fan J to the supply duct, which distributes it to maintain conditions within the spinning room. At the other end of each spinning frame are unitary-type filter-collectors consisting of enclosure N, collector unit screen O, and collector unit fan P.

Collector fan P draws air through the intake orifices spaced along the spinning frame. This air passes through the duct that runs lengthwise to the spinning frame, passes through the screen O, and is then discharged into the enclosure base (beneath the fan and screen). The air quantity is not constant; it drops slightly as material builds up on the filter screen.

Because the return air quantity must remain constant, and the air quantity discharged by fan P is slightly reduced at times, relief openings are necessary. Relief openings also may be required when the return air volume is greater than the amount of air the collector suction system can handle.

The discharge of fan P is split, so part of the air cools the spinning frame drive motor before rejoining the rest of the air in the return air tunnel. Regardless of whether the total return air quantity enters the return air tunnel through collector units, or through a combination of collector units and floor openings beneath spinning frames, return air fan R delivers it into the apparatus, ahead of return air damper T. Consideration should be given to filtering the return air prior to its delivery into the air-conditioning apparatus.

Mild-season operation causes more outdoor air to be introduced through damper U. This air is relieved through motorized damper S, which opens gradually as outdoor damper U opens, while return damper T closes in proportion. All other components perform as typical central station air-washer systems.

A system having the general configuration shown in Figure 2 may also be used for carding; the collector system portion of this arrangement is shown in Figure 3. A central collector filters the lint-laden air taken from multiple points on each card. This air is discharged to return air duct A and is then either returned to the air-conditioning system, exhausted outside, or returned directly to the room. A central collector filter may also be used with the spinning room system of Figure 2.

Air Distribution

Textile plants served by generally uniform air distribution may still require special handling for areas of load concentration.

Continuous Spinning Area. Methods of distribution are diverse and generally not critical. However, spot cooling or localized heat removal may be required. This area may be cooled by air conditioning, evaporative cooling, or ventilation.

Chimney (Quench Stack). Carefully controlled and filtered air or other gas is delivered to the chimneys; it is returned for conditioning and recovery of any valuable solvents present. Distribution of the air is of the utmost importance. Nonuniform temperature, humidity, or airflow disturbs the yarn, causing variations in fiber diameter, crystalline structure, and orientation. A fabric made of such fibers streaks when dyed.

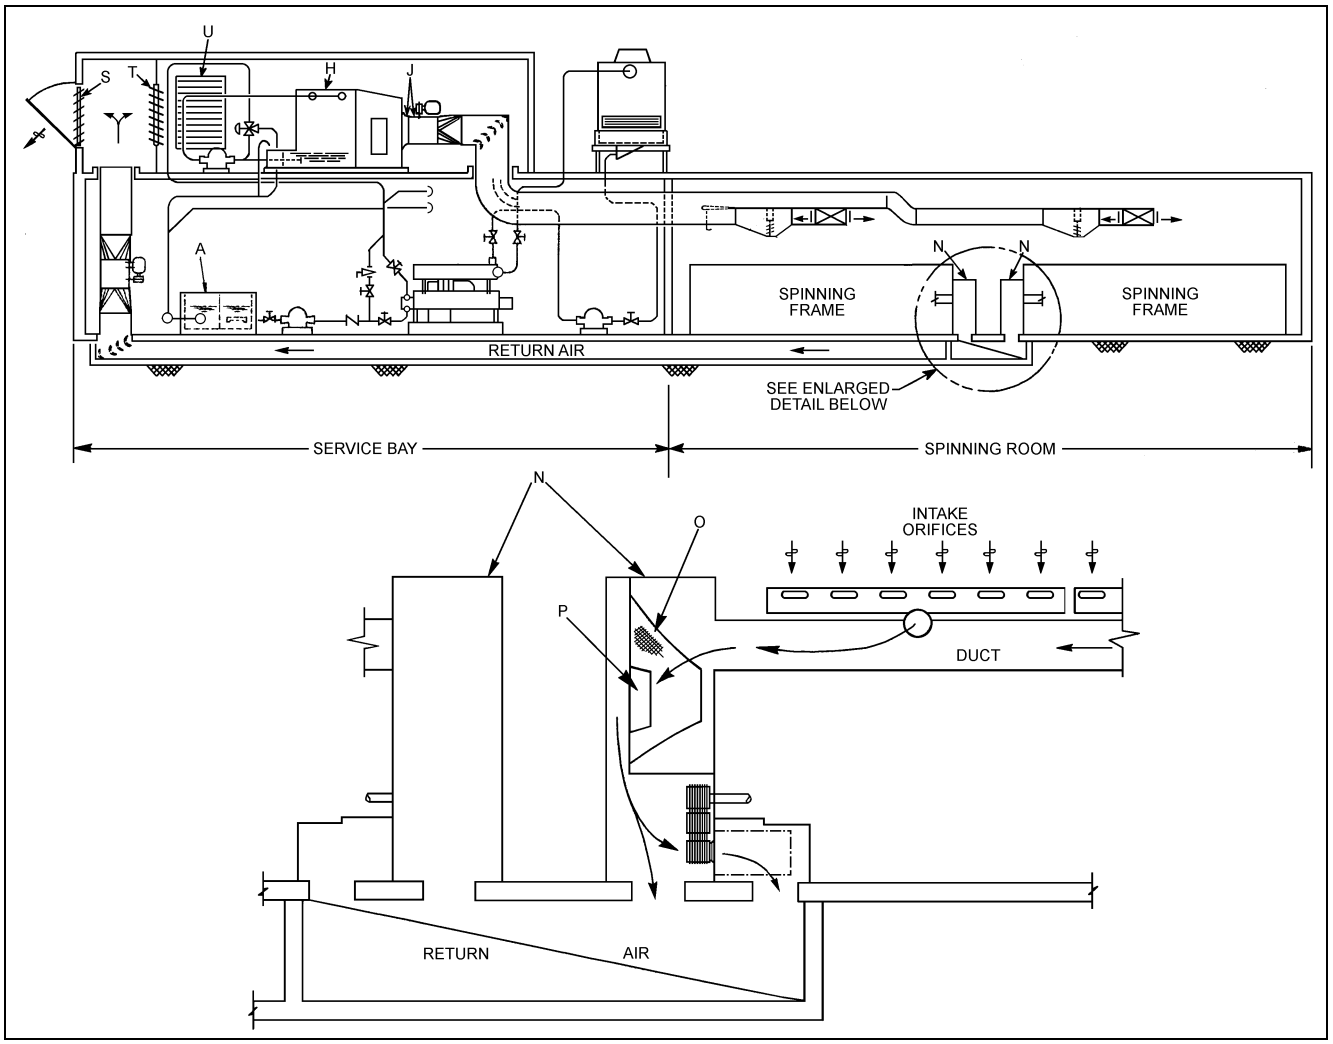

Fig. 2 Mechanical Spinning Room with Combined Air-Conditioning and Collector System

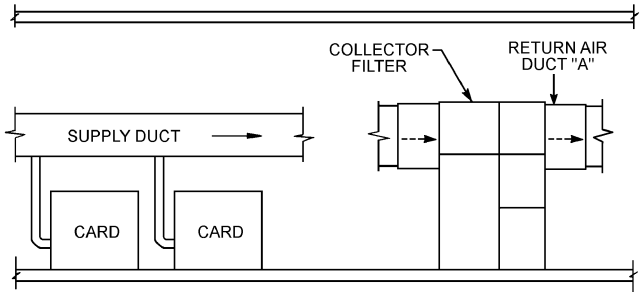

Fig. 3 Central Collector for Carding Machine

In melt spinning, the solvent concentration in the chimney air must be maintained below its explosive limit. Care is still required to prevent vapors from being ignited by a spark or flame. The air-conditioning system must be reliable, because interruption of the spinning causes the solution to solidify in the spinnerets.

Wind-Up or Take-Up Areas of Continuous Spinning. A heavy air-conditioning load is developed. Air is often delivered through branch ducts alongside each spinning machine. Diffusers are of the low-velocity, low-aspiration type, sized not to agitate delicate fibers.

Draw-Twist or Draw-Wind Areas of Fiber Manufacture. A heavy air-conditioning load is developed. Distribution, diffusion, and return systems are similar to those for the continuous spinning take-up area.

Opening and Picking. Usually, opening and picking require only a uniform distribution system. The area is subject to shutdown of machinery during portions of the day. Generally, an all-air system with independent zoning is installed.

Carding. A uniform distribution system is generally installed. There should be little air movement around the web in cotton carding. Central lint collecting systems are available but must be incorporated into the system design. An all-air system is often selected for cotton carding.

In wool carding, there should be less air movement than in cotton carding, not only to avoid disturbing the web, but also to reduce cross-contamination between adjacent cards. This is because different colors of predyed wool may be run side by side on adjacent cards. A split system may be considered for wool carding to reduce air movement. The method of returning air is also critical for achieving uniform conditions.

Drawing and Roving. Generally, a uniform distribution all-air system works well.

Mechanical Spinning Areas. A heavy air-conditioning load is generated, consisting of spinning frame power uniformly distributed

along the frame length and frame driver motor losses concentrated in the motor alley at one end of the frame.

Supply air ducts should run across the frames at right angles. Sidewall outlets between each of the two adjacent frames then direct the supply air down between the frames, where conditions must be maintained. Where concentrated heat loads occur, as in a double motor alley, placement of a supply air duct directly over the alley should be considered. Sidewall outlets spaced along the bottom of the duct diffuse air into the motor alley.

The collecting system, whether unitary or central, with intake points distributed along the frame length at the working level, assists in pulling supply air down to the frame, where maintenance of conditions is most important. A small percentage of the air handled by a central collecting system may be used to convey the collected lint and yarn to a central point, thus removing that air from the spinning room.

Machine design in spinning systems sometimes requires interfloor air pressure control.

Winding and Spooling. Generally, a uniform distribution, all-air system is used.

Twisting. This area has a heavy air-conditioning load. Distribution considerations are similar to those in spinning. Either all-air or split systems are installed.

Warping. This area has a very light load. Long lengths of yarn may be exposed unsupported in this area. Generally, an all-air system with uniform distribution is installed. Diffusers may be of the low-aspiration type. Return air is often near the floor.

Weaving. Generally, a uniform distribution system is necessary. Synthetic fibers are more commonly woven than natural fibers. The lower humidity requirements of synthetic fibers allow the use of an all-air system rather than the previously common split system. When lower humidity is coupled with the water jet loom, a high latent load results.

Health Considerations

Control of Oil Mist. Whenever textiles coated with lubricating oils are heated above 93°C in drawing operations in ovens, heated rolls, tenterframes, or dryers, an oil mist is liberated. If the oil mist is not collected at the source of emission and disposed of, a slightly odorous haze results.

Various devices have been proposed to separate oil mist from the exhaust air, such as fume incinerators, electrostatic precipitators, high-energy scrubbers, absorption devices, high-velocity filters, and condensers.

Spinning operations that generate oil mist must be provided with a high percentage (30 to 75%) of outside air. In high-speed spinning, 100% outside air is commonly used.

Operations such as drum cooling and air texturizing, which could contaminate the air with oil, require local exhausts.

Control of Monomer Fumes. Separate exhaust systems for monomers are required, with either wet- or dry-type collectors, depending on the fiber being spun. For example, caprolactam nylon spinning requires wet exhaust scrubbers.

Control of Hazardous Solvents. Provisions must be made for the containment, capture, and disposal of hazardous solvents.

Control of Cotton Dust. Byssinosis, also known as brown or white lung disease, is believed to be caused by a histamine-releasing substance in cotton, flax, and hemp dust. A cotton worker returning to work after a weekend experiences difficulty in breathing that is not relieved until later in the week. After 10 to 20 years, the breathing difficulty becomes continuous; even leaving the mill does not provide relief.

The U.S. Department of Labor enforces an OSHA standard of lint-free dust. The most promising means of control are improved exhaust procedures and filtration of recirculated air. Lint particles are 1 to 15 μm in diameter, so filtration equipment must be effective in this size range. Improvements in carding and picking that leave less trash in the raw cotton also help control lint.

Noise Control. The noise generated by HVAC equipment can be significant, especially if the textile equipment is modified to meet present safety criteria. For procedures to analyze and correct the noise due to ventilating equipment, see Chapter 46.

Safety and Fire Protection

Oil mist can accumulate in ductwork and create a fire hazard. Periodic cleaning reduces the hazard, but provisions should be made to contain a fire with suppression devices such as fire-activated dampers and interior duct sprinklers.

ENERGY CONSERVATION

The following are some steps that can be taken to reduce energy consumption:

1. Applying heat recovery to water and air.
2. Automating high-pressure dryers to save heat and compressed air.
3. Decreasing the hot water temperatures and increasing the chilled water temperatures for rinsing and washing in dyeing operations.
4. Replacing running washes with recirculating washes, where possible.
5. Changing double-bleaching procedures to single-bleaching, where possible.
6. Eliminating rinses and final wash in dye operations, where possible.
7. Drying by means of the “bump and run” process.
8. Modifying the drying or curing oven air-circulation systems to provide counterflow.
9. Using energy-efficient electric motors and textile machinery.
10. For drying operations, using discharge air humidity measurements to control the exhaust versus recirculation rates in full economizer cycles.

CHAPTER 19

PHOTOGRAPHIC MATERIALS

Storing Unprocessed Photographic Materials 19.1
Processing and Printing Photographic Materials 19.1
Storing Processed Film and Paper 19.3

THE processing and storage of sensitized photographic products requires temperature, humidity, and air quality control. Manufacturers of photographic products and processing equipment provide specific recommendations for facility design that should always be consulted. This chapter contains general information that can be used in conjunction with these recommendations.

STORING UNPROCESSED PHOTOGRAPHIC MATERIALS

Virtually all photosensitive materials deteriorate with age; the rate of photosensitivity deterioration depends largely on the storage conditions. Photosensitivity deterioration increases both at high temperature and at high relative humidity and usually decreases at lower temperature and humidity.

High humidity can accelerate loss of sensitivity and contrast, increase shrinkage, produce mottle, cause softening of the emulsion (which can lead to scratches), and promote fungal growth. Low relative humidity can increase the susceptibility of the film or paper to static markings, abrasions, brittleness, and curl.

Because different photographic products require different handling, product manufacturers should be consulted regarding proper temperature and humidity conditions for storage. Refrigerated storage may be necessary for some products in some climates.

Products not packaged in sealed vaportight containers are vulnerable to contaminants. Such products must be protected from solvent, cleanser, and formaldehyde vapors (emitted by particleboard and some insulation, plastics, and glues); industrial gases; and engine exhaust. In hospitals, industrial plants, and laboratories, all photosensitive products, regardless of their packaging, must be protected from x-rays, radium, and radioactive sources. For example, films stored 8 m away from 100 mg of radium require the protection of 90 mm of lead.

PROCESSING AND PRINTING PHOTOGRAPHIC MATERIALS

Ventilation with clean, fresh air maintains a comfortable working environment and prevents fume-related health problems. It is also necessary for the high-quality processing, safe handling, and safe storage of photographic materials.

Processing produces odors, fumes, high humidity, and heat (from lamps, electric motors, dryers, mounting presses, and high-temperature processing solutions). Thus, it is important to supply plentiful clean, fresh air at the optimum temperature and relative humidity to all processing rooms. Modern ventilation systems filter, supply, and distribute air, keep it moving, control its temperature and humidity, and adjust its pressure.

Air Conditioning for Preparatory Operations

During receiving operations, exposed film is removed from its protective packaging for presplicing and processing. **Presplicing** combines many individual rolls of film into a long roll to be processed. At high relative humidity, photographic emulsions become soft and can be scratched. At excessively low relative humidity, the film base is prone to static, sparking, and curl deformation. The presplice work area should be maintained at 50 to 55% rh and 21 to 24°C dry bulb.

Air Conditioning for Processing Operations

Processing exposed films or paper involves the use of a series of tempered chemical and wash tanks that emit heat, humidity, and fumes. Room exhaust must be provided, along with local exhaust at noxious tanks. To conserve energy, air from the pressurized presplice rooms can be used as makeup for processing room exhaust. Further supply air should maintain the processing space at a maximum of 27°C dry bulb and 50% rh.

The processed film or paper proceeds from the final wash to the dryer, which controls the moisture remaining in the product. Too little drying will cause the film to stick when wound, while too much drying will cause undesirable curl. Drying can be regulated by controlling drying time, humidity, and temperature.

The volume of incoming air should be sufficient to change the air in a processing room completely in about 8 min. Airflow should be diffused or distributed to avoid objectionable drafts. Apart from causing personnel discomfort, drafts can cause dust problems and disturb the surface temperature uniformity of drying drums and other heated equipment. For automated processing equipment, tempered fresh air should be supplied from the ceiling above the feed or head end of the machine at a minimum rate of 70 L/s per machine (see Figure 1). If the machine extends through a wall into another room, both rooms should be ventilated.

An exhaust system should be installed to remove humid or heated air and chemical vapors directly to the outside of the building. The room air from an open machine or tank area should be exhausted to the outdoors at a minimum rate of 80 L/s per machine. An exhaust rate higher than the supply rate produces a negative pressure and makes the escape of vapors or gases to

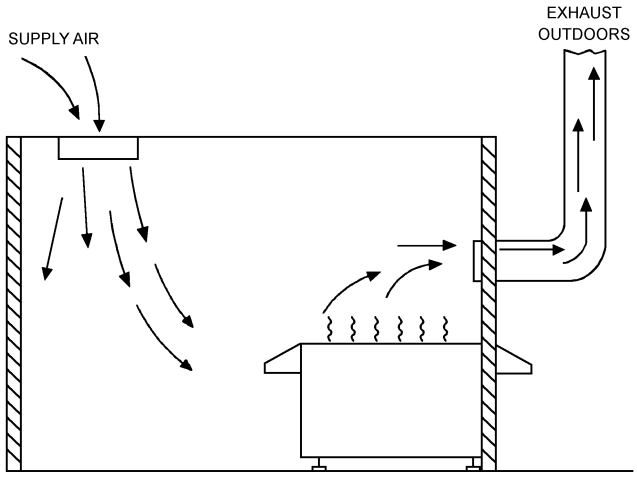

Fig. 1 Open Machine Ventilation

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

adjoining rooms less likely. The exhaust opening should be positioned so that the flow of exhausted air is away from the operator, as illustrated in Figure 2. This air should not be recirculated. The exhaust opening should always be as close as possible to the source of the contaminant for efficient removal. For a processing tank, an exhaust hood having a narrow opening at the back of and level with the top edge of the tank should be used.

If the processing tanks are enclosed and equipped with an exhaust connection, the minimum room air supply rate can be reduced to 42 L/s and the air removal rate to 47 L/s per machine (see Figure 3).

Air distribution to the drying area must provide a tolerable environment for operators. The exposed sides of the dryer should be insulated as much as is practical to reduce the large radiant and convected heat losses to the space. Return or exhaust grilles above the dryer can directly remove much of its rejected heat and moisture. The supply air should be directed to offset the remaining radiant losses.

The use of processor dryer heat to preheat cold incoming air during winter conditions can save energy. An economic evaluation is necessary to determine whether the energy savings justify the additional cost of the heat recovery equipment.

A canopy exhaust hood over the drying drum of continuous paper processors extracts heat and moisture. The dryers should be exhausted to the outside of the building to avoid undesirable humidity buildup. A similar hood over a sulfide-toning sink can be used to vent hydrogen sulfide. However, the exhaust duct must be placed on the side opposite the operator so that the vapor is not drawn toward the operator's face.

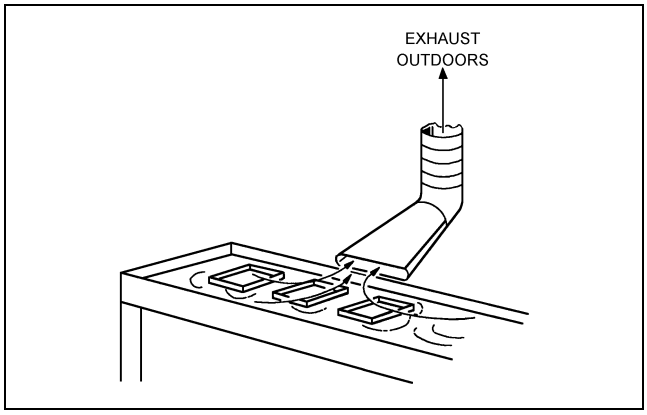

Fig. 2 Open-Tray Exhaust Ventilation from a Processing Sink

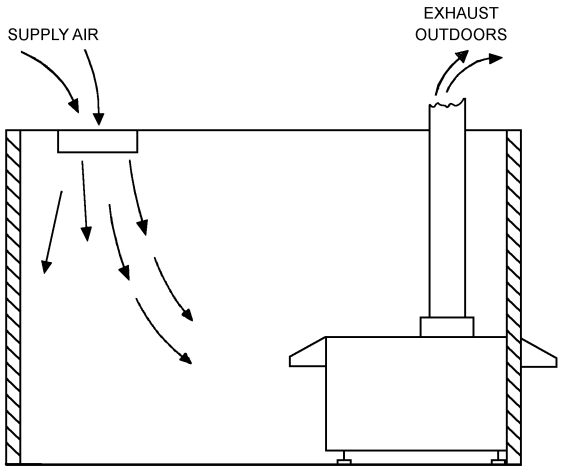

Fig. 3 Enclosed Machine Ventilation

Exhaust should draw off the vapor from the solvent and wax mixture that is normally applied to lubricate the motion picture film as it leaves the dryer.

Air Conditioning for the Printing/Finishing Operation

In printing, where a second sensitized product is exposed through the processed original, the amount of environmental control needed depends on the size and type of operation. For small-scale printing, close control of the environment is not necessary, except to minimize dust. In photofinishing plants, printers for colored products emit substantial heat. The effect on the room can be reduced by removing the lamphouse heat directly. Computer-controlled electronic printers transport the original film and raw film or paper at high speed. Proper temperature and humidity are especially important because, in some cases, two or three images from many separate films may be superimposed in register onto one film. For best results, the printing room should be maintained at between 21 and 24°C and at 50 to 60% rh to prevent curl, deformation, and static. Curl and film deformation affect the register and sharpness of the images produced. Static charge should be eliminated because it leaves static marks and may also attract dust to the final product.

Mounting of reversal film into slides is a critical finishing operation requiring a 21 to 24°C dry-bulb temperature with 50 to 55% rh.

Particulates in Air

Air conditioning for most photographic operations requires 85% efficient disposable bag-type filters with lower efficiency prefilters to extend filter life. In critical applications (such as high-altitude aerial films) and for microminiature images, filtering of foreign matter is extremely important. These products are handled in a laminar airflow room or workbench with HEPA filters plus prefilters.

Other Exhaust Requirements

A well-ventilated room should be provided for mixing the chemicals used in color processing and high-volume black-and-white work. The room should contain one or more movable exhaust hoods that provide a capture velocity of 0.5 m/s. Figure 4 shows a suitable mixing tank arrangement.

If prints are lacquered regularly, a spray booth is needed. A concentration of lacquer spray is both hazardous and very objectionable to personnel; spray booth exhaust must be discharged outside.

Processing Temperature Control

The density of a developed image on photographic material depends on characteristics of the emulsion, the exposure it has received, and the degree of development. With a particular emulsion, the degree of development depends on the time of development, the developer temperature, the degree of agitation, and the developer

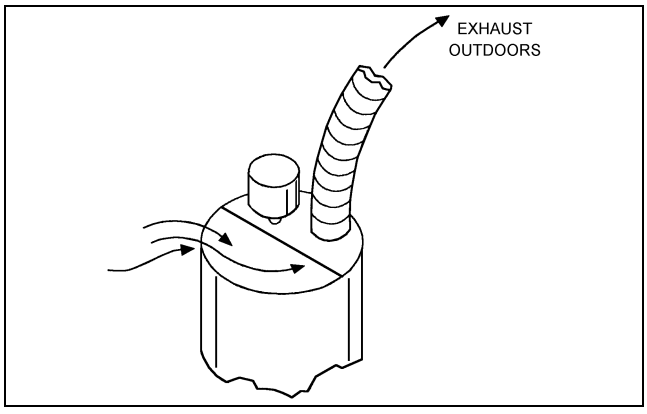

Fig. 4 Chemical Mixing Tank Exhaust

activity. Therefore, developer solution temperature control is critical. Once a developer temperature is determined, it should be maintained within 0.5 K for black-and-white products and within 0.3 K or better for color materials. Other solutions in the processor have a greater temperature tolerance.

Low processing volumes are typically handled in minilabs, which are often installed in retail locations. Minilabs are usually self-contained and equipped with temperature controls, heaters, and pumps. Typically, the owner only has to hook the lab up to water, electricity, exhaust (thimble connection), and a drain.

Higher volume processing is handled with processors that come from the manufacturer complete with controls, heat exchangers, pumps, and control valves designed for the process that the owner has specified. Electricity, hot water, cold water, drainage, and steam may be required, depending on the manufacturer, who typically provides the specifications for these utilities.

STORING PROCESSED FILM AND PAPER

Storage of developed film and paper differs from storage of the raw stock because the developed materials are no longer photosensitive, are seldom sealed against moisture, and are generally stored for much longer periods. Required storage conditions depend on (1) the value of the records, (2) the length of storage time, (3) whether the films are on nitrate or safety base, (4) whether the paper base is resin coated, and (5) the type of photographic image.

Photographic materials must be protected against fire, water, mold, chemical or physical damage, extreme relative humidity, and high temperature. Relative humidity is much more important than temperature. High relative humidity can cause films to stick together—particularly roll films, but also sheet films. High humidity also damages gelatin, encourages the growth of mold, increases dimensional changes, accelerates the decomposition of nitrate support, and accelerates the deterioration of both black-and-white and color images. Low relative humidity causes a temporary increase in curl and decrease in flexibility, but when the humidity rises again, these conditions are usually reversed. An exception occurs when motion picture film is stored for a long time in loosely wound rolls at very low humidities. The curl causes the film roll to resemble a polygon rather than a circle when viewed from the side. This **spokiness** occurs because a highly curled roll of film resists being bent in the length direction when it is already bent in the width direction. When a spoky roll is stored for a long time, the film flows permanently into the spoky condition, resulting in film distortion. Very low relative humidity in storage may also cause the film or paper to crack or break if handled carelessly.

Low temperature is desirable for film and paper storage provided that (1) the relative humidity of the cold air is controlled, and (2) the material is sufficiently warmed before opening to prevent moisture condensation. High temperature can accelerate film shrinkage, which may produce physical distortions and the fading of dye images. High temperature is also detrimental to the stability of any nitrate film still in storage.

Film Longevity

The American National Standards Institute (ANSI *Standard* IT9.11) defines longevities of films with a life expectancy (LE) rating. The **LE rating** is the minimum number of years information can be retrieved if the subject film is stored under long-term storage conditions. In order to achieve the maximum LE rating, a product must be stored under long-term storage conditions. Polyester black-and-white silver gelatin films have an LE rating of 500, while acetate black-and-white silver gelatin films have an LE rating of 100. No LE ratings have been assigned to color films or black-and-white silver papers. Medium-term storage conditions have been defined for materials that are to retain their information for at least 10 years.

Medium-Term Storage

Rooms for the medium-term storage of safety base film should be protected from accidental water damage by rain, flood, or pipe leaks. Air conditioning with controlled relative humidity is desirable but not always essential in moderate climates. Extremes of relative humidity are detrimental to film.

The most desirable storage relative humidity for processed film is about 50%, although the range from 30 to 60% is satisfactory. Air conditioning is required where the relative humidity of the storage area exceeds 60% for any appreciable period. For a small room, a dehumidifier may be used if air conditioning cannot be installed. The walls should be coated with a vapor retarder, and the controlling humidistat should be set at about 40% rh. If the prevailing relative humidity is under 25% for long periods, and problems from curl or brittleness are encountered, humidity should be controlled by a mechanical humidifier with a controlling humidistat set at 40%.

For medium-term storage, a room temperature between 20 and 25°C is recommended. Higher temperatures may cause shrinkage, distortion, and dye fading. Occasional peak temperatures of 32°C should not have a serious effect. Color films should be stored at temperatures below 10°C to reduce dye fading. Films stored below the ambient dew point should be allowed to warm up before being opened to prevent moisture condensation.

An oxidizing or reducing atmosphere may deteriorate the film base and gradually fade the photographic image. Oxidizing agents may also cause microscopically small colored spots on fine grain film such as microfilm (Adelstein et al. 1970). Typical gaseous contaminants include hydrogen sulfide, sulfur dioxide, peroxides, ozone, nitrogen oxides, and paint fumes. If such fumes are present in the intended storage space, they must be eliminated, or the film must be protected from contact with the atmosphere. Chapter 29 and Chapter 44 have further information on this subject.

Long-Term Storage

For films or records that are to be preserved indefinitely, long-term storage conditions should be maintained. The recommended space relative humidity ranges from 20 to 50% rh, depending on the film type. When several film types are stored within the same area, 30% rh is a good compromise. The recommended storage temperature is below 21°C. Low temperature aids preservation, but if the storage temperature is below the dew point of the outdoor air, the records must be allowed to warm up in a closed container before they are used, to prevent moisture condensation. Temperature and humidity conditions must be maintained year-round and should be continuously monitored.

Requirements of a particular storage application can be met by any one of several air-conditioning equipment combinations. Standby equipment should be considered. Sufficient outdoor air should be provided to keep the room under a slight positive pressure for ventilation and to retard the entrance of untreated air. The air-conditioning unit should be located outside the vault for ease of maintenance, with precautions taken to prevent water leakage into the vault. The conditioner casing and all ductwork must be well insulated. Room conditions should be controlled by a dry-bulb thermostat and either a wet-bulb thermostat, a humidistat, or a dew-point controller. For more information, see Chapter 45.

Air-conditioning installations and fire dampers in ducts carrying air to or from the storage vault should be constructed and maintained according to National Fire Protection Association (NFPA) recommendations for air conditioning (NFPA *Standard* 90A) and for fire-resistant file rooms (NFPA *Standard* 232).

All supply air should be filtered with noncombustible HEPA filters to remove dust, which may abrade the film or react with the photographic image. As is the case with medium-term storage, gaseous contaminants such as paint fumes, hydrogen sulfide, sulfur dioxide, peroxides, ozone, and nitrogen oxides may cause slow

deterioration of the film base and gradual fading of the photographic image. When these substances cannot be avoided, an air scrubber, activated carbon adsorber, or other purification method is required.

Films should be stored in metal cabinets with adjustable shelves or drawers and with louvers or openings located to facilitate circulation of conditioned air through them. The cabinets should be arranged in the room to permit free circulation of air around them.

All films should be protected from water damage due to leaks, fire sprinkler discharge, or flooding. Drains should have sufficient capacity to keep the water from sprinkler discharge from reaching a depth of 75 mm. The lowest cabinet, shelf, or drawer should be at least 150 mm off the floor and constructed so that water cannot splash through the ventilating louvers onto the records.

When fire-protected storage is required, the film should be kept in either fire-resistant vaults or insulated record containers (Class 150). Fire-resistant vaults should be constructed in accordance with NFPA *Standard* 232. Although the NFPA advises against air conditioning in valuable-paper record rooms because of the possible fire hazard from outside, properly controlled air conditioning is essential for long-term preservation of archival films. The fire hazard introduced by the openings in the room for air-conditioning ducts may be reduced by fire and smoke dampers activated by smoke detectors in the supply and return ducts.

Storage of Nitrate Base Film

Although photographic film has not been manufactured on cellulose nitrate film base for several decades, many archives, libraries, and museums still have valuable records on this material. The preservation of the nitrate film will be of considerable importance until the records have been printed on safety base.

Cellulose nitrate film base is chemically unstable and highly flammable. It decomposes slowly but continuously even under normal room conditions. The decomposition produces small amounts of nitric oxide, nitrogen dioxide, and other gases. Unless the nitrogen dioxide can escape readily, it reacts with the film base, accelerating the decomposition (Carrol and Calhoun 1955). The rate of decomposition is further accelerated by moisture and is approximately doubled with every 5 K increase in temperature.

All nitrate film must be stored in an approved vented cabinet or vault. Nitrate films should never be stored in the same vault with safety base films because any decomposition of the nitrate film will cause decomposition of the safety film. Cans in which nitrate film is stored should never be sealed, since this traps the nitrogen dioxide gas. Standards for the storage of nitrate film have been established (NFPA *Standard* 40). The National Archives and the National Institute of Standards and Technology have also investigated the effect of a number of factors on fires in nitrate film vaults (Ryan et al. 1956).

The storage temperature should be kept as low as economically possible. The film should be kept at below 50% rh. The temperature and humidity recommendations for the cold storage of color film in the following section also apply to nitrate film.

Storage of Color Film and Prints

All dyes fade in time. ANSI *Standard* IT9.11 does not define an LE for color films or black-and-white images on paper. However, many valuable color films and prints exist, and it is important to preserve them for as long as possible.

Light, heat, moisture, and atmospheric pollution contribute to the fading of color photographic images. Storage temperature should be as low as possible for the preservation of dyes. For maximum permanence of images, the materials should be stored in light-tight sealed containers or in moisture-proof wrapping materials at a temperature below freezing and at a relative humidity of 20 to 50%. The containers should be warmed to room temperature prior to opening to avoid moisture condensation on the surface. Photographic films can be brought to the recommended humidity by passing them through a conditioning cabinet with circulating air at about 20% rh for about 15 min.

An alternative is the use of a storage room or cabinet controlled at a steady (noncycled) low temperature and maintained at the recommended relative humidity. This eliminates the necessity of sealed containers, but involves an expensive installation. The dye-fading rate decreases rapidly with decreasing storage temperature.

Storage of Black-and-White Prints

The recommended storage conditions for processed black-and-white paper prints are given by ANSI (1982). The optimum limits for relative humidity of the ambient air are 30 to 50%, but daily cycling between these limits should be avoided.

A variation in temperature can drive relative humidity beyond the acceptable range. A temperature between 15 and 25°C is acceptable, but daily variations of more than 4 K should be avoided. Prolonged exposure to temperatures above 30°C should also be avoided. The degradative processes in black-and-white prints can be slowed considerably by low storage temperature. Exposure to airborne particles and oxidizing or reducing atmospheres should also be avoided, as mentioned for films.

CHAPTER 20

MUSEUMS, LIBRARIES, AND ARCHIVES

Design Targets for Mechanical Systems 20.1
Role of Relative Humidity and Temperature in Deterioration 20.2
Selection of Design Targets 20.5
Building Envelope Problem 20.6
Cocooned Zones 20.8
System Selection 20.8

APPRECIATION for the arts and history dictates a need for special temperature and humidity conditions in museums, libraries, and archives. Proper environments reduce the deterioration rate of stored materials and provide comfort for the occupants. Providing stability in the building environment is often as critical as establishing correct design criteria to protect the building contents. Facilities often have open traffic patterns and require different conditions between changing exhibits. Maintaining diverse environmental conditions that are so close to each other merits special consideration. The designer must also understand the effect environmental conditions will have on the building envelope, which is of serious concern in existing buildings.

In theory, a variety of systems can be successful in a building that requires environmental control, if properly applied. In practice, the available choices are limited by factors such as the material to be housed, collection value, length of time on exhibit (or in storage), operating costs, space allocation, architectural design, or project location. The selection process is most often driven by the past experience of the designers and available project funding. The operating benefits and constraints of the proposed system must be reviewed in detail with the building operators during conceptual stages to minimize the potential for misunderstandings at subsequent phases.

Heating and air conditioning that is simple in design and of the proper size for a given zone and building generally is economical to operate and maintain. For optimum results, the basic structure should include as much thermal and humidity control as is economically possible. Features might include materials with high thermal or impervious properties, insulation, multiple or special glazing, and shading devices.

The designer's input is essential in the early planning of the building. A good working relationship between the mechanical engineer, architect, interior designer, and owner is critical. All limitations must be defined at the beginning of the design. Some of the factors the designer must consider include

- The relationship between building shape, orientation, and environmental control.
- The amount of fenestration. When fenestration is a high percentage of the exterior envelope surface area the exterior load can be a significant part of the total air-conditioning load. Also, natural light may be detrimental to the buildings contents.
- Noise control, both inside and outside.
- Quality and quantity of indoor and outdoor air. Select appropriate filters to support the needs of the structure and consider the effects that off-gassing might have on its contents.
- Minimizing the building's influence on the environment, including reduction of pollution into the atmosphere.

Retrofitting existing buildings has become important because of the increased cost of new structures as well as the desire to preserve older buildings of historical significance. In some cases the effect of the environmental systems may be of more concern relative to the structure than the contents. Older buildings with minimal insulation or without vapor retarders must be protected from the potential damage that could be created by an environmental control system that affords year round, interior stability.

Selection of the HVAC system should be a team effort. Often, the most likely solutions will be compromises that do not meet all the criteria for all spaces. To a great extent, the selection will be based on interior design conditions, which are driven by the primary use of the structure. There are several opinions relative to the inside environment. All are based on the idea that materials deteriorate because of vapor, heat, gases, and radiation found naturally in the environment. Deterioration can be reduced by controlling temperature, humidity, sunlight, and particulates. The disagreement is over the acceptable limits of control and where to compromise. Buildings that house exhibitions are usually quite open, to promote ease in circulation of the occupants. However different exhibits may require contrasting conditions. Some exhibits may off-gas materials that are detrimental to others. The acceptable limits, budget, and architectural constraints must be established early in the design.

DESIGN TARGETS FOR MECHANICAL SYSTEMS

Museums, archives, and libraries have two groups of indoor air requirements. The first falls into the general category of health and safety as listed in ASHRAE *Standard* 55 and ASHRAE *Standard* 62. These standards consist of requirements such as concentrations of hazardous substances, air temperature, velocity, and relative humidity.

The second group of requirements pertains to the collections. Collection requirements are not simple, they are not yet clearly understood, and they often conflict across collection types. Besides, the building envelope often is incapable of maintaining the chosen conditions. For these reasons, the question of what is the risk of compromising on the values of relative humidity and temperature is asked. The following sections summarize the best information on these issues.

In terms of both health and safety and collection requirements, it is useful to label building spaces three ways, as shown in Table 1. First, collection versus noncollection; second, public versus nonpublic; and third, "dirty" versus "clean". These subdivisions distinguish between areas that have very different thermal and indoor air quality requirements, outdoor ventilation rates and air supply strategies, etc. Typically these areas require separate HVAC systems. See Chapters 13, 28, and 29 for more information on "dirty" rooms. Noncollection rooms are not considered in this chapter because their HVAC requirements are similar to those in other public buildings, which are discussed in Chapter 3.

Derivation of Collection Requirements

The hierarchy in the following paragraphs (Michalski 1996a) provides a logic for developing appropriate climate and indoor air quality (IAQ) parameters for different museums, libraries, and

The preparation of this chapter is assigned to TC 9.8, Large Building Air-Conditioning Applications.

Table 1 Classification of Rooms for Museums and Libraries

		High Internal Source of Contaminants (Dirty)	Low Internal Source of Contaminants (Clean)
Collection	Non-public access	Conservation laboratories, museum workshops (VOCs, fumes, dusts) "Wet" collections (alcohol evaporation from poorly sealed jars in natural history collections) Photographic collections ("vinegar syndrome" produces acetic acid vapors)	Most storage areas, vaults, library stacks
	Public access	Displays of conservation work in progress (unusual and temporary)	Galleries, reading rooms
Noncollection	Non-public access	Smoking offices (unusual)	Offices (nonsmoking)
	Public access	Cafeterias, rest rooms, spaces where smoking permitted	Public spaces without food preparation or smoking

archives. Further, it demonstrates that a single target is a compromise between a large number of different, often contradictory, requirements. Fortunately, many collections have sufficient uniformity that useful generalizations can be made about their requirements. Throughout this hierarchy, the term "effective" includes institutional value judgements as well as the science of deterioration.

Museum, library, archive. A set of collections. The target for a single climate and the indoor air quality (IAQ) for an entire institution is that which provides the most effective environment for all collection needs. Sometimes, but not always, a museum has a single type of collection. If the museum is split into zones with different targets, then specific collections can be given specific targets.

Collection. A set of artifacts. A single climate and IAQ target for an entire collection is that which provides the most effective environment for the collection. Sometimes, but not always, a collection consists of artifacts with identical climate and IAQ needs, e.g., a coin collection, photo collection, a rare book library, etc.

Artifact. Assembly of materials. A single microclimate and contaminant deposition target for an entire artifact is that which provides the most effective common environment for preservation of both the individual constituent materials and of the assembly itself. Some artifacts have an elementary assembly; i.e., they are a single piece of material such as a blank sheet of paper, or a pure mineral specimen, and hence have a simpler target to specify.

Material. A single microclimate and pollutant deposition target for a single piece of material is that which provides the most effective common environment for preservation of the material.

ROLE OF RELATIVE HUMIDITY AND TEMPERATURE IN DETERIORATION

Role of High Relative Humidity

Dampness causes rapid mold on most surfaces and rapid corrosion of base metals. It is the single most important factor that causes damage in museums and archives.

The most comprehensive mold data exists in the feed and food literature. Fortunately, this provides a conservative outer limit to dangerous conditions, because mold in museum objects occurs first on surfaces contaminated with sugars, starch, oils, etc.; or on objects made of grass, skin, bone, and other feed- or food-like materials. Water activity is identical to and always measured as the equilibrium relative humidity of air adjacent to the material. The equilibrium relative humidity, rather than equilibrium moisture content (EMC), provides a better measure for mold germination and growth on a wide variety of materials (Beuchat 1987). In Figure 1, the combined role of temperature and relative humidity is shown. The study of the most vulnerable book material by Groom and Panisset (1933) is consistent with the general trend of culture studies from Ayerst (1968). Ohtsuki (1990) reported microscopic mold occurring on clean metal surfaces at 60% rh. The DNA helix is known to collapse near 55% rh (Beuchat 1987), so a conservative limit for no mold

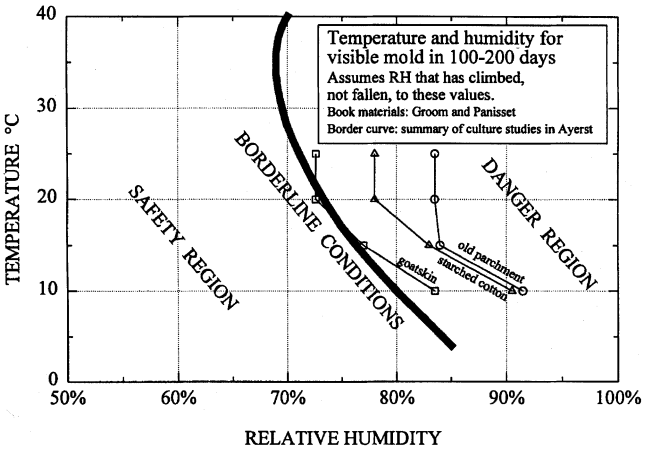

Fig. 1 Temperature and Humidity for Visible Mold in 100 to 200 Days

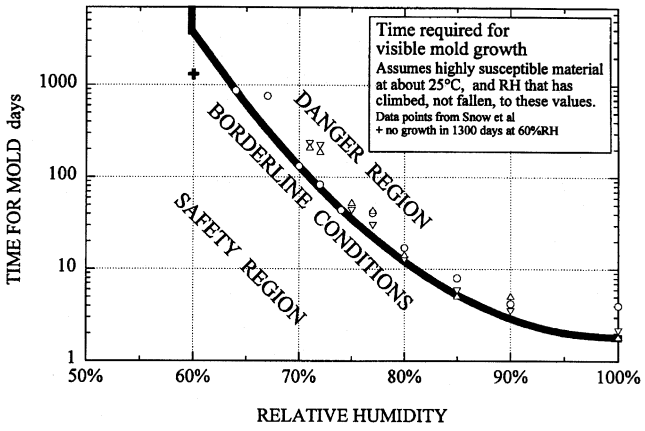

Fig. 2 Time Required for Visible Mold Growth

ever, on anything, at any temperature, is below 60% rh. Chapter 23, Figure 1, suggests a similar lower boundary for mold: 62% rh.

Snow et al. (1944) looked for visible mold growth on materials inoculated with a mixture of mold species. These are plotted in Figure 2, and follow the same trend as reported in the European building industry for wall mold (Hens 1993) and in Chapter 22, Figure 1.

Therefore, Figure 1 and Figure 2 show practical dangers, e.g., that growth in less than a summer season requires over 70% rh, in less than a week requires over 85% rh. The precise point between 0°C and –5°C where mold growth ceases is not well characterized.

Conditions for rapid drying of already wet collections following some disaster is a separate issue. The boundaries for rapid mold

growth shown in Figure 2 are still reasonably correct, but partially-dried porous objects are far from equilibrium relative humidity conditions.

Figure 1 and Figure 2 are conservative also for the onset of production of allergenic spores and human toxins in molds, since both are known to require slightly higher relative humidity than spore germination (Beuchat 1987). For both collection and occupant health, and given the need in museums to humidify air more than many applications in wintertime, special care must be taken to avoid cold spots along ductwork.

Rapid corrosion above 75% rh occurs for two reasons: increased surface adsorption of water, and contamination by salts. The adsorption of water on clean metal surfaces climbs rapidly from 3 molecules or less below 75% rh to bulk liquid layers above 75% rh (Graedel 1994). This phenomenon is aggravated by most surface contaminants, as shown in studies of the role of dust on clean steel corrosion. The most common contaminant of museum metals, sodium chloride, dissolves and becomes liquid (deliquesces) above 76% rh.

Role of Critical Relative Humidity

At some critical relative humidity, some minerals hydrate, dehydrate, or deliquesce. When such minerals are part of a salt-contaminated porous stone, a stone containing salt, a corroded metal, or a natural history specimen, they disintegrate the object. Dozens of minerals with distinct critical relative humidity values are known in natural history collections (Waller 1992). Pyrites that contaminate most fossils disintegrate if held above 60% rh (Howie 1992). One of the most important archaeological metals, bronze, has a complex chemistry of corrosion, with several critical relative humidity values (Scott 1990). This variety leads away from a generalized safe relative humidity, toward an emphasis on particular conditions for particular artifacts. Often this is achieved by local cabinets or small relative humidity controlled packages (Waller 1992). The only simple generalization for these materials is that relative humidity over 75% is almost always dangerous.

Role of Warmth and Relative Humidity above 0%

Warmth and moderate amounts of absorbed moisture lead to rapid decay in chemically unstable artifacts, especially some archival records. In archives, the most important deterioration mechanism of modern records is acid hydrolysis, which affects papers, photographic negatives, and magnetic media (both analog and digital). Michalski (1999) developed equations for relative lifetime as a function of relative humidity and temperature. Fortunately, for design purposes the dependence on relative humidity and temperature in all records is very similar. Although the precise quantification and meaning of record lifetime is debatable, all authorities agree that the most rapidly decaying records, such as videotape and acidic negatives, can become unusable within a few decades at normal room conditions, and much faster in hot, humid conditions. The relative increase in record lifetime due to cold, dry conditions is shown in Figure 3. The range in numbers on each line reflect the spread in the available data. The extension of the plots below 5% rh is uncertain; the rates of chemical decay may or may not approach zero, depending on slow, non-moisture-controlled mechanisms such as oxidation.

Lifetime improvement predictions specifically from photographic data has been derived by the Image Permanence Institute (Reilly 1993; Nishimura 1993) and used for a lifetime prediction wheel. Relative lifetime estimates from these wheels are less optimistic about improvement with low relative humidity, but the general trend is the same as the Michalski plots.

The rate of light fading of some colorants depends on relative humidity, although the rate does not drop to zero at 0% rh. Some lake pigments, some color photographs on display, can last twice as long at 10% rh as at 50% rh (Bailie et al. 1988; Bard et al. 1986).

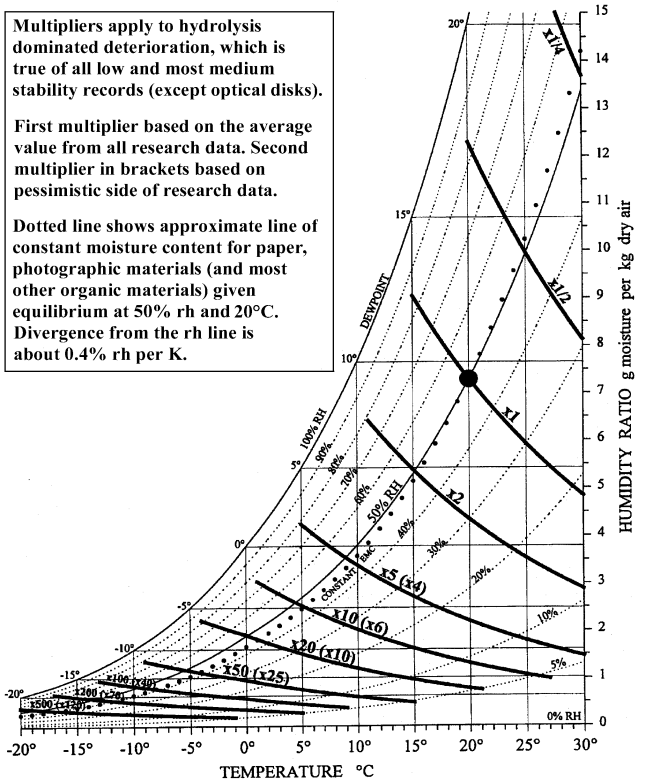

Fig. 3 Lifetime Multipliers Relative to 20°C and 50% rh

Role of Fluctuations and Low Temperature

Fluctuations in relative humidity, fluctuations in temperature, and cold by itself, can each lead to mechanical damage in artifacts. The fundamental cause is expansion and contraction of materials, combined with some form of internal or external restraint. Very low humidity or temperature has the added effect of increasing the stiffness of many organic materials, making them more vulnerable to fracture. Traditionally, these concerns led to extremely narrow specifications, such as 50 ± 3% rh and 21 ± 1°C (Lafontaine 1979), which still form the basis of many museum and archive guidelines. These specifications were derived from extrapolation of a common observation, that very large fluctuations fractured some objects, but with no experimental or theoretical basis for precise extrapolation to smaller fluctuations.

Research (Erhardt et al. 1994, 1996; Mecklenburg et al. 1991, 1998; Michalski 1991a, 1993) on objects, experience in historic building museums, and a comparison of historic buildings with and without air conditioning (Oreszczyn et al. 1994) have led to reappraisal of these fluctuation specifications. Despite some small disagreements over the interpretation of these studies, the practical conclusions are the same; that is, the traditional extrapolation to very narrow tolerances such as ±3% rh and ±1 K was an exaggeration of artifact needs. Somewhere between fluctuations of about ±10% rh, ±10 K and ±20% rh, ±20 K, the risk of fracture or deformation does climb from insignificant to significant for a mixed historic collection. Beyond this range, risk climbs even more quickly for increasingly large fluctuations. It is the range of ±20% rh to ±40% rh that has yielded the common observations of cracked cabinetry and paintings.

All research studies begin with the model of a restrained sample of organic material, typically paint, glue, or wood, subject to lowered relative humidity or temperature. The material both shrinks and stiffens. Mecklenburg (1991), Daly and Michalski (1987), and Hedley (1988) have collected consistent data on the increase in

tension for traditional painting materials; and Michalski (1991a, 1999) has shown this to be consistent in turn with other viscoelastic data on paints and their polymers. For example, acrylic paintings do not increase in tension at low relative humidity nearly as much as traditional oil paintings. On the other hand, acrylic paints increase in stiffness much more between 21°C and 5°C than oil paints, so cold temperatures increase the vulnerability of acrylic paintings to shock and handling damage much more so than oil paintings. The increase in material tension can be calculated as the modulus of elasticity times the coefficient of expansion integrated over the decrement in relative humidity or temperature, recognizing that each factor is a function of relative humidity and temperature (Perera and Vanden Eynde 1987; Michalski 1991a, 1998).

Modeling from the Smithsonian has used the material yield point, i.e., nonrecoverable deformation, as a threshold criterion for damage, and hence permissible fluctuations (Erhardt et al. 1994; Mecklenburg et al. 1998). From their data on expansion coefficients and tensile yield strain in wood, for example, they estimate a permissible relative humidity fluctuation of ±10% rh in pine and oak, more in spruce. The same modeling on all other materials they have studied (paint and glue) suggest ±15% as a safe range (Mecklenburg et al. 1994). More extensive data on compression yield stress across the grain, available for all useful species of wood in the *Wood Handbook* (USDA 1987), can be used along with the elasticity data on that species and the moisture content data to obtain a yield strain and hence yield relative humidity fluctuation. These show a wide range, but centered near ±15% rh.

Alternate modeling at the Canadian Conservation Institute has used fracture as the criterion for damage, and used the general pattern of fatigue fracture in wood and polymers to extrapolate the effect of smaller multiple cycles (Michalski 1991a). Assuming a benchmark of high probability of single-cycle fracture at ±40% rh (e.g., a drop from 50% rh to 10% rh) known from common observation of many museum artifacts, one can extrapolate to the fatigue threshold stress (10^7 cycles or more) by an approximate factor of 0.5 in wood (±20% rh) and 0.25 in brittle polymers (±10% rh) such as old paint. Fortunately, this is consistent with the yield criterion, inasmuch as the yield stress in these materials corresponds to stresses that cause very small or negligible crack growth per cycle. Both groups of researchers also noted that the coefficient of expansion in wood and other materials is at a minimum at moderate relative humidity due to their sigmoidal absorption isotherms, so fluctuations at lower and higher relative humidity set points tend to be even more risky.

Both models assume uniformly restrained materials. As a first approximation, many laminar objects, such as paintings on stretchers and many photographic records fall in this class. Many other artifacts, however, are complex assemblies of materials. Some are less vulnerable due to lack of restraint, such as floating wood panels, or books and photographic papers with components that dilate in reasonable harmony; while other assemblies contain sites of severe stress concentration that initiate early fracture. A table of vulnerabilities for wooden objects has been developed (Michalski 1996b) in which assembly vulnerability is classified as Very High, High, Medium (uniformly restrained components), and Low. Each category differs from the next lower category by a factor of two, i.e. needs half the relative humidity fluctuation for the same risk of damage.

Response Times of Artifacts

Very brief relative humidity fluctuations may not affect artifacts, for example, very few museum objects respond significantly to fluctuations under an hour in duration, so a 15 min cycle in HVAC output does not affect most artifacts (unless it is so large as to cause sudden damp conditions). Many objects take days to respond. Figure 4 shows calculated humidity response times of wooden artifacts. Figure 5 shows the interaction of air leakage, wood coating, and textile buffering on the response of a chest of drawers. It shows that museums cause greater risk than ordinary households if they display the piece empty and open, rather than closed and full, because response time falls from months to days.

Very long relative humidity and temperature fluctuations, such as seasonal changes, are slow enough to take advantage of stress relaxation in artifact components. Data on the effective modulus of elasticity of many oil and acrylic paints as a function of time, temperature, and relative humidity (Michalski 1991a) and direct stress relaxation data for both paint (Michalski 1995) and wood imply that the stress caused by a given strain applied over one day falls to about half or less if that strain is applied over 4 months at moderate room temperatures. Thus a four month seasonal ramp of ±20% rh

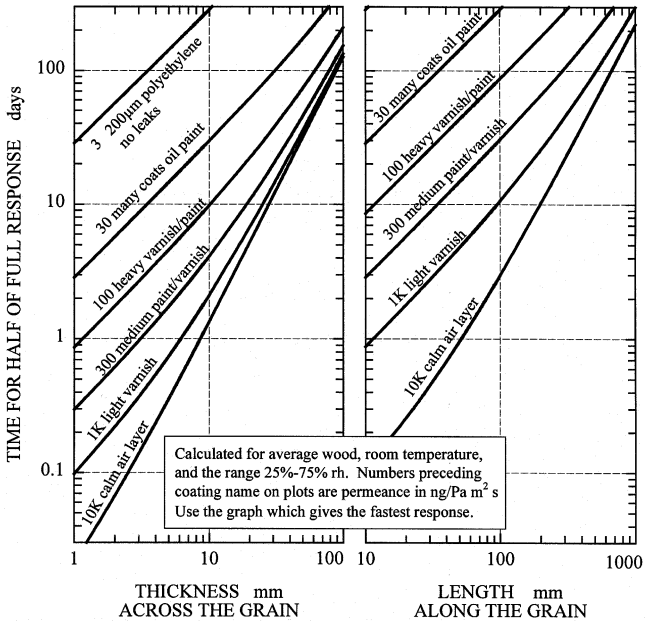

Fig. 4 Calculated Humidity Response Times of Wooden Artifacts

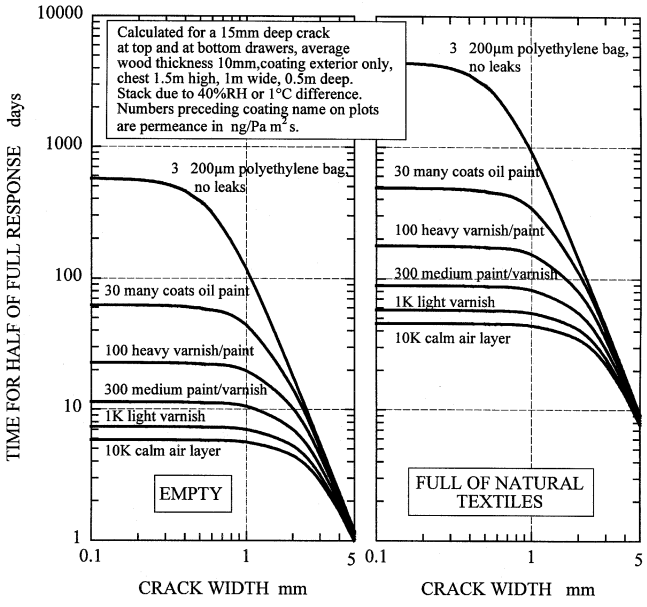

Fig. 5 Interaction of Air Leakage, Wood Coating, and Textile Buffering on Response of Chest of Drawers

(e.g. from 50% rh to 30% rh should cause less stress in most artifacts than a one week fluctuation of ±10% rh. Thus the most stressful relative humidity fluctuations are those shorter in rise-time than any stress relaxation mechanisms, but long enough for artifacts to respond.

Humidity Response Time of Cases, Cabinets, and Packages. Leakage of museum display cases has been studied using either moisture (Thompson 1977; Michalski 1994) or contaminants (Cass 1988) as tracer gases. Michalski (1994) developed equations to model all the mechanisms that contribute to the leakage of humidity between enclosures and the room. Some results are given in Figure 6, and show the transition between diffusion-dominated and infiltration-dominated leakage in a 1 m case, given a stack pressure in the case of 0.04 Padue to a temperature difference of 1 K or a humidity difference of 40% rh. Most museum cases leak in the range of 10 to 100 air changes per day (ACD) or 0.4 to 4 air changes per hour (ACH), but careful design can limit this to 0.1 ACD (0.004 ACH).

Any material that sorbs and desorbs moisture (thereby tending to moderate relative humidity change in an enclosure) is known in museums as a **humidity buffer**. The hygrometric halftime of an enclosure with natural buffers like wood, textile, paper, etc., equals (Thomson 1977):

$$\theta_{0.5} = \frac{0.693 \alpha \rho f_p}{N C_{ws}}$$

wherewhere

$\theta_{0.5}$ = time for enclosure to reach half of an external step in relative humidity, days
α = moisture absorption coefficient, typically 0.1 for natural organic materials, 0.3 for regular silica gel
ρ = bulk density of the buffer, conservatively 500 kg/m^3
f_p = packing factor, fraction of case volume filled with buffer, dimensionless
N = leakage or exchange rate of enclosure, air changes per day (ACD)
C_{ws} = absolute humidity of air at saturation, 0.0173 kg/m^3 at 20°C

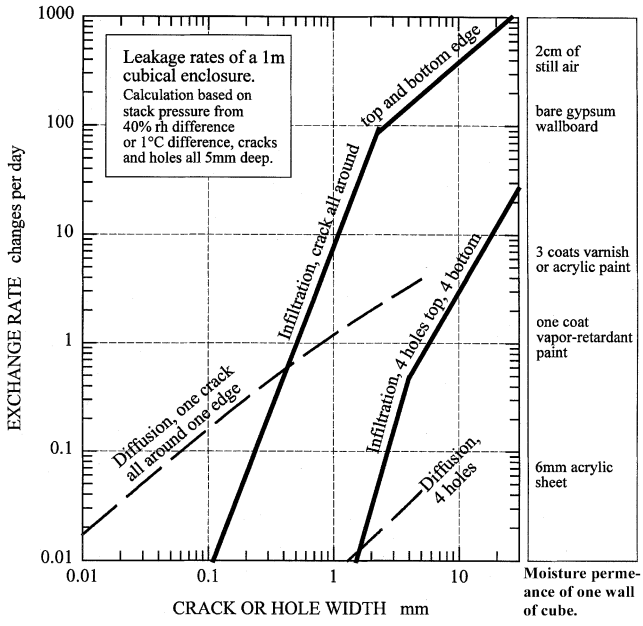

Fig. 6 Typical Contribution of Infiltration, Diffusion, and Permeation to Leakage of Museum Display Case or Cabinet

For wood, paper, textiles, leather, and similar natural organic materials, this reduces to approximately

$$\theta_{0.5} = \frac{2000 f_p}{N}$$

For ordinary cases and cabinets leaking at 10 to 100 ACD and f_p = 0.1, halftime would be 2 to 20 days. For a tight case, leaking 0.1 ACD, this improves to 2000 days, well beyond seasonal fluctuations. For an ordinary bookcase cabinet filled with books, f_p approaches 1, so halftimes would approach 20 to 200 days. These halftimes mean the artifacts ignore short fluctuations in relative humidity. On the other hand, there is a risk that after sustained periods of dampness or water entry these halftimes show a closed cabinet at 90% rh would take weeks to reach 70% rh, given a room at 50% rh. Such microenvironments can eliminate external humidity fluctuations; but the enclosure will settle at the mean relative humidity, which may be an undesirable value (e.g., most artifacts in humid climates and many artifacts in climates with winter heating and no humidification). Two solutions exist: periodic reconditioning of removable buffer, such as silica gel (Lafontaine 1984) or the active supply of correct humidity air to the exhibit case, as discussed in the section on Design Issues under System Selection.

SELECTION OF DESIGN TARGETS

The target specifications are summarized in Table 2, based on a balanced concern of all the deterioration processes previously described. The difficult issue of permissible fluctuations has been reduced to five classes: AA, A, B, C, and D. Gradients are conservatively considered to add to short-term fluctuations because artifacts can be moved from one part of a space to another, thereby adding a space gradient fluctuation to the dynamic fluctuations of the HVAC.

Class A is the optimum for most museums and galleries. Two possibilities with equivalent risks are given for Class A, either a larger gradient and short-term fluctuation, or a larger seasonal swing. Stress relaxation is used to equate an extra ±10% rh seasonal swing to a short-term ±5% rh.

A major institution with the mandate and resources to prevent even tiny risks legitimately demands the narrower fluctuations of Class AA. However, design for very long term reliability must take precedence over narrow fluctuations.

Classes B, C, and D should not be dismissed as ineffective. All of the material science described earlier points to a rapidly increasing risk with extreme conditions. Thus Class B and C control are useful and feasible for many medium to small institutions, and the best that can be done in most historic buildings. Class D recognizes that control of dampness is the single most important museum climate issue.

Library and Archive Dilemma

The whole issue of fluctuation control is secondary for libraries and archives. Except for rare and archaic records, their preservation problem is chemical decay of nineteenth and twentieth century records, and its acceleration by warmth and humidity. During retrieval and handling, however, the issues become mechanical, so here the conditions are identical to those required by museums and galleries. A detailed overview of all these issues is given by Michalski (1999) and in several standards on paper, photographic, and electronic records (ANSI *Standards* IT9.11, IT9.18, and IT9.25).

Specifications Apply to Entire Usable Space

The specifications in Table 2 are not simply HVAC targets for a single optimum point in the space or system. Museum and

Table 2 Temperature and Relative Humidity Specifications for Museum, Gallery, Library, and Archival Collections

Type	Set Point or Annual Average	Maximum Fluctuations and Gradients in Controlled Spaces			Collection Risks and Benefits
		Class of Control	Short Fluctuations plus Space Gradients	Seasonal Adjustments in System Set Point	
General Museums, Art Galleries, Libraries, and Archives All reading and retrieval rooms, rooms for storage of chemically stable collections, especially if mechanically medium to high vulnerability.	50% rh (or historic annual average for permanent collections) Temperature set between 15 and 25°C *Note*: Rooms intended for loan exhibitions must handle set point specified in loan agreement, typically 50% rh, 21°C, but sometimes 55% or 60% rh).	**AA** Precision control, no seasonal changes	±5% rh ±2 K	Relative humidity no change Up 5 K; down 5 K	No risk of mechanical damage to most artifacts and paintings. Some metals and minerals may degrade if 50% rh exceeds a critical relative humidity. Chemically unstable objects unusable within decades.
		A Precision control, some gradients or seasonal changes, not both	±5% rh ±2 K	Up 10% rh, down 10% rh Up 5 K; down 10 K	Small risk of mechanical damage to high vulnerability artifacts, no mechanical risk to most artifacts, paintings, photographs, and books. Chemically unstable objects unusable within decades.
			±10% rh ±2 K	RH no change Up 5 K; down 10 K	
		B Precision control, some gradients plus winter temperature setback	±10% rh ±5 K	Up 10%, down 10% rh Up 10 K, but not above 30°C Down as low as necessary to maintain RH control	Moderate risk of mechanical damage to high vulnerability artifacts, tiny risk to most paintings, most photographs, some artifacts, some books and no risk to many artifacts and most books. Chemically unstable objects unusable within decades, less if routinely at 30°C, but cold winter periods will double life.
		C Prevent all high risk extremes	Within 25 to 75% rh year-round Temperature rarely over 30°C, usually below 25°C		High risk of mechanical damage to high vulnerability artifacts, moderate risk to most paintings, most photographs, some artifacts, some books and tiny risk to many artifacts and most books. Chemically unstable objects unusable within decades, less if routinely at 30°C, but cold winter periods will double life.
		D Prevent dampness	Reliably below 75% rh		High risk of sudden or cumulative mechanical damage to most artifacts and paintings due to low humidity fracture; but high-humidity delamination and deformations, especially in veneers, paintings, paper, and photographs, is avoided. Mold growth and rapid corrosion avoided. Chemically unstable objects unusable within decades, less if routinely at 30°C, but cold winter periods will double life.
Archives, Libraries Storage of chemically unstable collections	Cold Store: −20°C, 40% rh	±10% rh ±2 K			Chemically unstable objects usable for millennia. Relative humidity fluctuations under one month do not affect most properly packaged records at these temperatures (time out of storage becomes the lifetime determinant).
	Cool Store: 10°C 30 to 50% rh	(Even if achieved only during winter setback, this is a net advantage to such collections, as long as damp is not incurred)			Chemically unstable objects usable for a century or more. Such books and papers tend to low mechanical vulnerability to fluctuations.
Special Metal Collections	Dry room: 0 to 30% rh	Relative humidity not to exceed some critical value, typically 30% rh			

Note: Short fluctuations means any fluctuation less than the seasonal adjustment. However, as noted in the section on Response Times of Artifacts, some fluctuations are too short to affect some artifacts or enclosed artifacts.

archive clients assume that stated specifications are performance targets for anywhere in the usable space, because they are defined by artifacts that can occupy any point in that space. These users usually monitor relative humidity and temperature independently of the HVAC sensors with thermohygrographs, data loggers, or handheld meters. These monitors often sit in shelves, in corners, against walls, or on floors, where temperature and moisture gradients are worst. Thus to meet a specification of ±10% rh in a space where the temperature gradient in the room may reach ±2 K, the system needs to maintain ±5% rh at the humidistat. Typical design implications for reduction of such gradients are better than average air distribution, and higher than average air change rates. It is important for client and engineer to agree on when and where the space will fall within specifications, and under what conditions of indoor loads and outdoor extremes.

BUILDING ENVELOPE PROBLEM

Museums, libraries, and archives often ask mechanical engineers for "improved climate control" in buildings never designed for such purposes. Conrad (1995) classified all such buildings by their possibilities and limitations. He found seven classes of building (or building part). In an abridged version of his scheme (Table 3), the possible classes of fluctuation control possible are listed for each class of building. Local climate determines which possibility is most likely.

Table 3 Classification of the Climatic Control Potential in Buildings

Category of Control	Building Class	Typical Building Construction	Typical Type of Building	Typical Building Use	System Used	Practical Limit of Climate Control	Class of Control Possible
Uncontrolled	I	Open structure	Privy, stocks, bridge, sawmill, well	No occupancy, open to viewers all year	No system.	None	D (if benign climate)
	II	Sheathed post and beam	Cabins, barns, sheds, silos, icehouse	No occupancy. Special event access.	Exhaust fans, open windows, supply fans, attic venting. No heat.	Ventilation	C (if benign climate) D (unless damp climate)
Partial control	III	Uninsulated masonry, framed and sided walls, single-glazed windows	Boat, train, lighthouse, rough frame house, forge	Summer tour use. Closed to public in winter. No occupancy.	Low level heat, summer exhaust ventilation, humidistatic heating for winter control.	Heating, ventilating	C (if benign climate) D (unless hot damp climate)
	IV	Heavy masonry or composite walls with plaster. Tight construction; storm windows	Finished house, church, meeting house, store, inn, some office buildings	Staff in isolated rooms, gift shop. Walk-through visitors only. Limited occupancy. No winter use.	Ducted low level heat. Summer cooling, on/off control, DX cooling, some humidification. Reheat capability.	Basic HVAC	B (if benign climate) C (if mild winter) D
Climate controlled	V	Insulated structures, double glazing, vapor retardant, double doors	Purpose built museums, research libraries, galleries, exhibits, storage rooms	Education groups. Good open public facility. Unlimited occupancy.	Ducted heat, cooling, reheat, and humidification with control dead band.	Climate control, often with seasonal drift	AA (if mild winters) A B
	VI	Metal wall construction, interior rooms with sealed walls and controlled occupancy	Vaults, storage rooms, cases	No occupancy. Access by appointment.	Special heating, cooling, and humidity control with precision constant stability control.	Special constant environments	AA A Cool Cold Dry

Historic Buildings

The New Orleans Charter, adopted by the American Institute for Conservation and the Association for Preservation Technology, calls for care in deciding on indoor environments in historic buildings. In particular, it warns against control of the indoor environment in ways that might be harmful to the building fabric. Generally, an indoor environment that varies seasonally and with changes in the weather is less detrimental to the building envelope than one that is designed for fixed set points of humidity and temperature. A common approach is to begin design with specified indoor conditions of temperature and humidity, then to expect the building envelope design (or redesign) to accommodate the indoor environment specification. This typically imposes thermal insulation, vapor retarders, and infiltration control. The New Orleans Charter suggests the following opposite approach for historic buildings:

1. Determine what tempering of the outdoor climate is already achieved by the building (including what fresh air requirements are provided by existing infiltration).
2. Determine what extremes of natural indoor climate swings are unacceptable.
3. Design mechanical services to prevent the undesirable extremes.

The advantages of this approach are (1) lowered stresses on the building envelope and (2) generally smaller equipment (beneficial in historic buildings, which rarely have generous service spaces). Of course, the mechanical equipment in historic buildings may be of historic value itself, and should not be removed or discarded without documentation.

Envelope Design

For detailed guidance on the thermal and moisture performance of building envelopes, see Chapter 22 and Chapter 23 of the 1997 *ASHRAE Handbook—Fundamentals*.

The often stringent requirements for humidity and filtration put special stresses on the building envelopes of museums and libraries. Museum buildings usually operate under positive pressure to help maintain good indoor air quality by ensuring that outdoor air enters the building at the air handler, thus allowing filtration. However, during cold weather, positive pressure in a humidified building may be detrimental. Humidified air contacts cold surfaces as it is forced outward through cracks and openings by the positive building pressure.

The building may be provided with either mechanical or natural relief vents to provide a path for exfiltrating air. With or without relief vents, however, a roughly quantifiable amount of moisture-laden air still passes through the building envelope. The pathways for the exfiltrating air should be elements of the building envelope design. In particular, the design should ensure that the exfiltration pathway will not wash potentially cold surfaces with humidified air. In analyzing the likelihood of condensation on potentially cold surfaces, the profile method described in Chapter 22 of the 1997 *ASHRAE Handbook—Fundamentals* should be followed. This analysis is important in order to determine the quantity of water that is likely to accumulate; and this quantity should be compared to the storage capacity of the critical building material. In many cases, even where the profile method indicates the possibility of condensation, the amount is small compared to the storage capacity of the material. It may be desirable in the design to include the capability to vary the pressurization of the building, so that it can be reduced during particularly cold weather.

Foundations. Water should not flow uncontrolled into any building through the foundation. This precaution is particularly true because the foundation areas are often used for storage where humidity control may be more critical than in public spaces. Chapter 23 of the 1997 *ASHRAE Handbook—Fundamentals* provides more information on this topic.

Windows. The classic and traditional means of determining excess humidity inside a building is to observe condensation on

windows. The early indication of condensation conditions is a slight film of dew or frost on the pane (or occasionally on the frame if it is of metal and more thermally conductive than the glass). Often such a film evaporates with rising temperatures with no detrimental effect. If the rate of water accumulation is so great that the beads collect into droplets and run onto the window frame, the conditions for damage are in place. Water may damage window finishes, and may collect and puddle and lead to mold growth in members that contain the collected water.

A useful rule, which may not always be true, says that condensation occurs when the temperature of the inside surface of the glass is at or below the dew point of the indoor air. However, a clean, dry surface, as it is chilled, may go 5 K or more below the dew-point temperature of the air and still remain dry. Usually window condensation occurs at temperatures below the dew point of the air, but once it has occurred, the temperature of the condensation itself is an excellent indicator of the dew-point temperature of the air.

In short, window condensation is a problem only to the extent that running condensation can damage finishes on the window and below. Window condensation is not a reliable early indicator of damage in other parts of the building envelope. Chapter 29 of the 1997 *ASHRAE Handbook—Fundamentals* provides more information about condensation on windows.

Walls. The classic concern for moisture in wall assemblies in humidified buildings is for interstitial condensation—that is, moisture damage to cold surfaces that is invisible from indoors. For most walls, vapor retarders are used against moisture diffusion. However, each building requires a different approach. In general, the common solution involves preventing moisture from entering the wall by diverting rain or adjusting the interior humidity. All of these concerns are the same as those for attic spaces.

Attic Spaces. A classic concern for an attic space is the formation of frost on the underside of the roof deck. The classic solution to this and wall problems is ventilation. Several elements of these problems and their solution deserve clarification.

Most water problems in attics are due not to vapor transport but rather to roof leaks, snow entry through vent devices, condensate on cold exposed pipes and ducts, leaking mechanical equipment, etc.

Interstitial condensation is a problem only in assemblies with cavities. Most low-slope roofs are constructed with dense cellular foam insulation directly beneath the roof membrane. Such systems are called compact roof systems, to distinguish them from cavity roof systems. Where there is no cavity, interstitial condensation is not possible.

The materials contained within attic cavities can be porous or hygroscopic, and their moisture content will vary with changes in the ambient air next to them. The moisture performance of cavities can be estimated and predicted only using transient rather than steady-state methods.

The moisture content of the materials strongly depend on the humidity characteristics of the air. The concentration of air in the attic is a function of the concentrations indoors and out, and the relative contributions of indoor air and outdoor air. Simply placing a vent to the outdoors does not guarantee a high concentration of outdoor air and a low concentration of indoor air—both of which is desirable. The relative concentrations of indoor and outdoor air is most affected by the aerodynamics of the roof and by any mechanical fans.

To design attics for good performance when the building is humidified requires preventing humidified indoor air from being transported into the attic. The first step in achieving this with cavity construction is to provide an airtight ceiling plane. Chapter 23 of the 1997 *ASHRAE Handbook—Fundamentals* discusses roof venting in detail.

COCOONED ZONES

Amdur (1965) suggested the use of a room-within-a-room or "cocoon" for humidity-controlled museum spaces. This concept has been applied both as a specially built box in an existing room, and as a zone of well-controlled rooms surrounded by a zone of less well-controlled perimeter rooms. In terms of Table 3, it is the creation of a class VI building environment in a building that may be as low as class II. It has been especially useful for creating display and storage zones in an historic building. The intent in all cases is to avoid direct contact between humidity controlled air and the building envelope. Such cocoons also reduce the risk of thermal and relative humidity gradients near the walls of the controlled zone.

Assuming the outer unhumidified zone is at least one room wide, has normal levels of air change, and is not subject to unusually high vapor and air pressure differences, the inner wall need not be extraordinarily airtight, because exfiltration between zones is much lower than exfiltration through the outer envelope. All doors between zones, however, must be closed most of the time.

If the gap between the cocoon and the building envelope becomes very small, the cocoon simply becomes a good air retarder installed on the inner face of the old wall. Such a cocoon must be extraordinarily airtight. In practice, when cocooning near the envelope of an historic, leaky building, the risk of humidity damage to the historic envelope is much less if the space between cocoon and envelope is heated with unhumidified air and is wide enough for human access. This access allows easy installation of services through this space and inspection for airtightness, water leaks, pest entry, and fire risks. Cocoons also permit the conversion of historic rooms to modern display areas without damage to the original wall finish.

SYSTEM SELECTION

A typical project consists of many types of spaces, such as galleries, reading rooms, search rooms, laboratories, conference rooms, stacks, storage rooms, restaurants or cafeterias, auditoriums, rare book vaults, offices, lounges, and study rooms. Only a few of these spaces will hold environmentally sensitive objects. One of the primary prerequisites for most buildings of this type is a high expectation for performance with low or limited budgets. This generally shifts the focus to capital cost and minimizes features that may reduce operating costs and problems.

Design Issues

Functional Organization. While the HVAC system is the main determinant for actively maintaining the preservation environment, an effective preservation environment involves more than just the HVAC system. The basic architectural design (such as windows and vapor retarders) and building operation (24 h operation and availability of tempering sources) must complement these purposes and not pose impractical challenges to the HVAC design.

This suggests involvement by the HVAC engineer in the early planning stages to ensure that the space layout does not present unnecessary problems. In the best case, collections are housed separately from visitors, users, staff and all other functions. Where separation is not possible, processes and activities that pose a threat to collections should be physically and mechanically separated from the collections. Separate systems for collection and noncollection areas allow isolation of environments and can reduce project costs for noncollection areas.

A typical issue, particularly in fine art museums, is whether to treat executive offices as collection spaces. This issue should be considered carefully, not only for the added capital and operating cost, but for the risks to the collection if the offices are not treated and are nonetheless used for collections display.

Frequently used entrances, such as the lobby and loading dock, are one of the most environmentally disruptive elements in a

museum or library. The designer should ensure that the loads from these spaces are managed and isolated from the primary collection areas.

Film, particularly a substantial amount, should be housed separately from other collections in order to minimize exposure to unfiltered acid gas emitted by many paper products. These gaseous pollutants are thought to contribute to vinegar syndrome and the formation of redox blemishes on film collections.

Reliability. While some collections cannot tolerate lost environmental conditions for more than a short period, most collections can tolerate several hours of lost conditions without major damage. The engineer should evaluate equipment failure scenarios against collection sensitivities and likely maintenance efforts to see what reasonable precautions can be taken to minimize down time and damage to the collection. In some cases spare equipment may need to be kept at the project site to allow timely repairs.

Loads. In most cases the HVAC system should operate 24 hours a day. Galleries and reading rooms generally only have a high occupancy at certain times. Some gallery occupancies are as high as 1 m^2 per person, in contrast to stack or storage areas where the density may be 100 m^2 per person or less. Areas in the building may be used for receptions or parties with higher than normal occupancy density. Not only should the system be designed to handle this load, but it should be able to deal efficiently with the more common part-load condition.

Lighting loads vary widely from space to space and at different times of the day. The most common driver of sizing for cooling in a museum is the display lighting. Lighting typically varies from 20 to 90 W/m^2 for display areas. Figures as high as 160 W/m^2 are sometimes requested by lighting designers, but rarely needed in fact. With the trend to more concern for collection damage by light, display areas for light-sensitive objects should have low illumination levels, and associated low lighting power densities.

Humidistatically Controlled Heating. In this approach, the heating system is controlled by a humidistat rather than a thermostat (Lafontaine and Michalski 1984). Where interior temperatures drop consistently below 10°C, it solves the problem of humidity in a building that does not have an adequate envelope. Cold, damp air is heated until the relative humidity drops to 50%. Obviously, humidistatically controlled heating does not provide human comfort in winter, but many small museums, historic village buildings, and reserve collection buildings are essentially unoccupied in winter. A high limit thermostat is necessary to stop overheating during warm weather, and a low limit thermostat is optional if freezing of water pipes is a concern. This approach has been applied in Canada (Lafontaine 1982; Marcon 1987) in the United States, such as Shelbourne historic village (Kerschner 1992), and in many historic buildings in Britain (Staniforth 1984).

Some cautions apply. Foundations in a previously heated building may heave if the ground is waterlogged prior to freeze-up. Improved drainage, insulation of the ground near the footings, and heating of the basement reduce this risk. Problems have been noted (Padfield and Jensen 1990) for a building with dense object storage and very low infiltration rate, such as a specially sealed storage space. In this situation, a very slow supply of dehumidified air to the space has been successful (Padfield 1996).

Overall, the approach is cost effective in seasonal museums in colder climates like the northern United States and Canada, especially for low-mass wood frame buildings and in maritime regions. Humidistat control does not work in warm, humid weather; in fact, without a high-limit thermostat it will heat hot, humid conditions to dangerous temperatures. In this case, humidistat control has been supplemented by domestic dehumidifiers.

Exhibit Cases. Exhibit cases should be designed to protect the collection from environmental extremes and excesses. Both sealed cases and vented cases are used. Sealed cases rely on isolation from the ambient environment in the exhibition room, and they usually require passive or special conditioning systems independent of the regular room air. Because sealed cases are subject to a buildup of gaseous contaminants, they should be made of inert materials. Cases that are inside, built-in, or back up to a properly conditioned space can be vented to the conditioned space.

HVAC supply air should not be blown into exhibit cases, nor return air drawn through the cases. The temperature and humidity of supply air varies as it corrects space conditions and can cause extremes in temperature and humidity if blown into a case. Even if temperature and humidity conditions are sensed inside the case as part of the control system, the typical high ratio of supply air to the case volume has made virtually all such treatments problematic in the past. Problems are usually caused by poor design, or the drastic effects of an HVAC system component failure; acute temperature or humidity conditions from the supply air are undiluted and immediately impact on what are usually the most sensitive objects in a collection. While return air is more stable, most return air accumulates particles, which then accumulate in the display case.

In spite of the recommendation against doing so, exhibit cases have been actively conditioned successfully—but it has been done by using special equipment designed specifically for the purpose. Such a system is not configured like a typical HVAC system. It includes various features, such as desiccant beds to stabilize the supply air humidity, that are part of a successful application. Its use has primarily been in cold climates where conditioning large, historic galleries has been problematic, and case conditioning is often the only solution. Moreover, the stability of conditions achieved with such systems has been less than ideal, and certainly less stable than sealed exhibit cases with passive conditioning agents. The primary value is where many cases need to be conditioned where rigorous sealing and reconditioning passive agents are impractical.

Two approaches to such local mechanical control of display cases have been used: one machine per case, and one machine for many cases. The Royal Ontario Museum in Toronto has taken a one machine per case approach. The equipment circulates air in a closed loop between case and machine via small ducts (50 mm diameter). A prototype and design plans for a machine to supply many cases was developed by the Canadian Conservation Institute (Michalski 1982). The unit supplies filtered and humidity controlled air via small tubes to each case (typically 6 mm diameter) without return air, relying instead on compensating leakage from the case. It uses multistage centrifugal blowers at about 2.5 kPa (gage) and a silica gel column, which controls humidity.

Such slow air exchange units take full advantage of the case buffering capacity, so that the relative humidity takes many days to rise or fall after mechanical failure, thereby making repair response time less critical. Sease (1990, 1991) described several units retrofitted in the Chicago Field Museum. Beale (1996) compared the cost and effectiveness of three approaches to relative humidity control in an existing museum building at the Boston Museum of Fine Arts: the CCI machine for many cases, HVAC retrofits for gallery zones, and silica gel in cases. Although case controlling machines are very cost effective compared to whole zone control, they currently suffer from inadequate support infrastructure, such as repair manuals, service parts, installation guidelines, and troubleshooting guides.

Cold Storage Vaults. Projects often require cold storage vaults to extend the life of materials particularly sensitive to thermal deterioration, such as acetate film and color photographic materials. These vaults usually require special equipment and most such successful systems are provided by experienced turnkey or design-build vendors (Wilhelm 1993).

Primary Elements and Features

The following primary functional elements and basic features of an HVAC system provide a good preservation environment for a museum or library, as suggested in Figure 7 (Lull 1990).

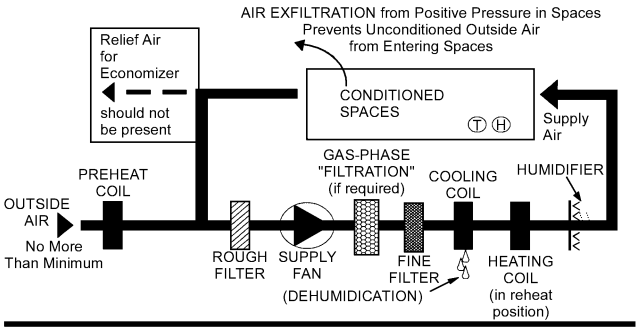

Fig. 7 Primary Elements of Preservation Environment HVAC System
(Lull 1990)

Constant Air Volume. Libraries and museums rely on mechanically assisted airflow to filter the air, ensure even temperature and humidity, suppress mold growth, and provide cooling or heating. Air should be constantly circulated at sufficient volume, regardless of space-tempering needs, to ensure good circulation throughout the collections space. In general, perimeter radiation and other sensible-only heating or cooling elements should be avoided, because they can create local humidity extremes near collections.

Cooling and Heating. The system should provide the necessary cooling and heating, but must subordinate temperature control, particularly excessive or capricious heating, to the need for stable relative humidity.

Humidification. Humidification should be provided by steam or water introduced in the air system. The humidification moisture source should be checked for potential contamination. In many cases the heating steam is treated with compounds that can pose a risk to the collection (Volent and Baer 1985). Systems should be selected and designed to prevent standing pools of water, and should follow good humidification design as described in Chapters 1 and 20 of the 2000 *ASHRAE Handbook—Systems and Equipment*.

While virtually all HVAC treatments are based on temperature control zones, for this type of building, humidity control is of more concern than temperature control. In spite of the averaging effect of a common mixed-return air and common humidifier on a central system, in several instances the retrofit of zone humidifiers have been required to recover from poor conditions even when the same humidity level is desired in each zone on the same system. However, maintaining widely different conditions in zones off the same air handler can be wasteful of energy and may ultimately be difficult to achieve. If possible, different zone conditions should have the same absolute moisture content, using zone reheat to modify space humidity for the different relative humidity conditions.

Dehumidification. The most common problem in museums and libraries is inadequate or ineffective dehumidification. Modest dehumidification can be achieved with most cooling systems, limited by the apparatus dew point at the cooling coil, and requiring adequate reheat. Most problems can be traced to compromises in the temperature of the cooling medium or the lack of reheat. Some chilled water systems may not be able to reliably deliver chilled water that is sufficiently cold, the chilled water temperature may be reset, or may have cooling coils too shallow to provide adequate dehumidification. Some reheat coils use a heating source that is unavailable in the summer or too expensive to operate.

Sebor (1995) notes the following typical approaches to more aggressive dehumidification, with increasing capability of reaching lower moisture content in the conditioned air:

- **Low-temperature chilled water**, which is usually based on a glycol solution. This method has the advantages of familiar operation and stable control and the disadvantage of managing glycol.
- **Direct-expansion (DX) refrigeration** is usually better for small systems and has lower capital costs; it generally is less reliable, requires more energy, and may require a defrost cycle.
- **Desiccant dehumidifiers** are not as familiar as the other approaches; desiccants can be quite effective if properly designed, installed, and maintained. Economy of operation is very sensitive to the cost of the regeneration heat source.

Desiccant and other dehumidification equipment needs to be applied with a cooling system; it cannot maintain comfort conditions alone. For library or archive projects requiring cool, dry conditions, a dehumidification system may be required. Chapter 22 of the 2000 *ASHRAE Handbook—Systems and Equipment* has further information on desiccants.

Outside Air. Economizer cooling is usually the primary cause of humidity fluctuations in museums and libraries. Outside air is seldom at a desirable temperature and humidity, and it can introduce particulate and gaseous contaminants as well. Air-side economizers should not be used unless (1) a bin analysis or other appropriate study shows outside air to have a favorable moisture content for an economical number of hours, and (2) favorable outside air can be reliably selected by the control system. Usually only the minimum amount of outside air should be provided for occupants as required by ASHRAE *Standard* 62, to pressurize the collection spaces, and to compensate for air evacuated by local exhausts. Relief air (see Figure 7) usually should not be used, unless required to support high outside air requirements for high occupancy conditions. Since peak occupancies are rare, outside air might be controlled by monitoring levels of carbon dioxide or other appropriate gases indicative of occupancy.

The added cost of preconditioning outside air, usually with a cooling coil, often benefits humidity control and economical operation. This cooling can reduce the amount of reheat needed for dehumidification, and may reduce the static pressure on the primary fan by keeping the cooling coil dry.

Outdoor air should be supplied by a separate duct with a fan connected to the inlet side of the HVAC system. The outdoor air supply rate for space pressurization depends on the building envelope and should be sufficient to create a small positive pressure of approximately 1 Pa. A typical outdoor air supply rate should create 0.2 ACH in the space (calculated using the volume of the empty space).

Where the major museum concern is external urban pollution, Cass et al. (1988) observed that the outside air supply rate (or natural infiltration such as open windows) determines the concentration of ozone found in the building. The authors recommended that the outside air supply be adjusted as necessary and not be fixed for maximum occupancy levels.

Particulate Filtration. To avoid particle buildup and cleaning problems, air filters should be effective down to the contamination particle size, typically $< 1\ \mu m$. This will likely require 90 to 95% atmospheric dust spot media filtration (as required in ASHRAE *Standard* 52.1) in an economical particulate filtration system.

High-voltage electrostatic air cleaners may not be suitable for this type of building because they may generate ozone. Any ozone runs the risk of oxidizing precious objects. An alternative filter is a permanently-polarized electret-plastic media, which cannot generate ozone.

Gas-Phase Filtration. Where new construction materials, interior contamination, collection off-gassing, or outdoor pollution present a gaseous contamination threat to a sensitive collection, active control of gaseous contaminants may be required. This is common practice for sensitive, valuable holdings, such as film media and rare books. Chapter 44 discusses filtration of gaseous contaminants.

Air Distribution. High, monumental spaces are prone to thermal stratification; if this condition places collections at risk then

appropriate return and supply air may be required to ensure air motion across the entire space. Diffusers typically create a uniform temperature distribution along the room height. Displacement ventilation may have an application in some buildings. Temperature differences between the occupied zone air and the return air of 3 to 5 K can be expected in this method of ventilation.

Galleries and display areas may have changing use and loads from varied lighting and visitors. While this can sometimes be addressed through temperature control zones, an adjustable supply air may be more economical and ultimately more effective.

Supply air should not blow on collections. In other types of buildings the supply air may be diffused along a wall. This airflow pattern can be a major problem in a gallery because collections are displayed on the walls, and a wall jet would produce high temperature and humidity gradients. A floor supply should also be avoided because particulates at the dirtiest level will be entrained in the air.

Factors affecting uniformity of air temperature in the occupied zone (usually within 2 m from the floor level) include the method of air supply, type of air diffuser used, the temperature difference between the supply and room air, the room air temperature, and the level of space obstruction (e.g. by partitions). However exhibits located above the normal height must be considered as well. Zhivov et al. (1996) define the maximum supply air temperature differential that does not cause greater than desired temperature differences in the occupied zone. The supply air temperature should be based on space loads moderated by the requirement for good air diffusion. Chapter 31 of the 1997 *ASHRAE Handbook—Fundamentals* has further information on air distribution design.

Controls. Sensors, thermostats, and humidistats must be located in the collection space itself, not in the return air stream. A variation in temperature is usually preferable to a prolonged swing in humidity. This method of control has strong implications for design, since conventional control approaches treat temperature as the primary goal and humidity as supplementary. In cases where comfort conditions are not required, humidity-controlled heating (Lafontaine 1982; Marcon 1987; Staniforth 1984) might be used. This modulates heating within a very broad temperature dead band to seek stable or moderated humidity conditions.

Types of Systems

Proper airflow is important to filter the air, control humidity, and suppress mold growth, as well as to heat and cool the collections space. Minimum airflow criteria vary from 6 to 8 air changes per hour (NBS 1983; Chapter 3 of this volume). This requirement is usually best met with a constant-volume system.

The problems most often overlooked in this type of building are maintenance access and risk to the collection from disruptions and leaks from overhead or decentralized equipment. Pipes carrying water or steam over and in collection areas always present the possibility of leaks. While some systems can provide full control without running any pipes to the zones, other systems require two to six pipes to be run to each zone. To reach collection spaces these pipes usually must be run over or in collection areas and are, unfortunately, the pipes most likely to leak. Leaks and maintenance can prevent effective use of spaces and result in lost space efficiency. For this reason, all-air systems are usually preferred.

Central air-handling stations keep filtration, dehumidification, humidification, maintenance, and monitoring equipment away from the collection. The investment in this added space and the expense of the more elaborate duct system provides major returns in reduced disruption to the collection spaces and a dramatically extended service life of the distribution system. Unlike most commercial projects, space turnover in museums and the like is low and rezoning is rarely needed. In some museums, 60-year old multizone duct systems have been reused; renovating the old system is quite economical, with the majority of the renovations confined entirely to the mechanical rooms. This is in comparison to common duct-distribution systems (such as terminal reheat, dual-duct, and variable-air-volume systems), where renovations often require a new duct system and terminal equipment, which involves a major expense from demolishing the old duct system, installing the new duct system, and demolishing and re-installing architectural finishes.

Constant-Volume Reheat. In many institutions, terminal reheat with steam or hot water coils located near or over collection spaces have caused chronic problems from steam and water leaks. Efficient zone-level humidification often suggests placing the humidifier downstream from the reheat coil; if the reheat coil is located near or over collection spaces, preventive maintenance on humidifiers further complicates the maintenance problems. Constant-volume reheat systems are quite effective when the reheat coils and humidifiers are installed entirely within the mechanical space, instead of at the terminal, feeding through what is effectively a "multizone" distribution system.

Multizone System. A multizone air handler with zone reheat and zone humidification can provide a stable and relatively energy-efficient solution. However, multizone systems without individual zone reheat and individual zone humidification have proved problematic in many institutions, requiring the retrofit of zone equipment for stable humidity control. With the proper layout and equipment compliment, a multizone system can reduce the amount of reheat and prove to be among the most energy efficient.

Bovill (1988, Figure 10) shows the preference for constant volume and multizone for this type of building. Without the requirement for many temperature control zones, but with the requirement for high air quality, the choices are limited to constant volume, multizone with bypass, dual-duct, and four-pipe induction. When air handlers are kept outside the collection areas (as recommended), the best choices are constant volume and multizone with bypass. When other systems are used, the client must be made fully aware of the compromises in performance, cost, and serviceability that may come with that system.

Dehumidification Coil. An important feature to multizone and dual-duct air handlers is a separate dehumidification coil upstream of both the hot and cold decks. This separate cooling coil, distinct from the cooling coil in the cold deck, is used when there is a dehumidification demand. In this way air might be cooled to dew point even if it eventually flows through the hot deck. Without this feature moist return air can be warmed in the hot deck and delivered back to the room without ever being dehumidified. An alternative is to locate a single cooling coil upstream of both decks, where the cold deck simply bypasses the hot deck, although this configuration can increase energy use.

Fan-Coil Units. Fan-coil units have been problematic when placed in and above collection areas. Fan-coil units expand and decentralize maintenance, causing much maintenance in the collection areas and a net increase in overall maintenance effort for the facility. Since they cool locally they need condensate drains. These drains have a history of leaking or backing up over time. As all-water systems, they require four pipes with pressurized water to run to each unit, increasing the chance of piping leaks in collection areas. On top of these problems, fan-coil units rarely, if ever, can provide the filtration and humidity control features required for collection spaces.

Variable Air Volume (VAV). VAV, while appropriate for other types of buildings, is generally inappropriate for museums, libraries, and archives. VAV systems used in this type of building have a reputation for poor humidity control, inadequate airflow, maintenance disruption, leaks in the collection spaces, and inflexibility to meet environmental needs. Many times the VAV system is chosen due to space and budget constraints. In virtually every case, the cost and space required for the properly designed VAV system (full filtration, local humidification, local dehumidification, minimum air-volume settings, well-planned piping,

well-planned maintenance access, and well-documented operating instructions) gives no advantages over the more conservative, less problematic, and easier to maintain constant volume systems. While the VAV system can be made to save energy compared to the constant-volume system, it usually does so at the expense of the client's collection.

If used, a VAV system should look much like a constant-volume reheat system, which has minimum airflow to prevent mold growth, contamination buildup, and uneven conditions in the conditioned space. Terminal equipment should include reheat for each zone, with the terminal equipment located in mechanical rooms or other spaces where access and service will not place a collection at risk. If the performance of a VAV system becomes a problem, it can be easily converted to a constant-volume reheat system with only an adjustment of controls.

Fan-Powered Mixing Boxes. These are generally inappropriate for this type of building. While fan-powered mixing boxes can help ensure air circulation to suppress mold growth, they do not provide the opportunity to effectively filter the air for particulates and gases. These fans also increase local maintenance requirements and present an added fire risk. If they include reheat, there is an added risk from leaks if the reheat is water or steam or from fire if the reheat is electric.

Energy and Operating Costs

In many cases the operation of a preservation environment is a significant expense, but for the long-term protection of a valuable collection, the annual cost of a good environment are a necessary expenditure. For the institution with a small or limited operating budget that cannot afford a major increase in the annual energy cost, some compromises might be warranted or some initial capital investments might be made to reduce the recurring annual costs.

Scope of Special Environments. One of the best ways to reduce operating costs is to treat as little of the building as possible with the special environments. Spaces not requiring the higher preservation criteria should be on separate air systems so they can be operated only when occupied.

Energy Efficiency. The recovery of condenser heat is an efficient way to provide reheat for dehumidification; it also substantially reduces the energy cost for dehumidification. Although an air-side economizer can cause problems, a water-side economizer can allow efficient winter cooling when condenser water is used. Due to the load diversity between day and night operations, particularly in museums, night cooling loads can sometimes best be met with a smaller off-hours chiller. Similarly, primary-secondary pumping can be of value as the loads vary throughout the day and from area to area.

Daylighting. The use of natural light is often proposed for this type of building. Ayres et al. (1990) observed that this feature is always a net energy penalty. Where used, the daylighting aperture should be kept to a minimum, and avoided as much as possible in and over collection areas. For lower risk of leaks and better-managed illumination, clerestory daylighting is preferred over skylights.

Maintenance and Ease of Operation. A common failing in many designs is little concern for on-going operation and maintenance. Most designs will work if properly adjusted and maintained, but many institutions find they do not have the staff, budget or expertise to give the system the attention it needs. The regular maintenance required should be matched against the institution's staff capabilities. For large projects in larger cities, code-required staffing for the plant should be considered; in some situations smaller reciprocating chillers can be used at night to preclude the licensed engineer required to operate larger chillers. Small projects without HVAC maintenance staff may need package equipment that does not require daily attention.

Note: Although the energy simulations in this research showed a net energy savings with skylights, this was only for the smallest skylight. Further, the only reason the smallest skylight showed a net energy savings is that it was assumed, unlike the larger skylights, to cause no increase in fan sizing and fan energy use. Instead, fan size and energy for the smallest skylight is increased proportionally on a par with the other skylights, it is a net energy loss. The only energy savings from the skylight in New York City is (apparently) from avoided reheat energy, and this does not offset its energy costs.

Heating 21.11
Cooling 21.13
Other Environmental Controls 21.14
Plant Growth Environmental Facilities 21.17
Other Plant Environmental Facilities 21.20

THE design of plant and animal housing is complicated by the many environmental factors affecting the growth and production of living organisms. The financial constraint that equipment must repay costs through improved economic productivity must be considered by the designer. The engineer must balance the economic costs of modifying the environment against the economic losses of a plant or animal in a less-than-ideal environment.

Thus, the design of plant and animal housing is affected by (1) economics, (2) concern for both workers and the care and well-being of animals, and (3) regulations on pollution, sanitation, and health assurance.

DESIGN FOR ANIMAL ENVIRONMENTS

Typical animal production plants modify the environment, to some degree, by housing or sheltering animals year-round or for parts of a year. The degree of modification is generally based on the expected increase in production. Animal sensible heat and moisture production data, combined with information on the effects of environment on growth, productivity, and reproduction, help designers select optimal equipment (Chapter 10 of the 1997 *ASHRAE Handbook—Fundamentals*). Detailed information is available in a series of handbooks published by the MidWest Plan Service. These include *Mechanical Ventilating Systems for Livestock Housing* (MWPS 1990), *Natural Ventilating Systems for Livestock Housing and Heating* (MWPS 1989), and *Cooling and Tempering Air for Livestock Housing* (MWPS 1990). ASAE *Monograph* No. 6, Ventilation of Agricultural Structures (Hellickson and Walter 1983), also gives more detailed information.

Design Approach

Environmental control systems are typically designed to maintain thermal and air quality conditions within an acceptable range and as near the ideal for optimal animal performance as is practicable. Equipment is usually sized assuming steady-state energy and mass conservation equations. Experimental measurements confirm that heat and moisture production by animals is not constant and that there may be important thermal capacitance effects in livestock buildings. Nevertheless, for most design situations, the steady-state equations are acceptable.

Achieving the appropriate fresh air exchange rate and establishing the proper distribution within the room are generally the two most important design considerations. The optimal ventilation rate is selected according to the ventilation rate logic curve (Figure 1).

During the coldest weather, the ideal ventilation rate is that required to maintain indoor relative humidity at or below the maximum desired, and air contaminant concentrations within acceptable ranges (Rates A and B in Figure 1). Supplemental heating is often required to prevent the temperature from dropping below optimal levels.

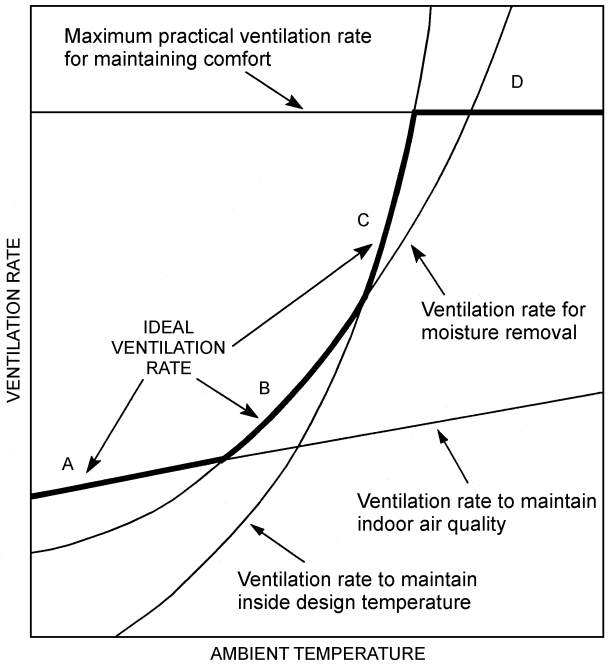

Fig. 1 Logic for Selecting the Appropriate Ventilation Rate in Livestock Buildings
(Adapted from Christianson and Fehr 1983)

In milder weather, the ventilation rate required for maintaining optimal room air temperature is greater than that required for moisture and air quality control (Rates C and D in Figure 1). In hot weather, the ventilation rate is chosen to minimize the temperature rise above ambient and to provide optimal air movement over animals. Cooling is sometimes used in hot weather. The maximum rate (D) is often set at 60 air changes per hour as a practical maximum.

Temperature Control

The temperature within an animal structure is computed from the sensible heat balance of the system, usually disregarding transient effects. Nonstandard buildings with low airflow rates and/or large thermal mass may require transient analysis. Steady-state heat transfer through walls, ceiling or roof, and ground is calculated as presented in Chapter 24 of the 1997 *ASHRAE Handbook—Fundamentals*.

The preparation of this chapter is assigned to TC 2.2, Plant and Animal Environment.

Mature animals typically produce more heat per of unit floor area than do young stock. Chapter 10 of the 1997 *ASHRAE Handbook—Fundamentals* presents estimates of animal heat loads. Lighting and equipment heat loads are estimated from power ratings and operating times. Typically, the designer selects indoor and outdoor design temperatures and calculates the ventilation rate to maintain the temperature difference. Outdoor design temperatures are given in Chapter 26 of the 1997 *ASHRAE Handbook—Fundamentals*. The section on Recommended Practices by Species in this chapter presents indoor design temperature values for various livestock.

Moisture Control

Moisture loads produced in an animal building may be calculated from data in Chapter 10 of the 1997 *ASHRAE Handbook—Fundamentals*. The mass of water vapor produced is estimated by dividing the animal latent heat production by the latent heat of vaporization of water at animal body temperature. Water spilled and evaporation of fecal water must be included in the estimates of latent heat production within the building. The amount of water vapor removed by ventilation from a totally slatted (manure storage beneath floor) swine facility may be up to 40% less than the amount removed from a solid concrete floor. If the floor is partially slatted, the 40% maximum reduction is decreased in proportion to the percentage of the floor that is slatted.

The ventilation should remove enough moisture to prevent condensation but should not reduce the relative humidity so low (less than 40%) as to create dusty conditions. Design indoor relative humidity for winter ventilation is usually between 70 and 80%. The walls should have sufficient insulation to prevent surface condensation at 80% rh inside.

During cold weather, the ventilation needed for moisture control usually exceeds that needed to control temperature. Minimum ventilation must always be provided to remove animal moisture. Up to a full day of high humidity may be permitted during extreme cold periods when normal ventilation rates could cause an excessive heating demand. Humidity level is not normally the controlling factor in mild or hot weather.

Air Quality Control

Contaminants. The most common and prevalent air contaminant in animal buildings is particulates. In animal buildings, particulates originate mainly from the feed, litter, fecal materials, and animals. Particulates include solid particles, liquid droplets, microorganisms, and moisture, and can be deposited deep within the respiratory system. Particulates carry the allergens which cause discomfort and health problems for workers in laboratory rodent facilities. They also carry much of the odors in animal facilities, and can carry the odors for long distances from the facilities. Consequently, particulates pose major problems for animals, workers, and neighbors. Particulate levels in swine buildings have been measured to range from 1.6 to 15 mg/m^3. Dust has not been a major problem in dairy buildings; one two-year study found an average of only 0.5 mg/m^3 in a naturally ventilated dairy barn. Poultry building dust levels average around 2 to 7 mg/m^3, but levels up to 18 to 29 mg/m^3 have been measured during high activity periods.

The most common gas contaminants are ammonia, hydrogen sulfide, other odorous compounds, carbon dioxide, and carbon monoxide. High moisture levels can also aggravate other contaminant problems. Ammonia, which results from the decomposition of manure, is the most important chronically present contaminant gas. Typical ammonia levels measured have been 7 to 37 mg/m^3 in poultry units, 0 to 15 mg/m^3 in cattle buildings, 4 to 22 mg/m^3 in swine units with liquid manure systems, and 7 to 37 mg/m^3 in swine units with solid floors (Ni et al. 1998a). Up to 150 mg/m^3 have been measured in swine units in winter. Ammonia should be maintained below 18 mg/m^3 and, ideally, below 7 mg/m^3.

Zhang et al. (1992) and Maghirang et al. (1995) found ammonia levels in laboratory animal rooms to be negligible, but concentrations could reach 45 mg/m^3 in cages. Weiss et al. (1991) found ammonia levels in rat cages of up to 260 mg/m^3 with four male rats per cage and 50 mg/m^3 with four female rats per cage. Hasenau et al. (1993) found that ammonia levels varied widely among various mouse microisolation cages; ammonia ranged from negligible to 380 mg/m^3 nine days after cleaning the cage.

Hydrogen sulfide, a by-product of the microbial decomposition of stored manure, is the most important acute gas contaminant. During normal operation, hydrogen sulfide concentration is usually insignificant (i.e., below 1 mg/m^3). A typical level of hydrogen sulfide in swine buildings is around 200 to 500 µg/m^3 (Ni et al. 1998b). However, levels can reach 280 to 460 mg/m^3, and possibly up to 1.4 to 11 g/m^3 during in-building manure agitation.

Odors from animal facilities are becoming an increasing concern, both in the facilities and in the surrounding areas. Odors result from both gases and particulates; particulates are of primary concern since odorous gases can be quickly diluted below odor threshold concentrations in typical weather conditions, while particulates can retain odor for long periods. Methods that control particulate and odorous gas concentrations in the air will reduce odors, but controlling odor generation at the source appears to be the most promising method of odor control.

Barber et al. (1993), reporting on 173 pig buildings, found that carbon dioxide concentrations were below 5400 mg/m^3 in nearly all instances when the external temperature was above 0°C. The report indicated that there was a very high penalty in heating cost in cold climates if the maximum-allowed carbon dioxide concentration was less than 9000 mg/m^3. Air quality control based on carbon dioxide concentrations was suggested by Donham et al. (1989). They suggested a carbon dioxide concentration of 2770 mg/m^3 as a threshold level, above which symptoms of respiratory disorders occurred in a population of swine building workers. For other industries, a carbon dioxide concentration of 9000 mg/m^3 is suggested as the time-weighted threshold limit value for 8 h of exposure (ACGIH 1998).

Other gas contaminants can also be important. Carbon monoxide from improperly operating unvented space heaters sometimes reaches problem levels. Methane is another occasional concern.

Control Methods. Three standard methods used to control air contaminant levels in animal facilities are

1. Reduce contaminant production at the source.
2. Remove contaminants from the air.
3. Reduce gas contaminant concentration by dilution (ventilation).

The first line of defense is to reduce release of contaminants from the source, or to at least intercept and remove them before they reach the workers and animals. Animal feces and urine are the largest sources of contaminants; but feed, litter, and the animals themselves are also a major source of contaminants, especially particulates. Successful operations effectively collect and remove all manure from the building within three days, before it decomposes sufficiently to produce large quantities of contaminants. Removing ventilation air uniformly from manure storage or collection areas helps remove contaminants before they reach animal or worker areas.

Ammonia production can be minimized by removing wastes from the room and keeping floor surfaces or bedding dry. Immediately covering manure solids in gutters and pits with water also reduces ammonia, which is highly soluble in water. Since adverse effects of hydrogen sulfide on production begin to occur at 30 mg/m^3, ventilation systems should be designed to maintain hydrogen sulfide levels below 30 mg/m^3 during agitation. When manure is agitated and removed from the storage, the building should be well ventilated and all animals and occupants evacuated due to potentially fatal concentrations of gases.

For laboratory animals, changing the bedding frequently and keeping the bedding dry with lower relative humidities and appropriate cage ventilation can reduce ammonia release. Individually ventilated laboratory animal cages or the placement of cages in mass air displacement units reduce contaminant production by keeping litter drier. Using localized contaminant containment work stations for dust-producing tasks such as cage-changing may also help. For poultry or laboratory animals, the relative humidity of air surrounding the litter should be kept between 50% and 75% to reduce particulate and gas contaminant release. Relative humidities between 40% and 75% also reduce the viability of pathogens in the air. A moisture content of 25 to 30% (wet basis) in the litter or bedding, keeps dust to a minimum. Adding 0.5 to 2% of edible oil or fat can significantly reduce dust emission from the feed. Respirable dust (smaller than 10 μm), which is most harmful to the health and comfort of personnel and animals, is primarily from feces, animal skins, and dead microorganisms. Respirable dust concentration should be kept below 0.23 mg/m^3. Some dust control technologies are available. For example, sprinkling oil at 5 mL/m^2 of floor area per day can reduce dust concentration by more that 80%. High animal activity levels release large quantities of particulates into the air, so management strategies to reduce agitation of animals are helpful.

Methods of removing contaminants from the air are essentially limited to particulate removal since gas removal methods are often too costly for animal facilities. Some animal workers wear personal protection devices (appropriate masks) to reduce inhaled particulates. Room air filters reduce animal disease problems, but they have not proven practical for large animal facilities due to the large quantity of particulates and the difficulty in drawing the particulates from the room and through a filter. Air scrubbers have the capability to remove gases and particulates, but the initial cost and maintenance make them impractical. Aerodynamic centrifugation is showing promise for removing the small particulates found in animal buildings.

Ventilation is the most prevalent method used to control gas contaminant levels in animal facilities. It is reasonably effective in removing gases, but not as effective in removing particulates. Pockets in a room with high concentrations of gas contaminants are common. These polluted pockets occur in dead air spots or near large contaminant sources. Providing high levels of ventilation can be costly in winter, can create drafts on the animals, and can increase the release of gas contaminants by increasing air velocity across the source.

Disease Control

Airborne microbes can transfer disease-causing organisms among animals. For some situations, typically with young animals where there are low-level infections, it is important to minimize air mixing among animal groups. It is especially important to minimize air exchange between different animal rooms, so buildings need to be fairly airtight.

Poor thermal environments and air contaminants can increase stress on the animals, which can make them more susceptible to disease. Therefore, a good environmental control system is important for disease control.

Air Distribution

Air speed should be maintained below 0.25 m/s for most animal species in both cold and mild weather. Animal sensitivities to draft are comparable to those of humans, although some animals are more sensitive at different stages. Riskowski and Bundy (1988) documented that air velocities for optimal rates of gain and feed efficiencies can be below 0.13 m/s for young pigs at thermoneutral conditions.

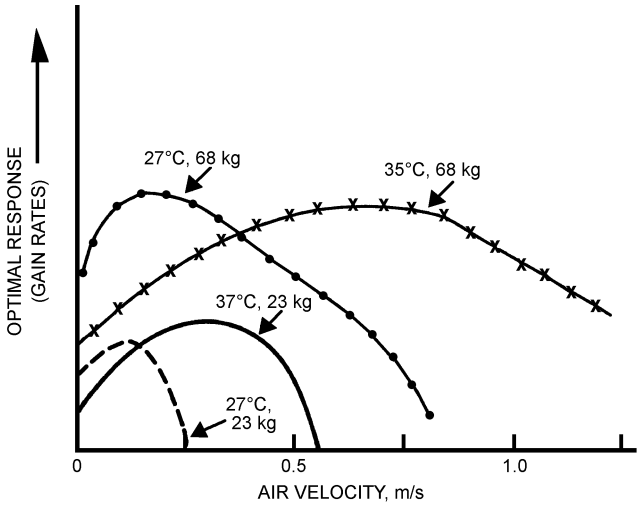

Fig. 2 Response of Swine to Air Velocity

Increased air movement during hot weather increases growth rates and improves heat tolerance. There are conflicting and limited data defining optimal air velocity in hot weather. Bond et al. (1965) and Riskowski and Bundy (1988) determined that both young and mature swine perform best when air speed is less than 1 m/s (Figure 2). Mount and Start (1980) did not observe performance penalties at air speeds increased to a maximum of 0.76 m/s.

Degree of Shelter

Livestock, especially young animals, need some protection from adverse climates. On the open range, mature cattle and sheep need protection during severe winter conditions. In winter, dairy cattle and swine may be protected from precipitation and wind with a three-sided, roofed shelter open on the leeward side. The windward side should also have approximately 10% of the wall surface area open to prevent a negative pressure inside the shelter; this pressure could cause rain and snow to be drawn into the building on the leeward side. Such shelters do not protect against extreme temperature or high humidity.

In warmer climates, shades often provide adequate shelter, especially for large, mature animals such as dairy cows. Shades are commonly used in Arizona; research in Florida has shown an approximate 10% increase in milk production and a 75% increase in conception efficiency for shaded versus unshaded cows. The benefit of shades has not been documented for areas with less severe summer temperatures. Although shades for beef cattle are also common practice in the southwest, beef cattle are somewhat less susceptible to heat stress, and extensive comparisons of various shade types in Florida have detected little or no differences in daily mass gain or feed conversion.

The energy exchange between an animal and various areas of the environment is illustrated in Figure 3. A well-designed shade makes maximum use of radiant heat sinks, such as the cold sky, and gives maximum protection from direct solar radiation and high surface temperature under the shade. Good design considers geometric orientation and material selection, including roof surface treatment and insulation material on the lower surface.

An ideal shade has a top surface that is highly reflective to solar energy and a lower surface that is highly absorptive to solar radiation reflected from the ground. A white-painted upper surface reflects solar radiation, yet emits infrared energy better than aluminum. The undersurface should be painted a dark color to prevent multiple reflection of shortwave energy onto animals under the shade.

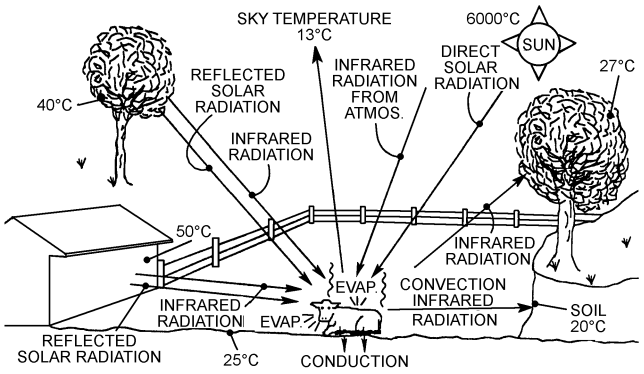

Fig. 3 Energy Exchange Between a Farm Animal and Its Surroundings in a Hot Environment

COOLING AND HEATING

Air Velocity

Increasing air velocity helps to facilitate the cooling of mature animals. It is especially beneficial when combined with skin wetting evaporative cooling. Mature swine benefit most with air velocities up to 1 m/s; cattle around 1.5 m/s; and poultry around 3 m/s. Air velocity can be increased with air circulation fans that blows air horizontally in circular patterns around the room, paddle fans that blow air downward, or tunnel cooling that moves air horizontally along the length of the building.

Evaporative Cooling

Supplemental cooling of animals in intensive housing conditions may be necessary during heat waves to prevent heat prostration, mortality, or serious losses in production and reproduction. Evaporative cooling, which may reduce ventilation air to 27°C or lower in most of the United States, is popular for poultry houses, and is sometimes used for swine and dairy housing.

Evaporative cooling is well suited to animal housing because the high air exchange rates effectively remove odors and ammonia, and increase air movement for convective heat relief. Initial cost, operating expense, and maintenance problems are all relatively low compared to other types of cooling systems. Evaporative cooling works best in areas with low relative humidity, but significant benefits can be obtained even in the humid southeastern United States.

Design. The pad area should be sized to maintain air velocities between 1.0 and 1.4 m/s through the pads. For most pad systems, these velocities produce evaporative efficiencies between 75 and 85%; they also increase pressures against the ventilating fans from 10 to 30 Pa, depending on the pad design.

The building and pad system must be airtight because air leaks due to the negative pressure ventilation will reduce the airflow through the pads, and hence reduce the cooling effectiveness.

The most serious problem encountered with evaporative pads for agricultural applications is clogging by dust and other airborne particles. Whenever possible, fans should exhaust away from pads on adjacent buildings. Regular preventive maintenance is essential. Water bleed-off and the addition of algaecides to the water are recommended. When pads are not used in cool weather, they should be sealed to prevent dusty inside air from exhausting through them.

High-pressure fogging with water pressure of 3.5 MPa is preferred to pad coolers for cooling the air in broiler houses with built-up litter. The high pressure creates a fine aerosol, causing minimal litter wetting. Timers and/or thermostats control the cooling. Evaporative efficiency and installation cost are about one-half those of a well-designed evaporative pad. Foggers can also be used with naturally ventilated, open-sided housing. Low-pressure systems are not recommended for poultry, but may be used during emergencies.

Nozzles that produce water mist or spray droplets to wet animals directly are used extensively during hot weather in swine confinement facilities with solid concrete or slatted floors. Currently, misting or sprinkling systems with larger droplets that directly wet the skin surface of the animals (not merely the outer portion of the hair coat) are preferred. Timers that operate periodically, (e.g., 2 to 3 min on a 15 to 20 min cycle) help to conserve water.

Mechanical Refrigeration

Mechanical refrigeration can be designed for effective animal cooling, but it is considered uneconomical for most production animals. Air-conditioning loads for dairy housing may require 2.5 kW or more per cow. Recirculation of refrigeration air is usually not feasible due to high contaminant loads in the air in the animal housing. Sometimes, zone cooling of individual animals is used instead of whole-room cooling, particularly in swine farrowing houses where a lower air temperature is needed for sows than for unweaned piglets. It is also beneficial for swine boars and gestating sows. Refrigerated air, 10 to 20 K below ambient temperature, is supplied through insulated ducts directly to the head and face of the animal. Air delivery rates are typically 10 to 20 L/s per animal for snout cooling, and 30 to 40 L/s per sow for zone cooling.

Earth Tubes

Some livestock facilities obtain cooling in summer and heating in winter by drawing ventilation air through tubing buried 2 to 4 m below grade. These systems are most practical in the north central United States for animals that benefit from both cooling in summer and heating in winter.

Cooling and Tempering Air for Livestock Housing (MWPS 1990) details design procedures for this method. A typical design uses 15 to 50 m of 200 mm diameter pipe to provide 150 L/s of tempered air. Soil type and moisture, pipe depth, airflow, climate, and other factors affect the efficiency of buried pipe heat exchangers. The pipes must slope to drain condensation, and must not have dips that could plug with condensation.

Heat Exchangers

Ventilation accounts for 70 to 90% of the heat losses in typical livestock facilities during winter. Heat exchangers can reclaim some of the heat lost with the exhaust ventilating air. However, predicting fuel savings based on savings obtained during the coldest periods will overestimate yearly savings from a heat exchanger. Estimates of energy savings based on air enthalpy can improve the accuracy of the predictions.

Heat exchanger design must address the problems of condensate freezing and/or dust accumulation on the heat exchanging surfaces. If unresolved, these problems result in either reduced efficiency and/or the inconvenience of frequent cleaning.

Supplemental Heating

For poultry with a mass of 1.5 kg or more, for pigs heavier than 23 kg, and for other large animals such as dairy cows, the body heat of the animals at recommended space allocations is usually sufficient to maintain moderate temperatures (i.e., above 10°C) in a well-insulated structure. Combustion-type heaters are used to supplement heat for baby chicks and pigs. Supplemental heating also increases the moisture-holding capacity of the air, which reduces the quantity of air required for removal of moisture. Various types of heating equipment may be included in ventilation, but they need to perform well in dusty and corrosive atmospheres.

Table 1 Minimum Recommended Overall Coefficients of Heat Transmission *U* for Insulated Assemblies[a,b]

Climatic Zone[d]	Recommended Minimum *U*, W/(m²·K)[c]					
	Cold		Modified Environment		Supplementally Heated	
	Walls	Ceiling	Walls	Ceiling	Walls	Ceiling
1	—	0.91[e]	0.91[e]	0.40	0.40	0.26
2	—	0.91	0.91	0.33	0.40	0.23
3	—	0.91	0.48	0.23	0.29	0.17

[a] Use assembly U-factors that include framing effects, air spaces, air films, linings, and sidings. Determine assembly U-factors by testing the full assembly in accordance with ASTM C 236 or C 976 or calculate by the procedures presented in the 1997 *ASHRAE Handbook—Fundamentals.*
[b] Values shown are not the values necessary to provide a heat balance between heat produced by products or animals and heat transferred through the building.
[c] Current practice for poultry grow-out buildings uses a *U* of 0.63 to 0.81 W/(m²·K) in the roof and walls.
[d] Refer to Figure 4.
[e] Where ambient temperature and radiant heat load are severe, use *U* = 0.48 W/(m²·K).

Insulation Requirements

The amount of building insulation required depends on climate, animal space allocations, and animal heat and moisture production. Refer to Figure 4 and Table 1 for selecting insulation levels. In warm weather, ventilation between the roof and insulation helps reduce the radiant heat load from the ceiling. Insulation in warm climates can be more important for reducing radiant heat loads in summer than reducing building heat loss in winter.

Cold buildings have indoor conditions about the same as outside conditions. Examples are free-stall barns and open-front livestock buildings. Minimum insulation is frequently recommended in the roofs of these buildings to reduce solar heat gain in summer and to reduce condensation in winter.

Modified environment buildings rely on insulation, natural ventilation, and animal heat to remove moisture and to maintain the inside within a specified temperature range. Examples are warm free-stall barns, poultry production buildings, and swine finishing units.

Supplementary heated buildings require insulation, ventilation, and extra heat to maintain the desired inside temperature and humidity. Examples are swine farrowing and nursery buildings.

VENTILATION

Mechanical Ventilation

Mechanical ventilation uses fans to create a static pressure difference between the inside and outside of a building. Farm buildings use either positive pressure, with fans forcing air into a building, or negative pressure, with exhaust fans. Some ventilation systems use a combination of positive pressure to introduce air into a building and separate fans to remove air. These zero-pressure systems are particularly appropriate for heat exchangers.

Positive Pressure Ventilation. Fans blow outside air into the ventilated space, forcing humid air out through any planned outlets and through leaks in walls and ceilings. If vapor barriers are not complete, moisture condensation will occur within the walls and ceiling during cold weather. Condensation causes deterioration of building materials and reduces insulation effectiveness. The energy used by fan motors and rejected as heat is added to the building—an advantage in winter but a disadvantage in summer.

Negative Pressure Ventilation. Fans exhaust air from the ventilated space while drawing outside air in through planned inlets and leaks in walls, in ceilings, and around doors and windows. Air distribution in negative pressure ventilation is often less complex and costly than positive or neutral pressure systems. Simple openings and baffled slots in walls control and distribute air in the building. However, at low airflow rates, negative pressure ventilation may not distribute air uniformly due to air leaks and wind pressure effects. Supplemental air mixing may be necessary.

Allowances should be made for reduced fan performance due to dust, guards, and corrosion of louver joints (Person et al. 1979). Totally enclosed fan motors are protected from exhaust air contaminants and humidity. Periodic cleaning helps prevent overheating. Negative pressure ventilation is more commonly used than positive pressure ventilation.

Ventilation should always be designed so that manure gases are not drawn into the building from manure storages connected to the building by underground pipes or channels.

Neutral Pressure Ventilation. Neutral pressure (push-pull) ventilation typically use supply fans to distribute air down a distribution duct to room inlets and exhaust fans to remove air from the room. Supply and exhaust fan capacities should be matched.

Neutral pressure systems are often more expensive, but they achieve better control of the air. They are less susceptible to wind effects and to building leakage than positive or negative pressure systems. Neutral pressure systems are most frequently used for young stock and for animals most sensitive to environmental conditions, primarily where cold weather is a concern.

Natural Ventilation

Either natural or mechanical ventilation is used to modify environments in livestock shelters. Natural ventilation is most common for mature animal housing, such as free-stall dairy, poultry growing, and swine finishing houses. Natural ventilation depends on pressure differences caused by wind and temperature differences. Well-designed natural ventilation keeps temperatures reasonably stable, if automatic controls regulate ventilation openings. Usually, a design includes an open ridge (with or without a rain cover) and openable sidewalls, which should cover at least 50% of the wall for summer operation. Ridge openings are about 17 mm wide for each metre of house width, with a minimum ridge width of 150 mm. to avoid freezing problems in cold climates. Upstand baffles on each side of the ridge opening greatly increase airflow (Riskowski et al. 1998). Small screens and square edges around sidewall openings can significantly reduce airflow through vents.

Openings can be adjusted automatically, with control based on air temperature. Some designs, referred to as flex housing, include a combination of mechanical and natural ventilation usually dictated by outside air temperature and/or the amount of ventilation required.

VENTILATION MANAGEMENT

Air Distribution

Pressure differences across walls and inlet or fan openings are usually maintained between 10 and 15 Pa. (The exhaust fans are usually sized to provide proper ventilation at pressures up to 30 Pa to compensate for wind effects.) This pressure difference creates inlet velocities of 3 to 5 m/s, sufficient for effective air mixing, but low enough to cause only a small reduction in fan capacity. A properly planned inlet system distributes fresh air equally throughout the building. Negative pressure ventilation that relies on cracks around doors and windows does not distribute fresh air effectively. Inlets require adjustment, since winter airflow rates are typically less than 10% of summer rates. Automatic controllers and inlets are available to regulate inlet areas.

Positive pressure ventilation, with fans connected directly to perforated air distribution tubes, may combine heating, circulation, and ventilation in one system. Air distribution tubes or ducts connected to circulating fans are sometimes used to mix the air in negative pressure ventilation. Detailed design procedures for perforated ventilation tubes are described by Zhang (1994). However, dust in the ducts is of concern when air is recirculated, particularly when cold incoming air condenses moisture in the tubes.

Inlet Design. Inlet location and size most critically affect air distribution within a building. Continuous or intermittent inlets can be placed along the entire length of one or both outside walls. Building widths narrower than 6 m may need only a single inlet along one wall. The total inlet area may be calculated by the system characteristic technique, which follows. Because the distribution of the inlet area is based on the geometry and size of the building, specific recommendations are difficult.

System Characteristic Technique. This technique determines the operating points for the ventilation rate and pressure difference across inlets. Fan airflow rate as a function of pressure difference across the fan should be available from the manufacturer. Allowances must be made for additional pressure losses from fan shutters or other devices such as light restriction systems or cooling pads.

Inlet flow characteristics are available for hinged baffle and center-ceiling flat baffle slotted inlets (Figure 5). Airflow rates can be calculated for the baffles in Figure 5 by the following:

For Case A:

$$Q = 1.1\ W\ p^{0.5} \tag{1}$$

For Case B:

$$Q = 0.71\ W\ p^{0.5} \tag{2}$$

For Case C (Total airflow from sum of both sides):

$$Q = 1.3\ W\ p^{0.5}(D/T)^{0.08} e^{(-0.867\ W/T)} \tag{3}$$

where

Q = airflow rate, L/s per metre length of slot opening
W = slot width, mm
p = pressure difference across the inlet, Pa
D = baffle width, mm
T = width of slot in ceiling, mm

Zhang and Barber (1995) measured infiltration rates of five rooms in a newly built swine building at 0.6 L/s per square metre of surface area at 20 Pa. Surface area included the area of walls and ceiling enclosing the room. It is important to include this infiltration rate into the ventilation design and management. For example, at 0.6 L/s per square metre of surface area, the infiltration represents 1.4 air changes per hour. In the heating season, the minimum ventilation is usually about 3 air changes per hour. Thus, large infiltration rates greatly reduce the airflow from the controlled inlet and adversely affect the air distribution.

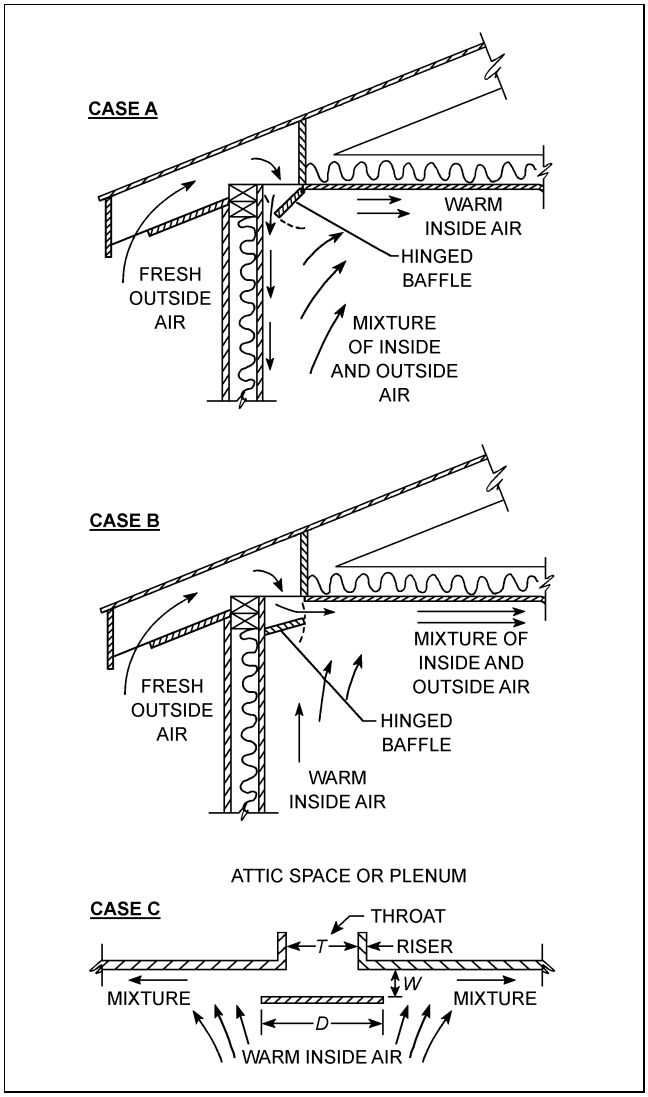

Fig. 5 Typical Livestock Building Inlet Configurations

Room Air Velocity. The average air velocity inside a slot ventilated structure relates to the inlet air velocity, inlet slot width (or equivalent continuous length for boxed inlets), building width, and ceiling height. Estimates of air velocity within a barn, based on air exchange rates, may be very low due to the effects of jet velocity and recirculation. Conditions are usually partially turbulent, and there is no reliable way to predict room air velocity at animal level. General design guidelines keep the throw distance less than 6 m from slots and less than 3 m from perforated tubes.

Fans

Fans should not exhaust against prevailing winds, especially for cold-weather ventilation. If structural or other factors require installing fans on the windward side, fans rated to deliver the required capacity against at least 30 Pa static pressure and with a relatively flat power curve should be selected. The fan motor should withstand a wind velocity of 50 km/h, equivalent to a static pressure of 100 Pa, without overloading beyond its service factor. Wind hoods on the fans or windbreak fences reduce the effects of wind.

Third-party test data should be used to obtain fan performance and energy efficiencies for fan selection (BESS Lab 1997). Fans should be tested with all accessories (such as louvers, guards, and hoods) in place, just as they will be installed in the building. The accessories have a major effect on fan performance.

Flow Control. Since the numbers and size of livestock and climatic conditions vary, means to modulate ventilation rates are often required beyond the conventional off/on thermostat switch. The minimum ventilation rate to remove moisture, reduce air contaminant concentrations, and keep water from freezing should always be provided. Methods of modulating ventilation rates include: (1) intermittent fan operation—fans operate for a percentage of the time controlled by a percentage timer with a 10 min cycle; (2) staging of fans using multiple units or fans with high/ low-exhaust capability; (3) the use of multispeed fans—larger fans (400 W and up) with two flow rates, the lower being about 60% of the maximum rate; and (4) the use of variable-speed fans—split-capacitor motors designed to modulate fan speed smoothly from maximum down to 10 to 20% of the maximum rate (the controller is usually thermostatically adjusted).

Generally, fans are spaced uniformly along the winter leeward side of a building. Maximum distance between fans is 35 to 40 m. Fans may be grouped in a bank if this range is not exceeded. In housing with side curtains, exhaust fans that can be reversed or removed and placed inside the building in the summer are sometimes installed to increase air movement in combination with doors, walls, or windows being opened for natural ventilation.

Thermostats

Thermostats should be placed where they respond to a representative temperature as sensed by the animals. Thermostats need protection and should be placed to prevent potential physical or moisture damage (i.e., away from animals, ventilation inlets, water pipes, lights, heater exhausts, outside walls, or any other objects that will unduly affect performance). Thermostats also require periodic adjustment based on accurate thermometer readings taken in the immediate proximity of the animal.

Emergency Warning

Animals housed in a high-density, mechanically controlled environment are subject to considerable risk of heat prostration if a failure of power or ventilation equipment occurs. To reduce this danger, an alarm and an automatic standby electric generator are highly recommended. Many alarms will detect failure of the ventilation. These alarms range from inexpensive power-off alarms to alarms that sense temperature extremes and certain gases. Automatic telephone-dialing systems are effective as alarms and are relatively inexpensive. Building designs that allow some side wall panels (e.g., 25% of wall area) to be removed for emergency situations are also recommended.

RECOMMENDED PRACTICES BY SPECIES

Mature animals readily adapt to a broad range of temperatures, but efficiency of production varies. Younger animals are more temperature sensitive. Figure 6 illustrates animal production response to temperature.

Relative humidity has not been shown to influence animal performance, except when accompanied by thermal stress. Relative humidity consistently below 40% may contribute to excessive dustiness; above 80%, it may increase building and equipment deterioration. Disease pathogens also appear to be more viable at either low or high humidity. Relative humidity has a major influence on the effectiveness of skin-wetting cooling methods.

Dairy Cattle

Dairy cattle shelters include confinement stall barns, free stalls, and loose housing. In a stall barn, cattle are usually confined to stalls approximately 1.2 m wide, where all chores, including milking and feeding, are conducted. Such a structure requires environmental modification, primarily through ventilation. Total space requirements are 5 to 7 m^2 per cow. In free-stall housing, cattle are not confined to stalls but can move freely. Space requirements per cow are 7 to 9 m^2. In loose housing, cattle are free to move within a fenced lot containing resting and feeding areas. Space required in sheltered loose housing is similar to that in free-stall housing. The shelters for resting and feeding areas are generally open-sided and require no air conditioning or mechanical ventilation, but supplemental air mixing is often beneficial during warm weather. The milking area is in a separate area or facility and may be fully or partially enclosed, thus requiring some ventilation.

For dairy cattle, climate requirements for minimal economic loss are broad, and range from 2 to 24°C with 40 to 80% rh. Below 2°C, production efficiency declines and management problems increase. However, the effect of low temperature on milk production is not as extreme as are high temperatures, where evaporative coolers or other cooling methods may be warranted.

Ventilation Rates for Each 500 kg Cow

Winter	Spring/Fall	Summer
17 to 22 L/s	67 to 90 L/s	110 to 220 L/s

Required ventilation rates depend on specific thermal characteristics of individual buildings and internal heating load. The relative humidity should be maintained between 50 and 80%.

Both loose housing and stall barns require an additional milk room to cool and hold the milk. Sanitation codes for milk production contain minimum ventilation requirements. The market being supplied should be consulted for all applicable codes. Some state codes require positive pressure ventilation of milk rooms. Milk rooms are usually ventilated with fans at rates of 4 to 10 air changes per hour to satisfy requirements of local milk codes and to remove heat from milk coolers. Most milk codes require ventilation in the passageway (if any) between the milking area and the milk room.

Beef Cattle

Beef cattle ventilation requirements are similar to those of dairy cattle on a unit mass basis. Beef production facilities often provide only shade and wind breaks.

Swine

Swine housing can be grouped into four general classifications:

1. Farrowing pigs, from birth to 14 kg, and sows
2. Nursery pigs, from 14 to 34 kg
3. Growing/finishing pigs, from 34 kg to market size
4. Breeding and gestation

In farrowing barns, two environments must be provided: one for sows and one for piglets. Because each requires a different temperature, zone heating and/or cooling is used. The environment within the nursery is similar to that within the farrowing barn for piglets. The requirements for growing barns and breeding stock housing are similar.

Currently recommended practices for **farrowing houses**:

- Temperature: 10 to 20°C, with small areas for piglets warmed to 28 to 32°C by means of brooders, heat lamps, or floor heat. Avoid cold drafts and extreme temperatures. Hovers are sometimes used. Provide supplemental cooling for sows (usually drippers or zone cooling) in extreme heat.

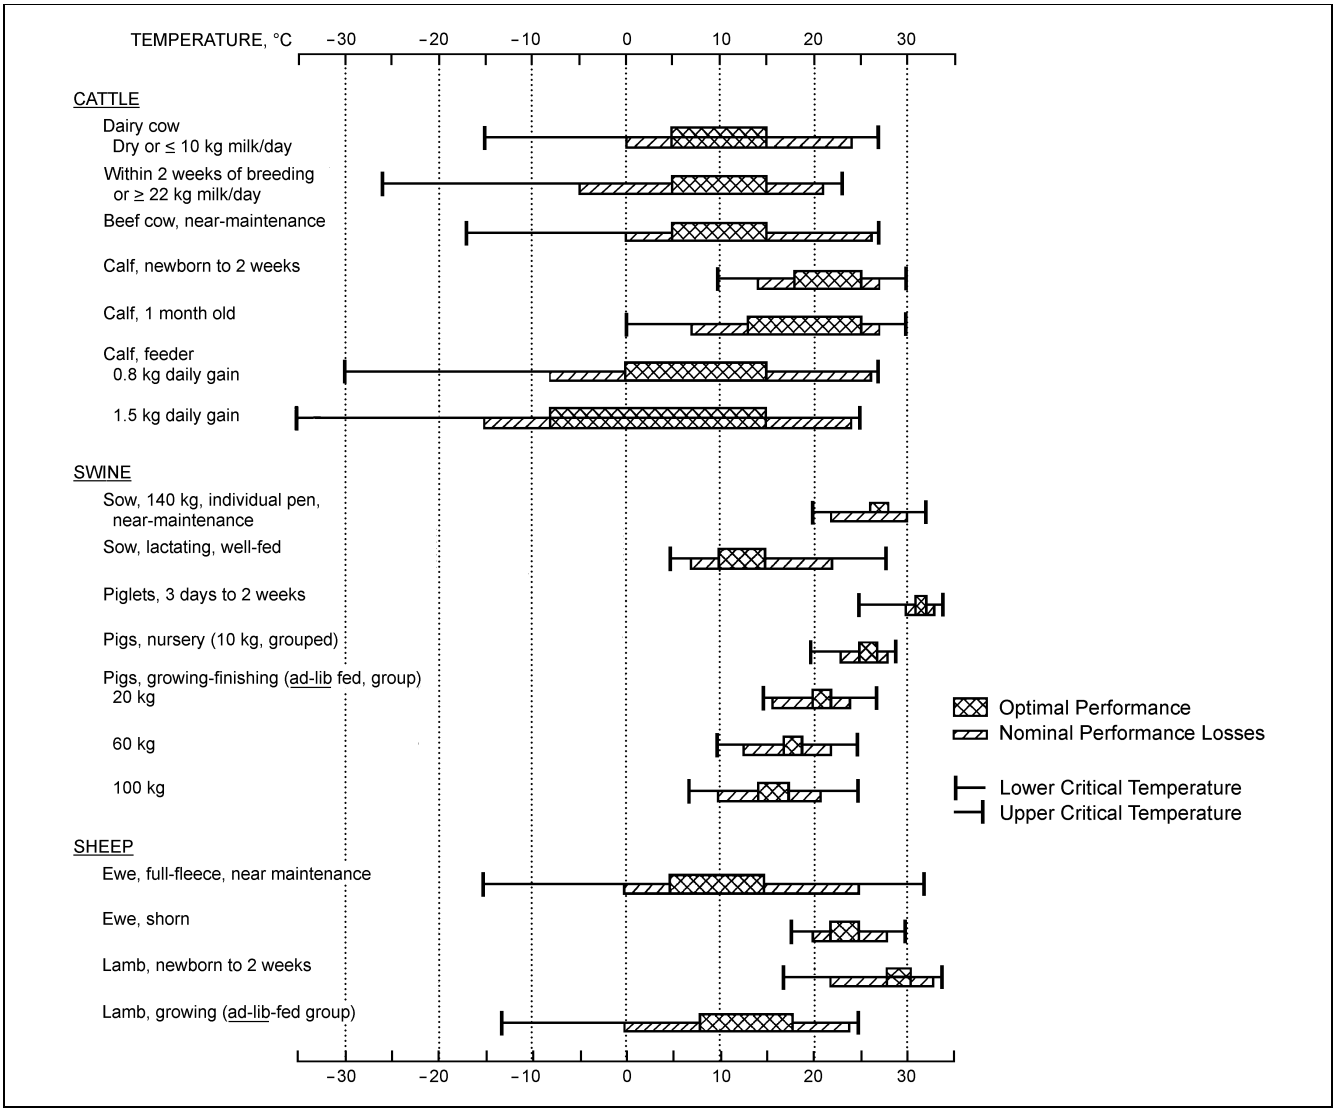

Fig. 6 Critical Ambient Temperatures and Temperature Zone for Optimum Performance and Nominal Performance Loss in Farm Animals
(Hahn 1985)

- Relative humidity: Up to 70% maximum
- Ventilation rate: 10 to 240 L/s per sow and litter (about 180 kg total mass). The low rate is for winter; the high rate is for summer temperature control.
- Space: 3.25 m^2 per sow and litter (stall); 6.0 m^2 per sow and litter (pens)

Recommendations for **nursery barns**:

- Temperature:
  27°C for first week after weaning. Lower room temperature 1.5 K per week to 21°C. Provide warm, draft-free floors. Provide supplemental cooling for extreme heat (temperatures 30°C and above).
- Ventilation rate:
  1 to 12 L/s per pig, 5.5 to 14 kg each
  1.5 to 18 L/s per pig, 6 to 36 kg each
- Space:
  0.19 to 0.23 m^2 per pig, 5.5 to 14 kg each
  0.28 to 0.37 m^2 per pig, 6 to 14 kg each

Recommendations for **growing** and **gestation barns**:

- Temperature:
  13 to 22°C preferred. Provide supplemental cooling (sprinklers or evaporative coolers) for extreme heat.
- Relative humidity:
  75% maximum in winter; no established limit in summer
- Ventilation rate:
  Growing pig (34 to 68 kg), 3 to 35 L/s
  Finishing pig (68 to 100 kg), 5 to 60 L/s
  Gestating sow (150 kg), 6 to 70 L/s
  Boar/breeding sow (180 kg), 7 to 140 L/s
- Space:
  0.55 m^2 per pig 34 to 68 kg each
  0.75 m^2 per pig 68 to 100 kg each
  1.3 to 2.2 m^2 per pig 110 to 130 kg each

Poultry

In broiler and brooder houses, growing chicks require changing environmental conditions, and heat and moisture dissipation

rates increase as the chicks grow older. Supplemental heat, usually from brooders, is used until the sensible heat produced by the birds is adequate to maintain an acceptable air temperature. At early stages of growth, moisture dissipation per bird is low. Consequently, low ventilation rates are recommended to prevent excessive heat loss. Litter is allowed to accumulate over 3 to 5 flock placements. Lack of low-cost litter material may justify the use of concrete floors. After each flock, caked litter is removed and fresh litter is added.

Housing for poultry may be open, curtain-sided or totally enclosed. Mechanical ventilation depends on the type of housing used. For open-sided housing, ventilation is generally natural airflow in warm weather, supplemented with stirring fans, and by fans with closed curtains in cold weather or during the brooding period. Mechanical ventilation is used in totally enclosed housing. Newer houses have smaller curtains and well-insulated construction to accommodate both natural and mechanical ventilation operation.

Recommendations for **broiler houses**:

- Room temperature: 15 to 27°C
- Temperature under brooder hover: 30 to 33°C, reducing 3 K per week until room temperature is reached
- Relative humidity: 50 to 80%
- Ventilation rate: Sufficient to maintain house within 1 to 2 K of outside air conditions during summer. Generally, rates are about 0.1 L/s per kilogram live mass during winter and 1 to 2 L/s per kilogram for summer conditions.
- Space: 0.06 to 0.1 m^2 per bird (for the first 21 days of brooding, only 50% of floor space is used)
- Light: Minimum of 10 lx to 28 days of age; 1 to 20 lx for growout (in enclosed housing).

Recommendations for **breeder houses** with birds on litter and slatted floors:

- Temperature: 10 to 30°C maximum; consider evaporative cooling if higher temperatures are expected.
- Relative humidity: 50 to 75%
- Ventilation rate: Same as for broilers on live mass basis.
- Space: 0.2 to 0.3 m^2 per bird

Recommendations for **laying houses** with birds in cages:

- Temperature, relative humidity, and ventilation rate: Same as for breeders.
- Space: 0.032 to 0.042 m^2 per hen minimum
- Light: Controlled day length using light-controlled housing is generally practiced (January through June).

Laboratory Animals

The well-being and experimental response of laboratory animals depends greatly on the design of the facilities. Cage type, noise levels, light levels, air quality, and thermal environment can affect animal well-being and, in many cases, affect how the animal responds to experimental treatments (Moreland 1975, Lindsey et al. 1978, Clough 1982, McPherson 1975). If any of these factors vary across treatments or even within treatments, it can affect the validity of experimental results, or at least increase experimental error. Consequently, laboratory animal facilities must be designed and maintained to expose the animals to appropriate levels of these environmental conditions and to ensure that all animals in an experiment are in a uniform environment. See Chapter 13 for additional information on laboratory animal facilities.

In the United States, recommended environmental conditions within laboratory animal facilities are usually dictated by the *Guide for the Care and Use of Laboratory Animals* (ILAR 1996). Temperature recommendations vary from 16 to 29°C depending on the species being housed. The acceptable range for relative humidity is 30 to 70%. For animals in confined spaces, daily temperature fluctuations should be kept to a minimum. Relative humidity must also be controlled, but not as precisely as temperature.

Ventilation recommendations are based on room air changes; however, cage ventilation rates may be inadequate in some cages and excessive in other cages depending on cage and facility design. ILAR (1996) recommendations for room ventilation rates of 10 to 15 air changes per hour are an attempt to provide adequate ventilation for the room and the cages. This recommendation is based on the assumption that adequate ventilation in the macroenvironment (room) provides sufficient ventilation to the microenvironment (cage). This may be a reasonable assumption when cages have a top of wire rods or mesh. However, several studies have shown that covering cages with filter tops provides a protective barrier for rodents and reduces airborne infections and diseases, especially neonatal diarrhea; but the filter can create significant differences in microenvironmental conditions.

Maghirang et al. (1995) and Riskowski et al. (1996) surveyed room and cage environmental conditions in several laboratory animal facilities and found that the animal's environmental needs may not be met even though the facilities were designed and operated according to ILAR (1996). The microenvironments were often considerably poorer than the room conditions, especially in microisolator cages. For example, ammonia levels in cages were up to 45 mg/m^3 even though no ammonia was detected in a room. Cage temperatures were up to 4 K higher than room temperature and relative humidities up to 41% higher.

Furthermore, cage microenvironments within the same room were found to have significant variation (Riskowski et al. 1996). Within the same room, cage ammonia levels varied from 0 to 45 mg/m^3; cage air temperature varied from 0.5 to 4 K higher than room temperature; cage relative humidity varied from 1 to 30% higher than room humidity, and average light levels varied from 2 to 337 lx. This survey found three identical rooms that had room ventilation rates from 4.4 to 12.5 air changes per hour (ACH) but had no differences in room or cage environmental parameters.

A survey of laboratory animal environmental conditions in seven laboratory rat rooms was conducted by Zhang et al. (1992). They found that room air ammonia levels were under 0.37 mg/m^3 for all rooms, even though room airflow varied from 11 to 24 ACH. Air exchange rates in the cages varied from less than 0.05 L/s to 1.2 L/s per rat, and ammonia levels ranged from negligible to 45 mg/m^3. Riskowski et al. (1996) measured several environmental parameters in rat shoebox cages in full-scale room mockups with various room and ventilation configurations. Significant variations in cage temperature and ventilation rates within a room were also found. Varying room ventilation rate from 5 to 15 ACH did not have large effects on the cage environmental conditions. These studies verify that designs based only on room air changes do not guarantee desired conditions in the animal cages.

In order to analyze the ventilation performance of different laboratory animal research facilities, Memarzadeh (1998) used **computational fluid dynamics** (CFD) to undertake computer simulation of over 100 different room configurations. CFD is a three-dimensional mathematical technique used to compute the motion of air, water, or any other gas or liquid. However, all conditions must be correctly specified in the simulation to produce accurate results. Empirical work defined inputs for such parameters as heat dissipation and surface temperature as well as the moisture, CO_2, and NH_3 mass generation rates for mice.

This approach compared favorably with experimentally measured temperatures and gas concentrations in a typical animal research facility. To investigate the relationships between room configuration parameters and the room and cage environments in laboratory animal research facilities, the following parameters were varied:

- Supply air diffuser type and orientation, air temperature, and air moisture content

- Room ventilation rate
- Exhaust location and number
- Room pressurization
- Rack layout and cage density
- Change station location, design, and status
- Leakage between the cage lower and upper moldings
- Room width

Room pressurization, change station design, and room width had little effect on ventilation performance. However, other factors found to affect either the macroenvironment or microenvironment or both led to the following observations:

- Ammonia production depends on relative humidity. Ten days after the last change of bedding, a high-humidity environment produced ammonia at about three times the rate of cages in a low-humidity environment.
- Acceptable room and cage ammonia concentrations after 5 days without changing cage bedding are produced by room supply airflow rates of around 4 L/s per kilogram of body mass of mice. This is equivalent to 5 ACH for the room with a single-density racks considered in this study, and 10 ACH for the room with double-density racks. The temperature of the supply air must be set appropriately for the heat load in the room. The room with single-density racks contained 1050 mice with a total mass of 21 kg and the room with double-density racks contained 2100 mice with a total mass of 42 kg.
- Increasing the room ventilation rate has a continuous beneficial effect on the room breathing zone ventilation (as measured by CO_2 and NH_3 concentrations). For single-density racks parallel to the walls, increasing the airflow from 5 ACH to 20 ACH reduces the breathing zone CO_2 concentration from 250 to 113 mg/m^3, a decrease of 55%. For double-density racks perpendicular to the walls, the reduction is even more dramatic—from over 540 to 167 mg/m^3 (over 70% reduction) when the airflow is increased from 5 ACH to 20 ACH.
- Increasing the room ventilation rate does not have a large effect on the cage ventilation. Increasing the supply airflow from 5 ACH to 20 ACH around single-density racks parallel to the walls reduces the CO_2 concentration from 3175 to 3000 mg/m^3, a reduction of only 6%. For the double-density racks perpendicular to the walls, the reduction is larger, but still only from about 4140 to 3240 mg/m^3 (around 20%)
- Both the cage and the room ammonia concentrations can be reduced by increasing the supply air temperatures. This reduces the relative humidity for a given constant moisture content in the air and the lower relative humidity leads to lower ammonia generation. Raising the supply discharge temperature from 19°C to 22°C at 15 ACH raises the room temperature by 3 K to around 23°C and the cages by 2 K to around 25°C. This can reduce ammonia concentrations by up to 50%.
- Using 22°C as the supply discharge temperature at 5 ACH (the lowest flow rate considered) for double-density racks produces a room temperature around 26°C with cage temperatures only slightly higher. Although this higher temperature provides a more comfortable environment for the mice (Gordon et al. 1997), the high room temperature may be unacceptable to the scientists working in the room.
- Ceiling or high-level exhausts tend to produce lower room temperatures (for a given supply air temperature, all CFD models were designed to have 22°C at the room exhaust) when compared to low-level exhausts. This indicates that low-level exhausts are less efficient at cooling the room.
- Low-level exhausts appear to ventilate the cages slightly better (up to 27% for the radial diffuser; much less for the slot diffuser) than ceiling or high-level exhausts when the cages are placed parallel to the walls, near the exhausts. Ammonia concentration in the cages decreased even further, although this is due to the higher temperatures in the low-level exhaust cases when compared to the ceiling and high-level exhausts. The room concentrations of CO_2 and ammonia do not show that any type of supply or exhaust is significantly better or worse than the other type.

DESIGN FOR PLANT FACILITIES

Greenhouses, plant growth chambers, and other facilities for indoor crop production overcome adverse outdoor environments and provide conditions conducive to economical crop production. The basic requirements of indoor crop production are (1) adequate light; (2) favorable temperatures; (3) favorable air or gas content; (4) protection from insects and disease; and (5) suitable growing media, substrate, and moisture. Because of their lower cost per unit of usable space, greenhouses are preferred over plant growth chambers for protected crop production.

This section covers greenhouses and plant growth facilities, and Chapter 10 of the 1997 *ASHRAE Handbook—Fundamentals* describes the environmental requirements in these facilities. Figure 7 shows the structural shapes of typical commercial greenhouses. Other greenhouses may have Gothic arches, curved glazing, or simple lean-to shapes. Glazing, in addition to traditional glass, now includes both film and rigid plastics. High light transmission by the glazing is usually important; good location and orientation of the house are important in providing desired light conditions. Location also affects heating and labor costs, exposure to plant disease and air pollution, and material handling requirements. As a general rule in the northern hemisphere, a greenhouse should be placed at a distance of at least 2.5 times the height of the object closest to it in the eastern, western, and southern directions.

GREENHOUSES

Site Selection

Sunlight. Sunlight provides energy for plant growth and is often the limiting growth factor in greenhouses of the central and northern areas of North America during the winter. When planning greenhouses that are to be operated year-round, a designer should design for the greatest sunlight exposure during the short days of midwinter. The building site should have an open southern exposure, and if the land slopes, it should slope to the south.

Soil and Drainage. When plants are to be grown in the soil covered by the greenhouse, a growing site with deep, well-drained, fertile soil, preferably sandy loam or silt loam, should be chosen. Even though organic soil amendments can be added to poor soil, fewer problems occur with good natural soil. However, when good soil is not available, growing in artificial media should be considered. The greenhouse should be level, but the site can and often should be sloped and well-drained to reduce salt buildup and insufficient soil aeration. A high water table or a hardpan may produce water-saturated soil, increase greenhouse humidity, promote diseases, and prevent effective use of the greenhouse. If present, these problems can be alleviated by tile drains under and around the

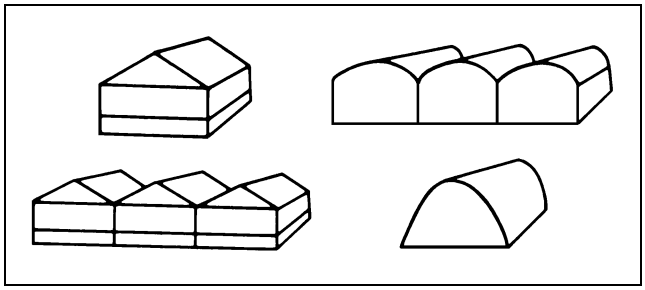

Fig. 7 Structural Shapes of Commercial Greenhouses

greenhouse. Ground beds should be level to prevent water from concentrating in low areas. Slopes within greenhouses also increase temperature and humidity stratification and create additional environmental problems.

Sheltered Areas. Provided they do not shade the greenhouse, surrounding trees act as wind barriers and help prevent winter heat loss. Deciduous trees are less effective than coniferous trees in midwinter, when the heat loss potential is greatest. In areas where snowdrifts occur, windbreaks and snowbreaks should be 30 m or more from the greenhouse to prevent damage.

Orientation. Generally, in the northern hemisphere, for single-span greenhouses located north of 35° latitude, maximum transmission during winter is attained by an east-west orientation. South of 35° latitude, orientation is not important, provided headhouse structures do not shade the greenhouse. North-south orientation provides more light on an annual basis.

Gutter-connected or ridge-and-furrow greenhouses are oriented preferably with the ridge line north-south regardless of latitude. This orientation permits the shadow pattern caused by the gutter superstructure to move from the west to the east side of the gutter during the day. With an east-west orientation, the shadow pattern would remain north of the gutter, and the shadow would be widest and create the most shade during winter when light levels are already low. Also, the north-south orientation allows rows of tall crops, such as roses and staked tomatoes, to align with the long dimension of the house—an alignment that is generally more suitable to long rows and the plant support methods preferred by many growers.

The slope of the greenhouse roof is a critical part of greenhouse design. If the slope is too flat, a greater percentage of sunlight is reflected from the roof surface (Figure 8). A slope with a 1:2 rise-to-run ratio is the usual inclination for a gable roof.

HEATING

Structural Heat Loss

Estimates for heating and cooling a greenhouse consider conduction, infiltration, and ventilation energy exchange. In addition, the calculations must consider solar energy load and electrical input, such as light sources, which are usually much greater for greenhouses than for conventional buildings. Generally, conduction q_c plus infiltration q_i are used to determine the peak requirements q_t for heating.

$$q_t = q_c + q_i \tag{4}$$

$$q_c = UA(t_i - t_o) \tag{5}$$

$$q_i = 0.5\ VN(t_i - t_o) \tag{6}$$

where

U = overall heat loss coefficient, W/(m^2·K) (Table 2 and Table 3)
A = exposed surface area, m^2
t_i = inside temperature, °C
t_o = outside temperature, °C
V = greenhouse internal volume, m^3
N = number of air exchanges per hour (Table 4)

Type of Framing

The type of framing should be considered in determining overall heat loss. Aluminum framing and glazing systems may have the metal exposed to the exterior to a greater or lesser degree, and the heat transmission of this metal is higher than that of the glazing material. To allow for such a condition, the U-factor of the glazing material should be multiplied by the factors shown in Table 3.

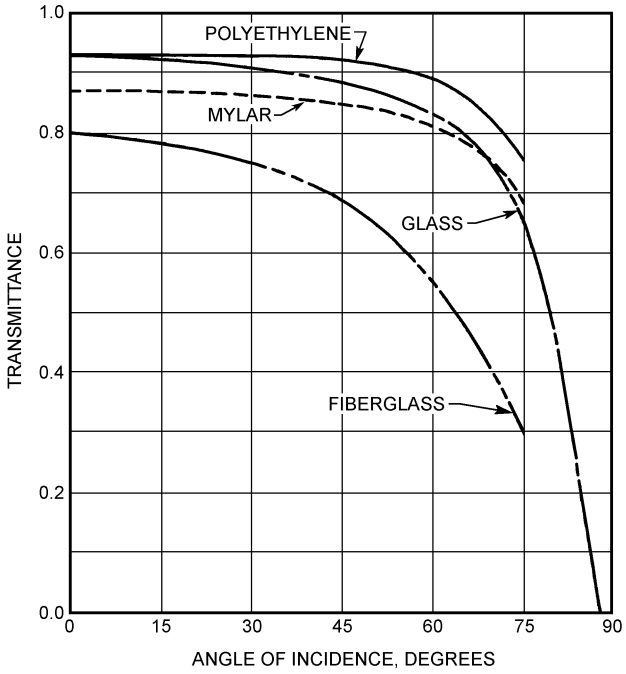

Fig. 8 Transmittance of Solar Radiation Through Glazing Materials for Various Angles of Incidence

Table 2 Suggested Heat Transmission Coefficients

		U, W/(m^2·K)
Glass		
	Single glazing	6.4
	Double glazing	4.0
	Insulating	Manufacturers' data
Plastic film		
	Single film[a]	6.8
	Double film, inflated	4.0
	Single film over glass	4.8
	Double film over glass	3.4
Corrugated glass fiber		
	Reinforced panels	6.8
Plastic structured sheet[b]		
	16 mm thick	3.3
	8 mm thick	3.7
	6 mm thick	4.1

[a]Infrared barrier polyethylene films reduce heat loss; however, use this coefficient when designing heating systems because the structure could occasionally be covered with non-IR materials.
[b]Plastic structured sheets are double-walled, rigid plastic panels.

Table 3 Construction U-Factor Multipliers

Metal frame and glazing system, 400 to 600 mm spacing	1.08
Metal frame and glazing system, 1200 mm spacing	1.05
Fiberglass on metal frame	1.03
Film plastic on metal frame	1.02
Film or fiberglass on wood	1.00

Table 4 Suggested Design Air Changes (N)

New Construction	
Single glass lapped (unsealed)	1.25
Single glass lapped (laps sealed)	1.0
Plastic film covered	0.6 to 1.0
Structured sheet	1.0
Film plastic over glass	0.9
Old Construction	
Good maintenance	1.5
Poor maintenance	2 to 4

Infiltration

Equation (6) may be used to calculate heat loss by infiltration. Table 4 suggests values for air changes *N*.

Radiation Energy Exchange

Solar gain can be estimated using the procedures outlined in Chapter 28 of the 1997 *ASHRAE Handbook—Fundamentals*. As a guide, when a greenhouse is filled with a mature crop of plants, one-half the incoming solar energy is converted to latent heat; and one-quarter to one-third, to sensible heat. The rest is either reflected out of the greenhouse or absorbed by the plants and used in photosynthesis.

Radiation from a greenhouse to a cold sky is more complex. Glass admits a large portion of solar radiation but does not transmit long-wave thermal radiation in excess of approximately 5000 nm. Plastic films transmit more of the thermal radiation but, in general, the total heat gains and losses are similar to those of glass. Newer plastic films containing infrared (IR) inhibitors reduce the thermal radiation loss. Plastic films and glass with improved radiation reflection are available at a somewhat higher cost. Normally, radiation energy exchange is not considered in calculating the design heat load.

Heating

Greenhouses may have a variety of heaters. One is a convection heater that circulates hot water or steam through plain or finned pipe. The pipe is most commonly placed along walls and occasionally beneath plant benches to create desirable convection currents. A typical temperature distribution pattern created by perimeter heating is shown in Figure 9. More uniform temperatures can be achieved when about one-third the total heat comes from pipes spaced uniformly across the house. These pipes can be placed above or below the crop, but temperature stratification and shading are avoided when they are placed below. Outdoor weather conditions affect temperature distribution, especially on windy days in loosely constructed greenhouses. Manual or automatic overhead pipes are also used for supplemental heating to prevent snow buildup on the roof. In a gutter-connected greenhouse in a cold climate, a heat pipe should be placed under each gutter to prevent snow accumulation.

An overhead tube heater consist sof a unit heater that discharges into 300 to 750 mm diameter plastic film tubing perforated to provide uniform air distribution. The tube is suspended at 2 to 3 m intervals and extends the length of the greenhouse. Variations include a tube and fan receiving the discharge of several unit heaters. The fan and tube system is used without heat to recirculate the air and, during cold weather, to introduce ventilation air. However, tubes sized for heat distribution may not be large enough for effective ventilation during warm weather.

Perforated tubing, 150 to 250 mm in diameter, placed at ground level heaters (underbench) can also improve heat distribution. Ideally, the ground-level tubing should draw air from the top of the greenhouse for recirculation or heating. Tubes on or near the floor have the disadvantage of being obstacles to workers and reducing usable floor space.

Underfloor heating can supply up to 25% or more of the peak heating requirements in cold climates. A typical underfloor system uses 20 mm plastic pipe spaced 300 to 400 mm on center, and covered with 100 mm of gravel or porous concrete. Hot water, not exceeding 40°C, circulates at a rate of 0.13 to 0.16 L/s per loop. Pipe loops should generally not exceed 120 m in length. This can provide 50 to 65 W/m^2 from a bare floor, and about 75% as much when potted plants or seedling flats cover most of the floor.

Similar systems can heat soil directly, but root temperature must not exceed 25°C. When used with water from solar collectors or other heat sources, the underfloor area can store heat. This storage consists of a vinyl swimming pool liner placed on top of insulation and a moisture barrier at a depth of 200 to 300 mm below grade, and filled with 50% void gravel. Hot water from solar collectors or other clean sources enters and is pumped out on demand. Some heat sources, such as cooling water from power plants, cannot be used directly but require closed-loop heat transfer to avoid fouling the storage and the power plant cooling water.

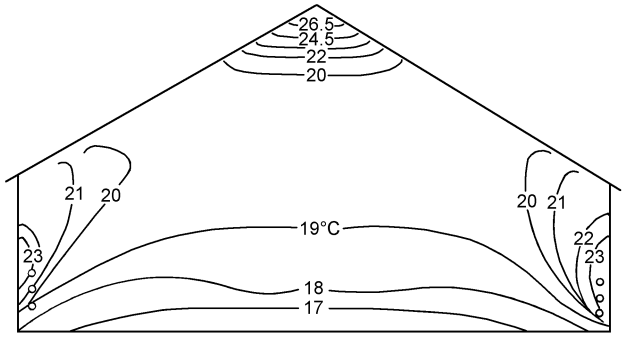

Fig. 9 Temperature Profiles in a Greenhouse Heated with Radiation Piping along the Sidewalls

Greenhouses can also be bottom heated with 6 mm diameter EPDM tubing (or variations of that method) in a closed loop. The tubes can be placed directly in the growing medium of ground beds or under plant containers on raised benches. The best temperature uniformity is obtained by flow in alternate tubes in opposite directions. This method can supply all the greenhouse heat needed in mild climates.

Bottom heat, underfloor heating, and under-bench heating are, because of the location of the heat source, more effective than overhead or peripheral heating, and can reduce energy loss by 20 to 30%.

Unless properly located and aimed, overhead unit heaters, whether hydronic or direct fired, do not give uniform temperature at the plant level and throughout the greenhouse. Horizontal blow heaters positioned so that they establish a horizontal airflow around the outside of the greenhouse offer the best distribution. The airflow pattern can be supplemented with the use of horizontal blow fans or circulators.

When direct combustion heaters are used in the greenhouse, combustion gases must be adequately vented to the outside to minimize danger to plants and humans from products of combustion. One manufacturer recommends that combustion air must have access to the space through a minimum of two permanent openings in the enclosure, one near the bottom. A minimum of 2200 mm^2 of free area per kilowatt input rating of the unit, with a minimum of 0.65 m^2 for each opening, whichever is greater, is recommended. Unvented direct combustion units should not be used inside the greenhouse.

In many greenhouses, a combination of overhead and perimeter heating is used. Regardless of the type of heating, it is common practice to calculate the overall heat loss first, and then to calculate the individual elements such as the roof, sidewalls, and gables. It is then simple to allocate the overhead portion to the roof loss and the perimeter portions to the sides and gables, respectively.

The annual heat loss can be approximated by calculating the design heat loss and then, in combination with the annual degree-day tables using the 18.3°C base, estimating an annual heat loss and computing fuel usage on the basis of the rating of the particular fuel used. If a 10°C base is used, it can be prorated.

Heat curtains for energy conservation are becoming more important in greenhouse construction. Although this energy savings may be considered in the annual energy use, it should not be used when calculating design heat load; the practice is to open the heat curtains

during snowstorms to facilitate the melting of snow, thereby nullifying its contribution to the design heat loss value.

Air-to-air and water-to-air heat pumps have been used experimentally on small-scale installations. Their usefulness is especially sensitive to the availability of a low-cost heat source.

Radiant (Infrared) Heating

Radiant heating is used in some limited applications for greenhouse heating. Steel pipes spaced at intervals and heated to a relatively high temperature by special gas heaters serve as the source of radiation. Because the energy is transmitted by radiation from a source of limited size, proper spacing is important to completely cover the heated area. Further, heavy foliage crops can shade the lower parts of the plants and the soil, thus restricting the radiation from warming the root zone, which is important to plant growth.

Cogenerated Sources of Heat

Greenhouses have been built near or adjacent to power plants to use the heat and electricity generated by the facility. While this energy may cost very little, an adequate standby energy source must be provided, unless the power supplier can assure that it will supply a reliable, continuous source of energy.

COOLING

Solar radiation is a considerable source of sensible heat gain; even though some of this energy is reflected from the greenhouse, some of it is converted into latent heat as the plants transpire moisture, and some is converted to plant material by photosynthesis. Natural ventilation, mechanical ventilation, shading, and evaporative cooling are common methods used to remove this heat. Mechanical refrigeration is seldom used to air condition greenhouses because the cooling load and resulting cost is so high.

Natural Ventilation

Most older greenhouses and many new ones rely on natural ventilation with continuous roof sashes on each side of the ridge and continuous sashes in the sidewalls. The roof sashes are hinged at the ridge, and the wall sashes are hinged at the top of the sash. During much of the year, vents admit enough ventilating air for cooling without the added cost of running fans.

The principles of natural ventilation are explained in Chapter 25 of the 1997 *ASHRAE Handbook—Fundamentals*. Ventilation air is driven by wind and thermal buoyancy forces. Proper vent openings take advantage of pressure differences created by wind. Thermal buoyancy caused by the temperature difference between the inside and the outside of the greenhouse is enhanced by the area of the vent opening and the stack height (vertical distance between the center of the lower and upper opening). Within the limits of typical construction, the larger the vents, the greater the ventilating air exchanged. For a single greenhouse, the combined area of the sidewall vents should equal that of the roof vents. In ranges of several gutter-connected greenhouses, the sidewall area cannot equal the roof vent area.

Mechanical (Forced) Ventilation

Exhaust fans provide positive ventilation without depending on wind or thermal buoyancy forces. The fans are installed in the side or end walls of the greenhouse and draw air through vents on the opposite side or end walls. The air velocity through the inlets should not exceed 2 m/s.

Air exchange rates between 0.75 and 1 change per minute effectively control the temperature rise in a greenhouse. As shown in Figure 10, the temperature inside the greenhouse rises rapidly at lower airflow rates. At higher airflow rates the reduction of the temperature rise is small, fan power requirements are increased, and plants may be damaged by the high air speed.

Shading

Shading compounds can be applied in varying amounts to the exterior of the roof of the greenhouse to achieve up to 50% shading. Durability of these compounds varies—ideally the compound will wear away during the summer and leave the glazing clean in the fall when shading is no longer needed. In practice, some physical cleaning is needed. Compounds used formerly usually contained lime, which corrodes aluminum and attacks some caulking. Most compounds used currently are formulated to avoid this problem.

Mechanically operated shade cloth systems with a wide range of shade levels are also available. They are mounted inside the greenhouse to protect them from the weather. Not all shading compounds or shade cloths are compatible with all plastic glazings, so the manufacturers' instructions and precautions should be followed.

Evaporative Cooling

Fan-and-Pad Systems. Fans for fan-and-pad evaporative cooling are installed in the same manner as fans used for mechanical ventilation. Pads of cellulose material in a honeycomb form are installed on the inlet side. The pads are kept wet continuously when evaporative cooling is needed. As air is drawn through the pads, the water evaporates and cools the air. New pads cool the air by about 80% of the difference between the outdoor dry-bulb and wet-bulb temperature, or to 1.5 to 2 K above the wet-bulb temperature.

The empirical base rate of airflow is 40 L/s per square metre of floor area. This flow rate is modified by multiplying it by factors for elevation (F_e), maximum interior light intensity (F_l), and the allowable temperature rise between the pad and the fans (F_t). These factors are listed in Table 5. The overall factor for the house is given by the following equation:

$$F_h = F_e F_l F_t \tag{7}$$

The maximum fan-to-pad distance should be kept to 53 m, although some greenhouses with distances of 68 m have shown no

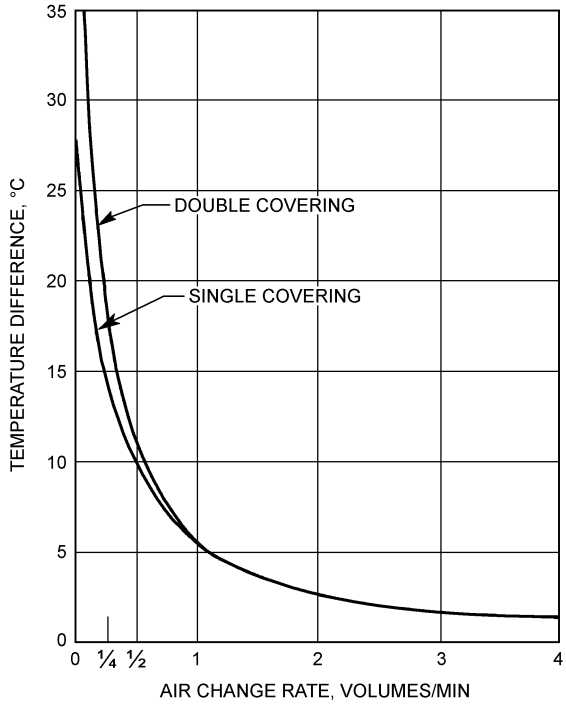

Fig. 10 Influence of Air Exchange Rate on Temperature Rise in Single- and Double-Covered Greenhouses

serious reduction in effectiveness. With short distances, the air velocity becomes so low that the air feels clammy and stuffy, even though the airflow is sufficient for cooling. Therefore, a velocity factor F_v listed in Table 6 is used for distances less than 30 m. For distance less than 30 m, F_v is compared to F_h. The factor that gives the greatest airflow is used to modify the empirical base rate. For fan-to-pad distances greater than 30 m, F_v can be ignored.

For best performance, pads should be installed on the windward side, and fans spaced within 7.5 m of each other. Fans should not blow toward pads of an adjacent house unless it is at least 15 m away. Fans in adjacent houses should be offset if they blow toward each other and are within 4.5 m of each other.

Recommended air velocities through commonly used pads are listed in Table 7. Water flow and sump capacities are shown in Table 8. The system should also include a small, continuous bleed-off of water to reduce the buildup of dirt and other impurities.

Unit Evaporative Coolers. This equipment contains the pads, water pump, sump, and fan in one unit. Unit coolers are primarily used for small compartments. They are mounted 4.5 to 6 m apart on the sidewall and blow directly into the greenhouse. They cool a distance of up to 15 m from the unit. A side sash on the outside opposite wall is the best outlet, but roof vents may also work. The roof vent on the same side as the unit should be slightly open for better air distribution. If the roof vent on the opposite side is opened instead, air may flow directly out the vent and not cool the opposite side of the greenhouse.

Fog. In a direct-pressure atomizer, a high-pressure pump forces water at 5.5 to 7 MPa through a special fog nozzle. Fog is considered to be a water droplet smaller than 40 μm in diameter. The direct-pressure atomizer generates droplets of 35 μm or less. This requires a superior filter to minimize clogging of the very small nozzle orifices.

A line of nozzles placed along the top of the vent opening can cool the entering air nearly to its wet-bulb temperature. Additional lines in the greenhouse continue to cool the air as it absorbs heat in the space.

Fogging will cool satisfactorily with less airflow than fan-and-pad systems, but the fan capacity must still be based on one air change per minute to ventilate the greenhouse when the cooler will be used without fog.

Table 5 Multipliers for Calculating Airflow for Fan-and-Pad Cooling

Elevation (Above Sea Level)		Max. Interior Light Intensity		Fan-to-Pad Temp. Difference	
m	F_e	klx	F_l	K	F_t

OTHER ENVIRONMENTAL CONTROLS

Humidity Control

At various times during the year, humidity may need to be controlled in the greenhouse. When the humidity is too high at night, it can be reduced by adding heat and ventilating simultaneously. When the humidity is too low during the day, it can be increased by turning on a fog or mist nozzle.

Winter Ventilation

During the winter, houses are normally closed tightly to conserve heat, but photosynthesis by the plants may lower the carbon dioxide level to such a point that it slows plant growth. Some ventilation helps maintain inside carbon dioxide levels. A normal rate of airflow for winter ventilation is 10 to 15 L/s per square metre of floor area.

Air Circulation

Continuous air circulation within the greenhouse reduces still-air conditions that favor plant diseases. Recirculating fans, heaters that blow air horizontally, and fans attached to polyethylene tubes are used to circulate air. The amount of recirculation has not been well defined, except that some studies have shown high air velocities (greater than 1.0 m/s) can harm plants or reduce growth.

Insect Screening

Insect screening is being used to cover vent inlets and outlets. These fine-mesh screens increase the resistance to airflow, which must be considered when selecting ventilation fans. The screen manufacturer should provide static pressure data for its screens. The pressure drop through the screen can be reduced by framing out from the vent opening to increase the area of the screen.

Carbon Dioxide Enrichment

Carbon dioxide is added in some greenhouse operations to increase growth and enhance yields. However, CO_2 enrichment is practical only when little or no ventilation is required for temperature control. Carbon dioxide can be generated from solid CO_2 (dry ice), bottled CO_2, and misting carbonated water. Bulk or bottled CO_2 gas is usually distributed through perforated tubing placed near the plant canopy. Carbon dioxide from dry ice is distributed by passing greenhouse air through an enclosure containing dry ice. Air movement around the plant leaf increases the efficiency with which the plant absorbs whatever CO_2 is available. One study found an air

Table 9 Constants to Convert to W/m²

Light Source	klx	μmol/(s·m²)
400 to 700 nm		
Incandescent (INC)	3.99	0.20

Low-pressure sodium (LPS)	1.92	0.20
Daylight	4.02	0.22

speed of 0.5 m/s to be equivalent to a 50% enrichment in CO_2 without forced air movement.

Radiant Energy

Light is normally the limiting factor in greenhouse crop production during the winter. North of the 35th parallel, light levels are especially inadequate or marginal in fall, winter, and early spring. Artificial light sources, usually high-intensity discharge (HID) lamps, may be added to greenhouses to supplement low natural light levels. High-pressure sodium (HPS), metal halide (MH), low-pressure sodium (LPS), and occasionally, mercury lamps coated with a color-improving phosphor, are currently used. Since differing irradiance or illuminance ratios are emitted by the various lamp types, the incident radiation is best described as radiant flux density (W/m^2) between 400 and 850 nm, or as photon flux density between 400 and 700 nm, rather than in photometric terms of lux.

To assist in relating irradiance to more familiar illuminance values,Table 9 shows constants for converting illuminance (lux) and photon flux density [$\mu mol/(s \cdot m^2)$] of HPS, MH, LPS, and other lamps to the irradiance (W/m^2).

Table 10 gives values of suggested irradiance at the top of the plant canopy, duration, and time of day for supplementing natural light levels for specific plants.

HID lamps in luminaires developed specifically for greenhouse use are often placed in a horizontal position, which may decrease both the light output and the life of the lamp. These drawbacks may be balanced by improved horizontal and vertical uniformity as compared to industrial parabolic reflectors.

Photoperiod Control

Artificial light sources are also used to lengthen the photoperiod during the short days of winter. Photoperiod control requires much lower light levels than those needed for photosynthesis and growth. Photoperiod illuminance needs to be only 6 to 12 W/m^2. The incandescent lamp is the most effective light source for this purpose due to its higher far-red component. Lamps such as 150 W (PS-30) silverneck lamps spaced 3 to 4 m on centers and 4 m above the plants provide a cost-effective system. Where a 4 m height is not practical, 60 W extended service lamps on 2 m centers are satisfactory. One method of photoperiod control is to interrupt the dark period by turning the lamps on at 2200 and off at 0200. The 4 h interruption, initially based on chrysanthemum response, induces a satisfactory long-day response in all photoperiodically sensitive species. Many species, however, respond to interruptions of 1 h or less. Demand charges can be reduced in large installations by operating some sections from 2000 to 2400 and others from 2400 to 0400. The biological response to these schedules, however, is much weaker than with the 2200 to 0200 schedule, so some varieties may flower prematurely. If the 4 h interruption period is used, it is not necessary to keep the light on throughout the interruption period. Photoperiod control of most plants can be accomplished by operating the lamps on light and dark cycles with 20% "on" times; for example, 12 s/min. The

Table 10 Suggested Radiant Energy, Duration, and Time of Day for Supplemental Lighting in Greenhouses

		Duration

early-flowering			

length of the dark period in the cycle is critical, and the system may fail if the dark period exceeds about 30 min. Demand charges can be reduced by alternate scheduling of the "on" times between houses or benches without reducing the biological effectiveness of the interruption.

Plant displays in places such as showrooms or shopping malls require enough light for plant maintenance and a spectral distribution that best shows the plants. Metal halide lamps, with or without incandescent highlighting, are often used for this purpose. Fluorescent lamps, frequently of the special phosphor plant-growth type, enhance color rendition, but are more difficult to install in aesthetically pleasing designs.

Design Conditions

Plant requirements vary from season to season and during different stages of growth. Even different varieties of the same species of plant may vary in their requirements. State and local cooperative extension offices are a good source of specific information on design conditions affecting plants. These offices also provide current, area-specific information on greenhouse operations.

Alternate Energy Sources and Energy Conservation

Limited progress has been achieved in heating commercial greenhouses with solar energy. Collecting and storing the heat requires a volume at least one-half the volume of the entire greenhouse. Passive solar units work at certain times of the year and, in a few localities, year-round.

If available, reject heat is a possible source of winter heat. Winter energy and solar (photovoltaic) sources are possible future energy sources for greenhouses, but the development of such systems is still in the research stage.

Energy Conservation. A number of energy-saving measures (e.g., thermal curtains, double glazing, and perimeter insulation) have been retrofitted to existing greenhouses and incorporated into new construction. Sound maintenance is necessary to keep heating system efficiency at a maximum level.

Automatic controls, such as thermostats, should be calibrated and cleaned at regular intervals, and heating-ventilation controls should interlock to avoid simultaneous operation. Boilers that can burn more than one type of fuel permit use of the most inexpensive fuel available.

Modifications to Reduce Heat Loss

Film covers that reduce heat loss are used widely in commercial greenhouses, particularly for growing foliage plants and other species that grow under low light levels. Irradiance (intensity) is reduced 10 to 15% per layer of plastic film.

One or two layers of transparent 0.10 or 0.15 mm continuous-sheet plastic is stretched over the entire greenhouse (leaving some vents uncovered), or from the ridge to the sidewall ventilation opening. When two layers are used, (outdoor) air at a pressure of 50 to 60 Pa is introduced continuously between the layers of film to maintain the air space between them. When a single layer is used, an air space can be established by stretching the plastic over the glazing bars and fastening it around the edges, or a length of polyethylene tubing can be placed between the glass and the plastic and inflated (using outside air) to stretch the plastic sheet.

Double-Glazing Rigid Plastic. Double-wall panels are manufactured from acrylic and polycarbonate plastics, with walls separated by about 10 mm. Panels are usually 1.2 m wide and 2.4 m or longer. Nearly all types of plastic panels have a high thermal expansion coefficient and require about 1% expansion space (10 mm/m). When a panel is new, light reduction is roughly 10 to 20%. Moisture accumulation between the walls of the panels must be avoided.

Double-Glazing Glass. The framing of most older greenhouses must be modified or replaced to accept double glazing with glass. Light reduction is 10% more than with single glazing. Moisture and dust accumulation between glazings increases light loss. As with all types of double glazing, snow on the roof melts slowly and increases light loss. Snow may even accumulate sufficiently to cause structural damage, especially in gutter-connected greenhouses.

Silicone Sealants. Transparent silicone sealant in the glass overlaps of conventional greenhouses reduces infiltration and may produce heat savings of 5 to 10% in older structures. There is little change in light transmission.

Precautions. The various methods described above reduce heat loss by reducing conduction and infiltration. They may also cause more condensation, higher relative humidity, lower carbon dioxide concentration, and an increase in ethylene and other pollutants. Combined with the reduced light levels, these factors may cause delayed crop production, elongated plants, soft plants, and various deformities and diseases, all of which reduce the marketable crop.

Thermal blankets are any flexible material that is pulled from gutter to gutter and end to end in a greenhouse, or around and over each bench, at night. Materials ranging from plastic film to heavy cloth, or laminated combinations, have successfully reduced heat losses by 25 to 35% overall. Tightness of fit around edges and other obstructions is more important than the kind of material used. Some films are vaportight and retain moisture and gases. Others are porous and permit some gas exchange between the plants and the air outside the blanket. Opaque materials can control crop day length when short days are part of the requirement for that crop. Condensation may drip onto and collect on the upper sides of some blanket materials to such an extent that they collapse.

Multiple-layer blankets, with two or more layers separated by air spaces, have been developed. One such design combines a porous-material blanket and a transparent film blanket; the latter is used for summer shading. Another design has four layers of porous, aluminum foil-covered cloths, with the layers separated by air.

Thermal blankets may be opened and closed manually as well as automatically. The decision to open or close should be based on the irradiance level and whether it is snowing, rather than on the time of day. Two difficulties with thermal blankets are the physical problems of installation and use in greenhouses with interior supporting columns, and the loss of space due to shading by the blanket when it is not in use during the day.

Other Recommendations. While the foundation can be insulated, the insulating materials must be protected from moisture, and the foundation wall should be protected from freezing. All or most of the north wall can be insulated with opaque or reflective-surface materials. The insulation reduces the amount of diffuse light entering the greenhouse and, in cloudy climates, causes reduced crop growth near the north wall.

Ventilation fan cabinets should be insulated, and fans not needed during the winter should be sealed against air leaks. Efficient management and operation of existing facilities are the most cost-effective ways to reduce energy use.

PLANT GROWTH ENVIRONMENTAL FACILITIES

Controlled-environment rooms (CERs), also called plant growth chambers, include all controlled or partially controlled environmental facilities for growing plants, except greenhouses. CERs are indoor facilities. Units with floor areas less than 5 m^2 may be moveable with self-contained or attached refrigeration units. CERs usually have artificial light sources, provide control of temperature and, in some cases, control relative humidity and CO_2 level.

CERs are used to study all aspects of botany. Some growers use growing rooms to increase seedling growth rate, produce more uniform seedlings, and grow specialized, high-value crops. The main components of the CER are (1) an insulated room or an insu-

lated box with an access door; (2) a heating and cooling mechanism with associated air-moving devices and controls; and (3) a lamp module at the top of the insulated box or room. CERs are similar to walk-in cold storage rooms, except for the lighting and larger refrigeration system needed to handle heat produced by the lighting.

Location

The location for a CER must have space for the outside dimensions of the chamber, refrigeration equipment, ballast rack, and control panels. Additional space around the unit is necessary for servicing the various components of the system and, in some cases, for substrate, pots, nutrient solutions, and other paraphernalia associated with plant research. The location also requires electricity (on the order of 300 W/m^2 of controlled environment space), water, and compressed air.

Construction and Materials

Wall insulation should have a thermal conductance of less than 0.15 $W/(m^2 \cdot K)$. Materials should resist corrosion and moisture. The interior wall covering should be metal, with a high-reflectance white paint, or specular aluminum with a reflectivity of at least 80%. Reflective films or similar materials can be used, but will require periodic replacement.

Floors and Drains

Floors that are part of the CER should be corrosion-resistant. Tar or asphalt waterproofing materials and volatile caulking compounds should not be used because they will likely release phytotoxic gases into the chamber atmosphere. The floor must have a drain to remove spilled water and nutrient solutions. The drains should be trapped and equipped with screens to catch plant and substrate debris.

Plant Benches

Three bench styles for supporting the pots and other plant containers are normally encountered in plant growth chambers: (1) stationary benches; (2) benches or shelves built in sections that are adjustable in height; and (3) plant trucks, carts, or dollies on casters, which are used to move plants between chambers, greenhouses, and darkrooms. The bench supports containers filled with moist sand, soil, or other substrate, and is usually rated for loads of at least 240 kg/m^2. The bench or truck top should be constructed of nonferrous, perforated metal or metal mesh to allow free passage of air around the plants and to let excess water drain from the containers to the floor and subsequently to the floor drain.

Normally, benches, shelves, or truck tops are adjustable in height so that small plants can be placed close to the lamps and thus receive a greater amount of light. As the plants grow, the shelf or bench is lowered so that the tops of the plants continue to receive the original radiant flux density.

Control

Environmental chambers require complex controls to provide the following:

- Automatic transfer from heating to cooling with 1 K or less dead zone and adjustable time delay.
- Automatic daily switching of the temperature set point for different day and night temperatures (setback may be as much as 5 K).
- Protection of sensors from radiation. Ideally, the sensors are located in a shielded, aspirated housing, but satisfactory performance can be attained by placing them in the return air duct.
- Control of the daily duration of light and dark periods. Ideally, this control should be programmable to change the light period each day to simulate the natural progression of day length. Photoperiod control, however, is normally accomplished with mechanical time clocks, which must have a control interval of 5 min or less for satisfactory timing.
- Protective control to prevent the chamber temperature from going more than a few degrees above or below the set point. Control should also prevent short cycling of the refrigeration system, especially when the condensers are remotely located.
- Audible and visual alarms to alert personnel of malfunctions.
- Maintenance of relative humidity to prescribed limits.

Data loggers, recorders, or recording controllers are recommended to aid in monitoring daily operation. Solid-state, microprocessor-based control is not yet widely used. However, programming flexibility and control performance are expected to improve as microprocessor control is developed for CER use.

Heating, Air Conditioning, and Airflow

When the lights are on, cooling will normally be required, and the heater will rarely be called on to operate. When the lights are off, however, both heating and cooling may be needed. Conventional refrigeration is generally used with some modification. Direct expansion units usually operate with a hot-gas bypass to prevent numerous on-off cycles, and secondary coolant may use aqueous ethylene glycol rather than chilled water. Heat is usually provided by electric heaters, but other energy sources can be used, including hot gas from the refrigeration.

The plant compartment is the heart of the growth chamber. The primary design objective, therefore, is to provide the most uniform, consistent, and regulated environmental conditions possible. Thus, airflow must be adequate to meet specified psychrometric conditions, but it is limited by the effects of high air speed on plant growth. As a rule, the average air speed in CERs is restricted to about 0.5 m/s.

To meet the uniform conditions required by a CER, conditioned air is normally moved through the space from bottom to top, although an increasing number of CERs use top-to-bottom airflow. There is no apparent difference in plant growth between horizontal, upward, or downward airflow when the speed is less than 0.9 m/s. Regardless of the method, a temperature gradient is certain to exist, and the design should keep the gradient as small as possible. Uniform airflow is more important than the direction of flow; thus, selection of properly designed diffusers or plenums with perforations is essential for achieving it.

The ducts or false sidewalls that direct air from the evaporator to the growing area should be small, but not so small that the noise increases appreciably more than acceptable building air duct noise. CER design should include some provision for cleaning the interior of the air ducts.

Air-conditioning equipment for relatively standard chambers provides temperatures that range from 7 to 35°C. Specialized CERs that require temperatures as low as −20°C need low-temperature refrigeration equipment and devices to defrost the evaporator without increasing the growing area temperature. Other chambers that require temperatures as high as 45°C need high-temperature components. The air temperature in the growing area must be controlled with the least possible variation about the set point. Temperature variation about the set point can be held to 0.3 K using solid-state controls, but in most existing facilities, the variation is 0.5 to 1 K.

The relative humidity in many CERs is simply an indicator of the existing psychrometric conditions and is usually between 50 and 80%, depending on the temperature. Relative humidity in the chamber can be increased by steam injection, misting, hot-water evaporators, and other conventional humidification methods. Steam injection causes the least temperature disturbance, and sprays or misting cause the greatest disturbance. Complete control of relative humidity requires dehumidification as well as humidification.

Table 11 Input Power Conversion of Light Sources

Lamp Identification		Total Input Power, W	Radiation (400-700 nm), %	Radiation (400-850 nm), %	Other Radiation, %	Conduction and Convection, %	Ballast Loss, %
Incandescent	INC, 100A	100	7	15	75	10	0
Fluorescent

Infrared	FIR	46	2	9	39	39	13
Discharge							
Clear mercury	HG	440	12	13	61	17	9
Mercury deluxe	HG/DX	440	13	14	59	18	9
Metal halide	MH	460	27	30	42	15	13
High-pressure sodium	HPS	470	26	36	36	13	15
Low-pressure sodium	LPS	230	27	31	25	22	22

Note: Conversion efficiency is for lamps without luminaire. Values compiled from manufacturers' data, published information, and unpublished test data by R.W. Thimijan.

A typical humidity control includes a cold evaporator or steam injection to adjust the chamber air dew point. The air is then conditioned to the desired dry-bulb temperature by electric heaters, a hot-gas bypass evaporator, or a temperature-controlled evaporator. A dew point lower than about 5°C cannot be obtained with a cold plate dehumidifier because of icing. Dew points lower than 5°C usually require a chemical dehumidifier in addition to the cold evaporator.

Lighting Environmental Chambers

The type of light source and the number of lamps used in CERs are determined by the desired plant response. Traditionally, cool-white fluorescent plus incandescent lamps that produce 10% of the fluorescent illuminance are used. Nearly all illumination data are based on either cool-white or warm-white fluorescent, plus incandescent lamps. A number of fluorescent lamps have special phosphors hypothesized to be the spectral requirements of the plant. Some of these lamps are used in CERs, but there is little data to suggest that they are superior to cool-white and warm-white lamps. In recent years, high-intensity discharge lamps have been installed in CERs, either to obtain very high radiant flux densities, or to reduce the electrical load while maintaining a light level equal to that produced by the less efficient fluorescent-incandescent systems.

One method to design lighting for biological environments is to base light source output recommendations on photon flux density $\mu mol/(s \cdot m^2)$ between 400 and 700 nm, or, less frequently, as radiant flux density between 400 and 700 nm, or 400 and 850 nm. Rather than basing illuminance measurements on human vision, this enables comparisons between light sources as a function of plant photosynthetic potential. Table 9 shows constants for converting various measurement units to W/m^2. However, instruments that measure the 400 to 850 nm spectral range are generally not available, and some controversy exists about the effectiveness of 400 to 850 nm as compared to the 400 to 700 nm range in photosynthesis. The power conversion of various light sources is listed in Table 11.

Table 12 Approximate Mounting Height and Spacing of Luminaires in Greenhouses

Lamp and Wattage	Irradiation, W/m^2			
	6	12	24	48
	Height and Spacing, m			
HPS (400 W)	3.0	2.3	1.6	1.0
LPS (180 W)	2.4	1.7	1.2	0.8
MH (400 W)	2.7	2.0	1.4	0.9

The design requirements for plant growth lighting differ greatly from those for vision lighting. Plant growth lighting requires a greater degree of horizontal uniformity and, usually, higher light levels than vision lighting. In addition, plant growth lighting should have as much vertical uniformity as possible—a factor rarely important in vision lighting. Horizontal and vertical uniformity are much easier to attain with linear or broad sources, such as fluorescent lamps, than with point sources, such as HID lamps. Tables 12 and 13 show the type and number of lamps, mounting height, and spacing required to obtain several levels of incident energy. Since the data were taken directly under lamps with no reflecting wall surfaces nearby, the incident energy is perhaps one-half of what the plants would receive if the lamps had been placed in a small chamber with highly reflective walls.

Extended-life incandescents or traffic signal lamps, which have a much longer life, will lower lamp replacement requirements. These lamps have lower lumen output, but are nearly equivalent in the red portion of the spectrum. For safety, porcelain lamp holders and heat-resistant lamp wiring should be used. Lamps used for CER lighting include fluorescent lamps (usually 1500 mA), 250, 400, and occasionally 1000 W HPS and MH lamps, 180 W LPS lamps, and various sizes of incandescent lamps. In many installations, the abnormally short life of incandescent lamps is due to vibration from the lamp loft ventilation or from cooling fans. Increased incandescent lamp life under these conditions can be attained by using lamps constructed with a C9 filament.

Energy-saving lamps have approximately equal or slightly lower irradiance per input watt. Since the irradiance per lamp is lower, there is no advantage to using these lamps, except in tasks that can be accomplished with low light levels. Light output of all lamps declines with use, except perhaps for low-pressure sodium (LPS) lamps, which appear to maintain approximately constant output but require an increase in input power during use.

Fluorescent and metal halide designs should be based on 80% of the initial light level. Most CER lighting systems have difficulty maintaining a relatively constant light level over considerable periods of time. Combinations of MH and HPS lamps compound the problem, because the lumen depreciation of the two light sources is significantly different. Thus, over time, the spectral energy distribution at plant level will shift toward the HPS. Lumen output can be maintained in two ways: (1) individual lamps, or a combination of lamps, can be switched off initially and activated as the lumen output decreases; and (2) the oldest 25 to 33% of the lamps can be replaced periodically. Solid-state dimmer systems are commercially available only for low-wattage fluorescent lamps and for mercury lamps.

Table 13 Height and Spacing of Luminaires

Light Source	Radiant Flux Density, W/m^2

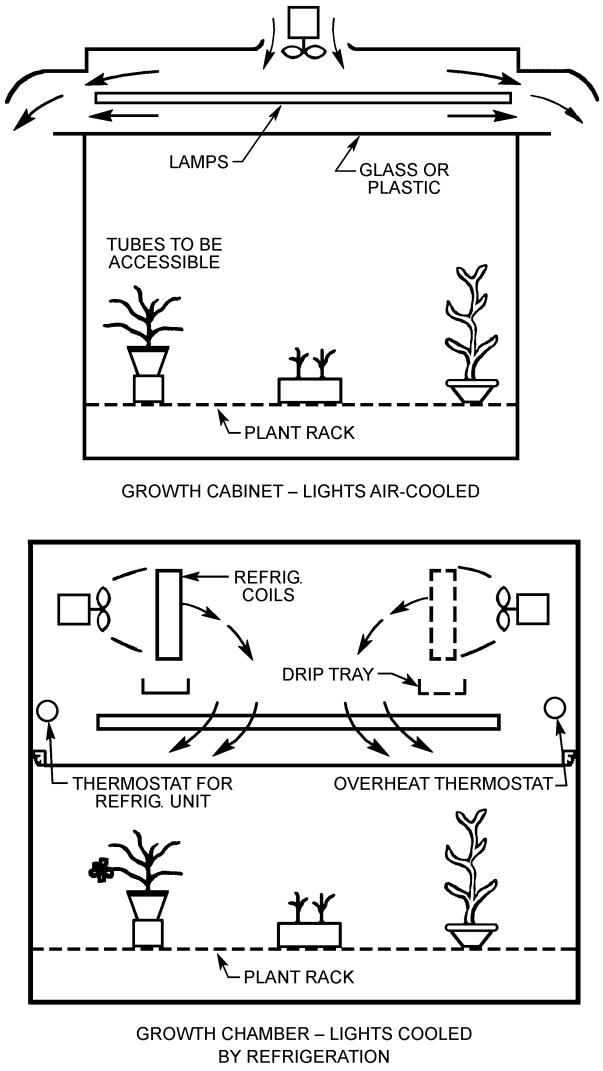

Fig. 11 Cooling Lamps in Growth Chambers

Large rooms, especially those constructed as an integral part of the building and retrofitted as CERs, rarely separate the lamps from the growing area with a transparent barrier. Rooms designed as CERs (at the time a building is constructed) and freestanding rooms or chambers usually separate the lamp from the growing area with a barrier of glass or rigid plastic. Light output from fluorescent lamps is a function of the temperature of the lamp. Thus, the barrier serves a two-fold purpose: (1) to maintain optimum lamp temperature when the growing area temperature is higher or lower than optimum, and (2) to reduce the thermal radiation entering the growing area. Fluorescent lamps should operate in an ambient temperature and airflow environment that will maintain the tube wall temperature at 40°C. Under most conditions, the light output of HID lamps is not affected by ambient temperature. The heat must be removed, however, to prevent high thermal radiation from causing adverse biological effects (see Figure 11).

Transparent glass barriers remove nearly all radiation from about 350 to 2500 nm. Rigid plastic is less effective than glass; however, the lower mass and lower breakage risk of plastic makes it a popular barrier material. Ultraviolet is also screened by both glass and plastic (more by plastic). Special UV-transmitting plastic (which degrades rapidly) can be obtained if the biological process requires UV light. When irradiance is very high, especially from HID lamps or large numbers of incandescent lamps or both, rigid plastic can soften from the heat and fall from the supports. Furthermore, very high irradiance and the resulting high temperatures can cause plastic to darken, which can increase the absorptivity and temperature enough to destroy it. Under these conditions, heat-resistant glass may be necessary. The lamp compartment and barrier absolutely require positive ventilation regardless of the light source, and the lamp loft should have limit switches that will shut down the lamps if the temperature rises to a critical level.

OTHER PLANT ENVIRONMENTAL FACILITIES

Plants may be held or processed in warehouse-type structures prior to sale or use in interior landscaping. Required temperatures range from slightly above freezing for cold storage of root stock and cut flowers, to 20 to 25°C for maintaining growing plants, usually in pots or containers. Provision must be made for venting fresh air to avoid CO_2 depletion.

Light duration must be controlled by a time clock. When they are in use, lamps and ballasts produce almost all the heat required in an insulated building. Ventilation and cooling may be required. Illumination levels depend on plant requirements. Table 14 shows approximate mounting heights for two levels of illumination. Luminaires mounted on chains permit lamp height to be adjusted to compensate for varying plant height.

The main concerns for interior landscape lighting are how it renders the color of plants, people, and furnishings, as well as how it meets the minimum irradiation requirements of plants. The temperature required for human occupancy is normally acceptable for plants. Light level and duration determine the types of plants that can be grown or maintained. Plants grow when exposed to higher levels, but do not survive below the suggested minimum. Plants may be grouped into three levels based on the following of irradiances:

Low (survival): A minimum light level of 0.75 W/m^2 and a preferred level of 3 W/m^2 irradiance for 8 to 12 h daily.

Medium (maintenance): A minimum of 3 W/m^2 and a preferred level of 9 W/m^2 irradiance for 8 to 12 h daily.

High (propagation): A minimum of 9 W/m^2 and a preferred level of 24 W/m^2 irradiance for 8 to 12 h daily.

Fluorescent (warm-white), metal halide, or incandescent lighting is usually chosen for public places. Table 13 lists the irradiance of various light sources.

Table 14 Mounting Height for Luminaires in Storage Areas

	Survival = 3 W/m^2		Maintenance = 9 W/m^2	
	Distance, m	lux	Distance, m	lux
Fluorescent (F)				
FCW two 40 W	0.9	1000	0.75	3000

CHAPTER 22

DRYING AND STORING SELECTED FARM CROPS

Drying Equipment and Practices 22.2
Shallow-Layer Drying 22.3
Deep-Bed Drying 22.4
DRYING SPECIFIC CROPS 22.7
Soybeans 22.7
Hay 22.8
Cotton 22.8
Peanuts 22.9
Rice 22.9
STORAGE PROBLEMS AND PRACTICES 22.9
Moisture Migration 22.9
Grain Aeration 22.10
SEED STORAGE 22.12

CONTROL of moisture content and temperature during storage is critical to preserving the nutritional and economic value of farm crops as they move from the field to the market. Fungi (mold) and insects feed on poorly stored crops and reduce crop quality. Relative humidity and temperature affect mold and insect growth, which is reduced to a minimum if the crop is kept cooler than 10°C and if the relative humidity of the air in equilibrium with the stored crop is less than 60% (Figure 1).

Mold growth and spoilage are a function of elapsed storage time, temperature, and moisture content above critical values. The approximate allowable storage life for cereal grains is shown in Table 1. For example, corn at 16°C and 20% wet basis (w.b.) moisture has a storage life of about 25 days. If the corn is dried to 18% w.b. after 12 days, half of its storage life has elapsed. Thus, the remaining storage life at 16°C and 18% w.b. moisture content is 25 days, not 50 days.

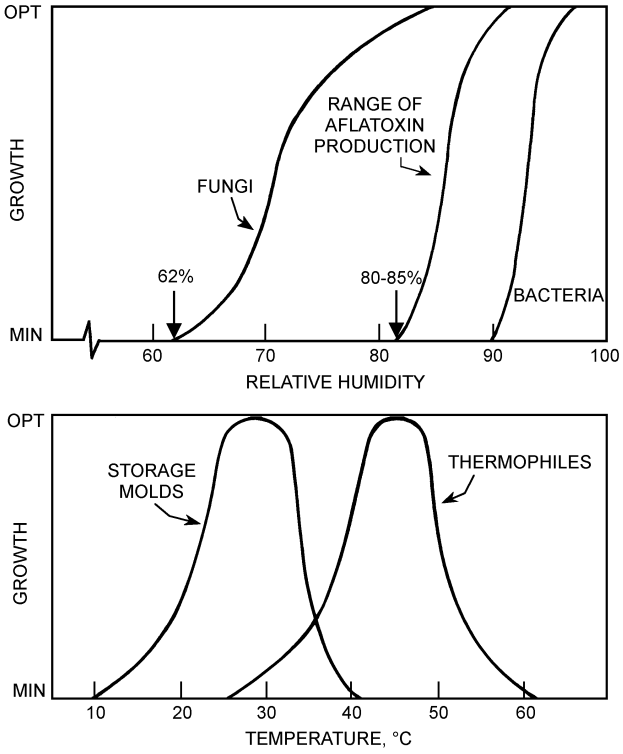

Fig. 1 Microbial Growth as Affected by Relative Humidity and Temperature
(University of Kentucky 1973)

The preparation of this chapter is assigned to TC 2.2, Plant and Animal Environment.

Table 1 Approximate Allowable Storage Time (Days) for Cereal Grains

Based on composite of 0.5% maximum dry matter loss calculated on the basis of USDA research; *Transactions of ASAE* 333-337, 1972; and "Unheated Air Drying," Manitoba Agriculture Agdex 732-1, rev. 1986.

[a]Grain moisture content calculated as percent wet basis: (mass of water in a given amount of wet grain ÷ mass of the wet grain) × 100.
*Approximate allowable storage time exceeds 300 days.

Insects thrive in stored grain if the moisture content and temperature are not properly controlled. At low moisture contents and temperatures below 10°C, insects remain dormant or die.

Most farm crops must be dried to, and maintained at, a suitable moisture content. For most grains, a suitable moisture content is in the range of 12 to 15% w.b., depending on the specific crop, storage temperature, and length of storage. Oilseeds such as peanuts, sunflower seeds, and flaxseeds must be dried to a moisture content of 8 to 9% w.b. Grain stored for more than a year, grain that is damaged, and seed stock should be dried to a lower moisture content. Moisture levels above these critical values lead to the growth of fungi, which may produce toxic compounds such as aflatoxin.

The maximum yield of dry matter can be obtained by harvesting when the corn has dried in the field to an average moisture content of 26% w.b. However, for quality-conscious markets, the minimum damage occurs when corn is harvested at 21 to 22% w.b. Wheat can be harvested when it has dried to 20% w.b., but harvesting at these moisture contents requires expensive mechanical drying. Although field drying requires less expense than operating drying equipment, total cost may be greater because field losses generally increase as the moisture content decreases.

The price of grain to be sold through commercial market channels is based on a specified moisture content, with price discounts for moisture levels above the specified amount. These discounts compensate for the mass of excess water, cover the cost of water removal, and control the supply of wet grain delivered to market. Grain dried to below the base moisture content set by the market (15.0% w.b. for corn, 13.0% w.b. for soybeans, and 13.5% w.b. for wheat) is not generally sold at a premium; thus, the seller loses the opportunity to sell water for the price of grain.

Table 2 Calculated Densities of Grains and Seeds Based on U.S. Department of Agriculture Data

	Bulk Density, kg/m^3
Alfalfa	768

Nonoil	307
Oilseed	410
Wheat	768

Grain Quantity

The bushel is a volume measure (0.03524 m^3) that is the common measure used for marketing grain in the United States, while the tonne (Mg) is the more common international measure. The legal mass for the bushel in the United States is set at 25.40 kg for corn and 27.22 kg for wheat. The densities of some crops are listed in Table 2.

The percent of mass lost due to water removed may be calculated by the following equation:

$$\text{Moisture shrink, \%} = \frac{M_o - M_f}{100 - M_f} \times 100$$

where

M_o = original or initial moisture content, wet basis
M_f = final moisture content, wet basis

Applying the formula to drying a crop from 25% to 15%,

$$\text{Moisture shrink} = \frac{25 - 15}{100 - 15} \times 100 = 11.76\%$$

In this case, the moisture shrink is 11.76%, or an average 1.176% mass reduction for each percentage point of moisture reduction. The moisture shrink varies depending on the final moisture content. For example, the average shrink per point of moisture when drying from 20% to 10% is 1.111.

Table 3 Estimated Corn Drying Energy Requirement

Dryer Type	kJ/kg of Water Removed
Unheated air	2300 to 2800
Low temperature	2800 to 3500
Batch-in-bin, continuous-flow in-bin	3500 to 4700
High temperature	
Air recirculating	4200 to 5100
Without air recirculating	4700 to 7000
Combination drying, dryeration	3300 to 4200

Note: Includes all energy requirements for fans and heat.

Economics

Producers generally have the choice of drying their grain on the farm before delivering it to market, or delivering wet grain with a price discount for excess moisture. The expense of drying on the farm includes both fixed and variable costs. Once a dryer is purchased, the costs of depreciation, interest, taxes, and repairs are fixed and minimally affected by volume of crops dried. The costs of labor, fuel, and electricity vary directly with the volume dried. Total drying costs vary widely, depending on the volume dried, the drying equipment, and fuel and equipment prices. Energy consumption depends primarily on dryer type. Generally, the faster the drying speed, the greater the energy consumption (Table 3).

DRYING EQUIPMENT AND PRACTICES

Contemporary crop-drying equipment depends on mass and energy transfer between the drying air and the product to be dried. The drying rate is a function of the initial temperature and moisture content of the crop, the air-circulation rate, the entering condition of the circulated air, the length of flow path through the products, and the time elapsed since the beginning of the drying operation. Outdoor air is frequently heated before it is circulated through the product. Heating increases the rate of heat transfer to the product, increases its temperature, and increases the vapor pressure of the product moisture. For more information on crop responses to drying, see Chapter 11 of the 1997 *ASHRAE Handbook—Fundamentals*.

Most crop-drying equipment consists of (1) a fan to move the air through the product, (2) a controlled heater to increase the ambient air temperature to the desired level, and (3) a container to distribute the drying air uniformly through the product. The exhaust air is vented to the atmosphere. Where climate and other factors are favorable, unheated air is used for drying, and the heater is omitted.

Fans

The fan selected for a given drying application should meet the same requirements important in any air-moving application. It must deliver the desired amount of air against the static resistance of the product in the bin or column, the resistance of the delivery system, and the resistance of the air inlet and outlet.

Foreign material in the grain can significantly change the required air pressure in the following ways:

- Foreign particles larger than the grain (straw, plant parts, and larger seeds) reduce airflow resistance. The airflow rate may be increased by 60% or more.
- Foreign particles smaller than the grain (broken grain, dust, and small seeds) increase the airflow resistance. The effect may be dramatic, decreasing the airflow rate by 50% or more.
- The method used to fill the dryer or the agitation or stirring of the grain after it is placed in the dryer can increase pressure requirements by up to 100%. In some grain, high moisture causes less pressure drop than does low moisture.

Vaneaxial fans are normally recommended when static pressures are less than 0.75 kPa. Backward-curved centrifugal fans are commonly recommended when static pressures are higher than 1.0 kPa column. Low-speed centrifugal fans operating at 1750 rpm perform well up to about 1.75 kPa, and high-speed centrifugal fans operating at about 3500 rpm have the ability to develop static pressure up to about 2.5 kPa. The in-line centrifugal fan consists of a centrifugal fan impeller mounted in the housing of an axial flow fan. A bell-shaped inlet funnels the air into the impeller. The in-line centrifugal fan operates at about 3450 rpm and has the ability to develop pressures up to 2.5 kPa with 6 kW or larger fans.

After functional considerations are made, the initial cost of the dryer fan should be taken into account. Drying equipment has a low

percentage of annual use in many applications, so the cost of dryer ownership per unit of material dried is sometimes greater than the energy cost of operation. The same considerations apply to other components of the dryer.

Heaters

Most crop dryer heaters are fueled by either natural gas, liquefied petroleum gas, or fuel oil, though some electric heaters are used. Dryers using coal, biomass (such as corn cobs, stubble, or wood), and solar energy have also been built.

Fuel combustion in crop dryers is similar to combustion in domestic and industrial furnaces. Heat is transferred to the drying air either indirectly, by means of a heat exchanger, or directly, by combining the combustion gases with the drying air. Direct combustion heating is generally limited to natural gas or liquefied petroleum (LP) gas heaters. Most grain dryers use direct combustion. Indirect heating is sometimes used in drying products such as hay because of its greater fire hazard.

Controls

In addition to the usual temperature controls for drying air, all heated air units must have safety controls similar to those found on space-heating equipment. These safety controls shut off the fuel in case of flame failure and stop the burner in case of overheating or excessive drying air temperatures. All controls should be set up to operate the machinery safely in the event of power failure.

SHALLOW-LAYER DRYING

Batch Dryers

The batch dryer cycles through the loading, drying, cooling, and unloading of the grain. Fans force hot air through columns (typically 300 mm wide) or layers (600 to 1500 mm thick) of grain. Drying time depends on the type of grain and the amount of moisture to be removed. Some dryers circulate and mix the grain to prevent significant moisture content gradients from forming across the column. A circulation rate that is too fast or a poor selection of handling equipment may cause undue damage and loss of market quality. Batch dryers are suitable for farm operations and are often portable.

Continuous-Flow Dryers

This type of self-contained dryer passes a continuous stream of grain through the drying chamber. Some dryers use a second chamber to cool the hot, dry grain prior to storage. Handling and storage equipment must be available at all times to move grain to and from the dryers. These dryers have crossflow, concurrent flow, or counterflow designs.

Crossflow Dryers. A crossflow dryer is a column dryer that moves air perpendicular to the grain movement. These dryers commonly consist of two or more vertical columns surrounding the drying and cooling air plenums. The columns range in thickness from 200 to 400 mm. Airflow rates range from 0.7 to 2.7 m^3/s per cubic metre of grain. The thermal efficiency of the drying process increases as column width increases and decreases as airflow rate increases. However, moisture uniformity and drying capacity increase as airflow rate increases and as column width decreases. Dryers are designed to obtain a desirable balance of airflow rate and column width for the expected moisture content levels and drying air temperatures. Performance is evaluated in terms of drying capacity, thermal efficiency, and dried product moisture uniformity.

As with the batch dryer, a moisture gradient forms across the column because the grain nearest the inside of the column is exposed to the driest air during the complete cycle. Several methods minimize the problem of uneven drying.

One method is to place in the columns turnflow devices that split the grain stream and move the inside half of the column to the outside and the outside half to the inside. Although effective, turnflow devices tend to plug if the grain is trashy. Under these conditions, a scalper/cleaner should be used to clean the grain before it enters the dryer.

Another method is to divide the drying chamber into sections and duct the hot air so that its direction through the grain is reversed in alternate sections. This method produces about the same effect as the turnflow method.

A third method is to divide the drying chamber into sections and reduce the drying air temperature in each section consecutively. This method is the least effective.

Rack-Type Dryers. In this special type of crossflow dryer, grain flows over alternating rows of heated air supply ducts and air exhaust ducts (Figure 2). This action mixes the grain and alternates exposure to relatively hot drying air and air cooled by previous contact with the grain, promoting moisture uniformity and equal exposure of the product to the drying air.

Concurrent-Flow Dryers. In the concurrent-flow dryer, grain and drying air move in the same direction in the drying chamber. The drying chamber is coupled to a counterflow cooling section. Thus, the hottest air is in contact with the wettest grain, allowing the use of higher drying air temperatures (up to 230°C). Rapid evaporative cooling in the wettest grain prevents the grain temperature from reaching excessive levels. Because higher drying air temperatures are used, the energy efficiency is better than that obtained with a conventional crossflow dryer. In the cooling section, the coolest air initially contacts the coolest grain. The combination of drying and cooling chambers results in lower thermal stresses in the grain kernels during drying and cooling and, thus, a higher-quality product.

Counterflow Dryers. The grain and drying air move in opposite directions in the drying chamber of this dryer. Counterflow is common for in-bin dryers. Drying air enters from the bottom of the bin and exits from the top. The wet grain is loaded from overhead, and floor sweep augers can be used to bring the hot, dry grain to a center sump, where it is removed by another auger. The travel of the sweep is normally controlled by moisture- or temperature-sensing elements.

A drying zone exists only in the lower layers of the grain mass and is truncated at its lower edge so that the grain being removed is not overdried. As a part of the counterflow process, the warm, saturated or near-saturated air leaving the drying zone passes through the cool incoming grain. Some energy is used to heat the cool grain, but some moisture may condense on the cool grain if the bed is deep and the initial grain temperature is low.

Reducing Energy Costs

Recirculation. In most commercially available continuous-flow dryers, optional ducting systems recycle some of the exhaust air from the drying and cooling chambers back to the inlet of the drying chamber (Figure 3). Systems vary, but most make it possible to recirculate all of the air from the cooling chamber and from the lower two-thirds of the drying chamber. The relative humidity of this recirculated air for most crossflow dryers is less than 50%. Energy savings of up to 30% can be obtained from a well-designed system.

Dryeration. This is another means of reducing energy consumption and improving grain quality. In this process, hot grain with a moisture content one or two percentage points above that desired for storage is removed from the dryer (Figure 4). The hot grain is placed in a dryeration bin, where it tempers without airflow for at least 4 to 6 h. After the first grain delivered to the bin has tempered, the cooling fan is turned on as additional hot grain is delivered to the bin. The air cools the grain and removes 1 to 2% of its moisture before the grain is moved to final storage. If the cooling rate equals the filling rate, cooling is normally completed about 6 h after the last hot grain is added. The crop cooling rate should equal the filling rate of the dryeration bin. A faster cooling rate cools the grain before it has tempered. A slower rate may result in spoilage, since the allowable storage time for hot, damp grain may be only a few days. The required airflow rate is based on dryer capacityand crop density. An airflow rate of 0.2 m^3/s for each cubic metre per hour of grain capacity provides cooling capacity to keep up with the dryer when drying corn that has a density of 900 kg/m^3. Recommended airflow rates for some crops are listed in Table 4.

Table 4 Recommended Airflow Rates for Dryeration

Crop	Density, kg/m^3	Recommended Dryeration Airflow Rate, m^3/s per cubic metre per hour dryer capacity
Barley	768	0.17
Corn	896	0.20

Nonoil sunflower seeds	384	0.09
Oil sunflower seeds	512	0.11
Hard red spring wheat	960	0.21

Note: Basic air volume is 0.80 m^3/kg

Combination Drying. This method was developed to improve drying thermal efficiency and corn quality. First, a high-temperature dryer dries the corn to 18 to 20% moisture content. Then it is transferred to a bin, where the full-bin drying system brings the moisture down to a safe storage level.

Dryer Temperature. For energy savings, operating temperatures of batch and continuous-flow dryers are usually set at the highest level that will not damage the product for its particular end use. The energy requirements of a conventional crossflow dryer as a function of drying air temperature and airflow rate are shown in Figure 5.

DEEP-BED DRYING

A deep-bed drying system can be installed in any structure that holds grain. Most grain storage structures can be designed or adapted for drying if a means of distributing the drying air uniformly through the grain is provided. A perforated floor (Figure 6) and duct systems placed on the floor of the bin (Figure 7) are the two most common means.

Perforations in the floor should have a total area of at least 10% of the floor area. A perforated floor distributes air more uniformly and offers less resistance to airflow than do ducts, but a duct system is less expensive for larger floor area systems. Ducts can be removed after the grain is removed, and the structure can be

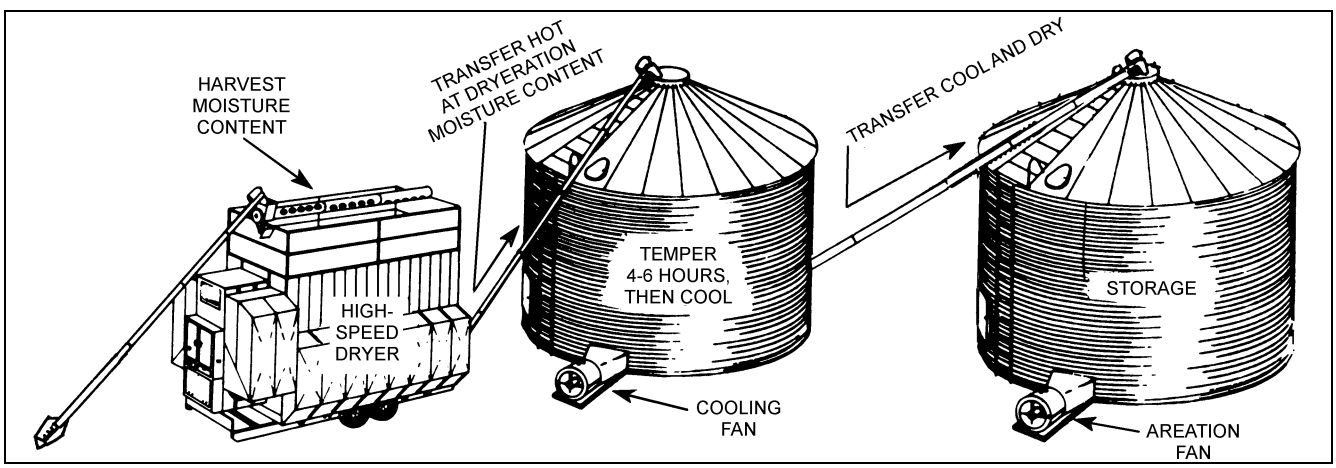

Fig. 4 Dryeration System Schematic

(University of Nebraska)

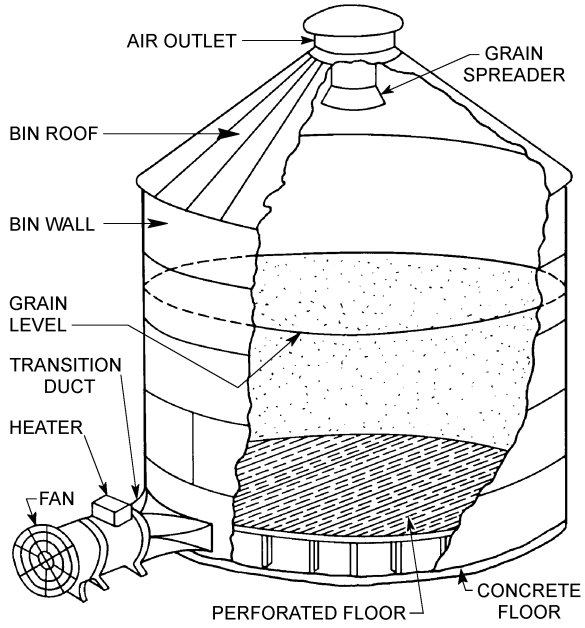

Fig. 6 Perforated Floor System for Bin Drying of Grain

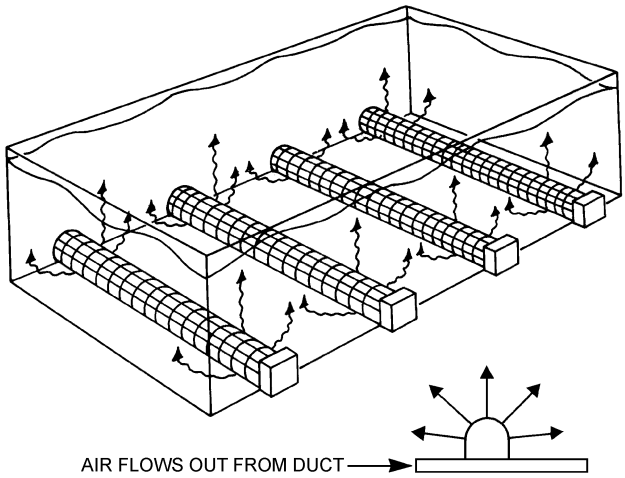

Fig. 7 Tunnel or Duct Air Distribution System

cleaned and used for other purposes. Ducts should not be spaced farther apart than one-half times the depth of the grain. The amount of perforated area or the duct length will affect airflow distribution uniformity.

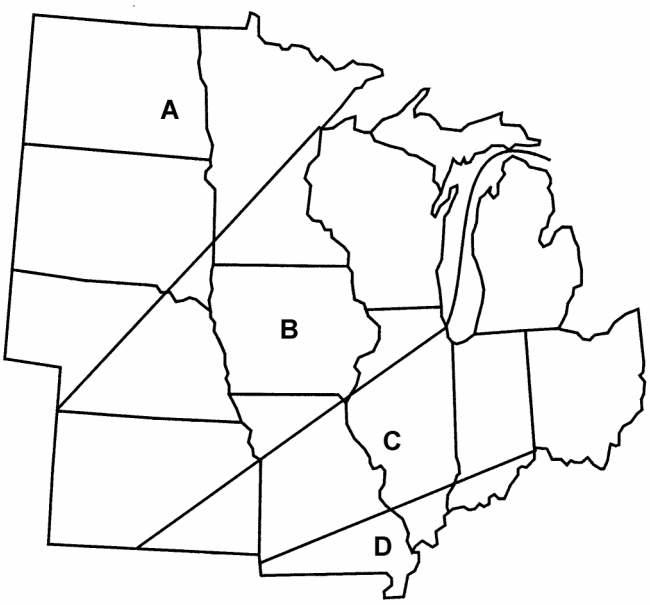
Air ducts and tunnels that disperse air into the grain should be large enough to prevent the air velocity from exceeding 10 m/s; slower speeds are desirable. Sharp turns, obstructions, or abrupt changes in duct size should be eliminated, as they cause pressure loss. Operating methods for drying grain in storage bins are (1) full-bin drying, (2) layer drying, (3) batch-in-bin drying, and (4) recirculating/continuous-flow bin drying.

Full-Bin Drying

Full-bin drying is generally performed with unheated air or air heated up to 6 K above ambient. A humidistat is frequently used to sense the humidity of the drying air and turn off the heater if the weather conditions are such that heated air would cause overdrying. A humidistat setting of 55% stops drying at approximately the 12% moisture level for most farm grains, assuming that the ambient relative humidity does not go below this point.

Airflow rate requirements for full-bin drying are generally calculated on the basis of cubic metre per second of air required per cubic metre of grain. The airflow rate recommendations depend on the weather conditions and on the type of grain and its moisture content. Airflow rate is important for successful drying. Because faster drying results from higher airflow rates, the highest economical airflow rate should be used. However, the cost of full-bin drying at high airflow rates may exceed the cost of using column dryers, or the electric power requirement may exceed the available capacity.

Recommendations for full-bin drying with unheated air are shown in Tables 5, 6, and 7. These recommendations apply to the principal production areas of the continental United States and are based on experience under average conditions; they may not be applicable under unusual weather conditions or even usual weather conditions in the case of late-maturing crops. Full-bin drying may not be feasible in some geographical areas.



The maximum practical depth of grain to be dried (distance of air travel) is limited by the cost of the fan, motor, air distribution system, and power required. This depth seems to be 6 m for corn and soybeans, and about 4.5 m for wheat.

To ensure satisfactory drying, heated air may be used during periods of prolonged fog or rain. Burners should be sized to raise the temperature of the drying air by no more than 6 K above ambient. The temperature should not exceed about 27°C after heating. Overheating the drying air causes the grain to overdry and dry nonuniformly; heat is recommended only to counteract adverse weather conditions. Electric controllers are available to assist in controlling fan and heater operation to achieve the final desired grain moisture content.

Drying takes place in a drying zone, which advances upward through the grain (Figure 8). Grain above this drying zone remains at or slightly above the initial moisture content, while grain below

the drying zone is at a moisture content in equilibrium with the drying air.

As the direction of air movement does not affect the rate of drying, other factors must be considered in choosing the direction. A pressure system moves the moisture-laden air up through the grain, and it is discharged under the roof. If there are insufficient roof outlets, moisture may condense on the underside of metal roofs. During pressure system ventilation, the wettest grain is near the top surface and is easy to monitor. Fan and motor waste heat enter into the airstream and contribute to drying.

Compiled from USDA *Leaflet* 332 (1952) and Univ. of Georgia *Bulletin* NS 33 (1958).

A negative-pressure system moves the air down through the grain. The moisture-laden air discharges from the fan into the outside atmosphere; thus, roof condensation is not a problem. Also, the air picks up some solar heat from the roof. However, the wettest grain is near the bottom of the mass and is difficult to sample. Of the two systems, the pressure system is recommended because it is easier to manage.

The following management practices must be observed to ensure the best performance of the dryer:

1. Minimize foreign material. A scalper-cleaner is recommended for cleaning the grain to reduce air pressure and energy requirements and to help provide uniform airflow for the elimination of wet spots.
2. Distribute the remaining foreign material uniformly by installing a grain distributor.
3. Place the grain in layers and keep it leveled.
4. Start the fan as soon as the floor or ducts are covered with grain.
5. Operate the fan continuously with unheated air unless it is raining heavily or there is a dense ground fog. Once all the grain is within 1% of desired storage moisture content, run the fans only when the relative humidity is below 70%.

Layer Drying

In layer drying, successive layers of wet grain are placed on top of dry grain. When the top 150 mm has dried to within 1% of the desired moisture content, another layer is added (Figure 9). In comparison to full-bin drying, layering reduces the time that the top layers of grain remain wet. Because the effective airflow rate is greater for lower layers, allowable harvest moisture content of grain in these levels can be greater than that in the upper layers. Either unheated air or air heated 6 to 11°C above the ambient may be used, but the use of heated air controlled with a humidistat to prevent overdrying is most common. The first layer may be about 2 m deep, with successive layers of about 1 m.

Batch-in-Bin Drying

A storage bin adapted for drying may be used to dry several batches of grain during a harvest season, if the grain is kept to a shallow layer so that higher airflow rates and temperatures can be used. After the batch is dry, the bin is emptied, and the cycle is repeated. The drying capacity of the batch system is greater than that of other in-storage drying systems. In a typical operation, batches of corn in 1 m depths are dried from an initial moisture content of 25% with air at the rate of about 0.33 m^3/s per cubic metre. Considerable nonuniformity of moisture content may be present in the batch after drying is stopped; therefore, the grain should be well mixed as it is placed into storage. If the mixing is done well, grain that is too wet equalizes in moisture with grain that is too dry before spoilage can occur. Aeration of the grain in storage will facilitate the equalization of moisture.

Grain may be cooled in the dryer to ambient temperature before it is stored. Cooling is accomplished by operating the fan without the heater for about 1 h. Some additional drying occurs during the cooling process, particularly in the wetter portions of the batch.

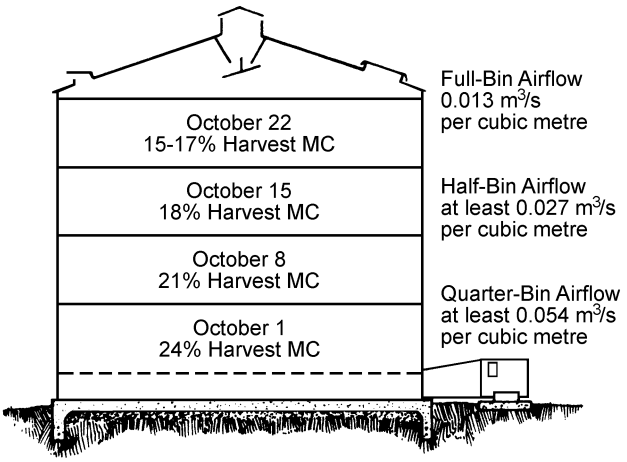

Fig. 9 Example of Layer Filling of Corn

Grain stirring devices are used with both full-bin and batch-in-bin drying systems. Typically, these devices consist of one or more open, 50 mm diameter, standard pitch augers suspended from the bin roof and extending to near the bin floor. The augers rotate and simultaneously travel horizontally around the bin, mixing the drying grain to reduce moisture gradients and prevent overdrying of the bottom grain. The augers also loosen the grain, allowing a higher airflow rate for a given fan. Stirring equipment reduces bin capacity by about 10%. Furthermore, commercial stirring devices are available only for round storage enclosures.

Recirculating/Continuous-Flow Bin Drying

This type of drying incorporates a tapered sweep auger that removes uniform layers of grain from the bottom of the bin as it dries (Figure 10). The dry grain is then redistributed on top of the pile of grain or moved to a second bin for cooling. The sweep auger may be controlled by temperature or moisture sensors. When the desired condition is reached, the sensor starts the sweep auger, which removes a layer of grain. After a complete circuit of the bin, the sweep auger stops until the sensor determines that another layer is dry. Some drying takes place in the cooling bin. Up to two percentage points of moisture may be removed, depending on the management of the cooling bin.

DRYING SPECIFIC CROPS

SOYBEANS

Soybeans usually need drying only when there is inclement weather during the harvest season. Mature soybeans left exposed to rain or damp weather develop a dark brown color and a mealy or chalky texture. Seed quality deteriorates rapidly. Oil from weather-damaged beans costs more to refine and is often not of edible grade. In addition to preventing deterioration, the artificial drying of soybeans offers the advantage of early harvest, which reduces the chance of loss from bad weather and reduces natural and combine shatter loss. Soybeans harvested with a wet basis moisture content greater than 13.5% exhibit less damage.

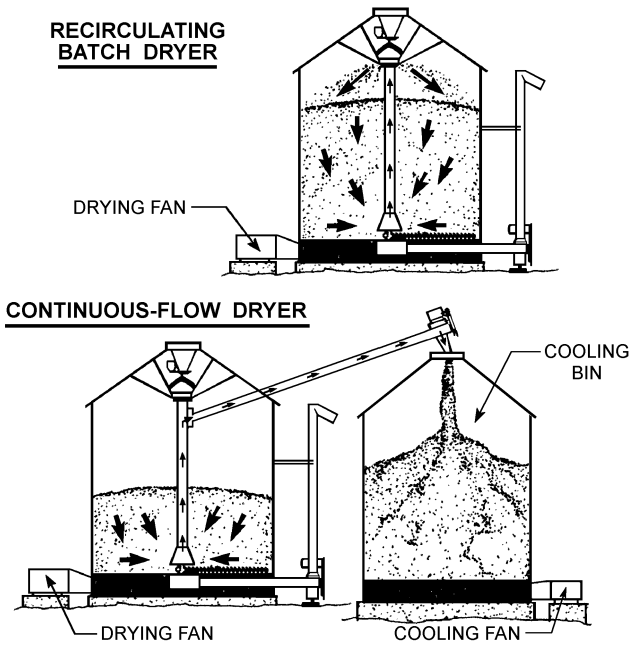

Fig. 10 Grain Recirculators Convert Bin Dryer to High-Speed Continuous-Flow Dryer

Drying Soybeans for Commercial Use

Conventional corn-drying equipment can be used for soybeans, with some limitations on heat input. Soybeans for commercial use can be dried at 55 to 60°C; drying temperatures of 90°C reduce the oil yield. If the relative humidity of the drying air is below 40%, excessive seedcoat cracking occurs, causing many split beans in subsequent handling. Physical damage can cause fungal growth on the beans, storage problems, and a slight reduction in oil yield and quality. Flow-retarding devices should be used during handling, and beans should not be dropped more than 6 m onto concrete floors.

Drying Soybeans for Seed and Food

The relative humidity of the drying air should be kept above 40%, regardless of the amount of heat used. The maximum drying temperature to avoid germination loss is 43°C. Natural air drying at a flow rate of 0.0267 m^3/s per cubic metre is adequate for drying seed with an initial moisture content of up to 16% w.b.

If adding heat, raise the drying air temperature no more than 3°C above ambient. This drying method is slow, but it results in excellent quality and avoids overdrying. However, drying must be completed before spoilage occurs. At higher moisture contents, good results have been obtained using an airflow rate of 0.0534 m^3/s per cubic metre with humidity control. Data on the allowable drying time for soybeans are unavailable. In the absence of better information, an estimate of storage life for oil crops can be made based on the values for corn, using an adjusted moisture content calculated by the following equation:

$$\text{Comparable moisture content} = \frac{\text{Oilseed moisture content}}{100 - \text{Seed oil content}} \times 100$$

A corn moisture content 2% greater than that of the soybeans should generally be used to estimate allowable drying time (e.g., 12% soybeans are comparable to 14% corn). Soybeans are dried from a lower initial moisture content than corn.

Dry high-moisture soybeans in a bin with the air temperature controlled to keep the relative humidity at 40% or higher. Airflow rates of 0.130 m^3/s per cubic metre are recommended, with the depth of the beans not to exceed 1.2 m.

HAY

Hay normally contains 65 to 80% wet basis moisture at cutting. Field drying to 20% may result in a large loss of leaves. Alfalfa hay leaves average about 50% of the crop by mass, but they contain 70% of the protein and 90% of the carotene. The quality of hay can be increased and the risk of loss due to bad weather reduced if the hay is put under shelter when partially field dried (35% moisture content) and then artificially dried to a safe storage moisture content. In good drying weather, hay conditioned by mechanical means can be dried sufficiently in one day and placed in the dryer. Hay may be long, chopped, or baled for this operation; unheated or heated air can be used.

In-Storage Drying

Unheated air is normally used for in-storage or mow drying. The hay is dried in the field to 30 to 40% moisture content before being placed in the dryer. For unheated air drying, the airflow should be at least 0.10 m^3/s per megagram. The fan should be capable of delivering the required airflow against a static pressure of 250 to 500 Pa.

Slotted floors, with at least 50% of the area open, are generally used for drying baled hay. For long or chopped hay in mows narrower than 11 m wide, the center duct system is the most popular. A slotted floor should be placed on each side of the duct to within 1.5 m of its ends and the outside walls (Figure 11). If the mow is wider than 11 m, it should be divided crosswise into units of 8.5 m or narrower. These should then be treated as individual dryers. If the storage depth exceeds about 4 m, vertical flues and/or additional levels of ducts may be used. If tiered ducts are used, a vertical air chamber, about 75% of the probable hay depth, should be used. The supply ducts are then connected at 2 to 3 m vertical intervals as the mow is filled. With either of these methods, hay in total depths up to 9 m can be dried. The duct size should be such that the air velocity is less than 5 m/s.

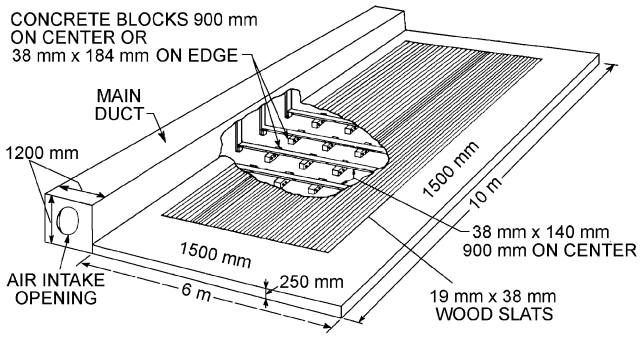

Fig. 11 Central Duct Hay-Drying System with Lateral Slatted Floor for Wide Mows

The maximum depth of wet hay that should be placed on a hay-drying system at any time depends on hay moisture content, weather conditions, the physical form of the hay, and the airflow rate. The maximum drying depth is about 5 m for long hay, 4 m for chopped hay, and 7 small rectangular bales deep for baled hay. Baled hay should have a density of about 130 kg/m^3. For best results, bales should be stacked tightly together on edge (parallel to the stems) to ensure that no openings exist between them.

For mow drying, the fan should run continuously during the first few days. Afterward, it should be operated only during low relative humidity weather. During prolonged wet periods, the fan should be operated only enough to keep the hay cool.

Batch Wagon Drying

Batch drying can be done on a slotted floor platform; however, because this method is labor-intensive, wagon dryers are more commonly used. With a wagon dryer system, hay is baled at about 45% moisture content to a density of about 180 kg/m^3. The hay is then stacked onto a wagon with tight, high sides and a slotted or expanded metal floor. Drying is accomplished most efficiently by forcing the heated air (up to 70°C) down the canvas duct of a plenum chamber secured to the top of the wagon. After 4 or 5 h of drying, the exhaust air is no longer saturated with moisture, and about 75% of it may be recirculated or passed through a second wagon of wet hay for greater drying efficiency.

In this method, the amount of hay harvested each day is limited by the capacity of the drying wagons. In this 24 h process, the hay cut one day is stored the following day; only enough hay to load the drying wagons should be harvested each day.

The airflow rate in this method is normally much higher than when unheated air is used. About 0.2 m^3/s per square metre of wagon floor space is required. As with mow drying, the duct size should be such that the air velocity is less than 5 m/s.

COTTON

Producers normally allow cotton to dry naturally in the field to 12% moisture content or less before harvest. Cotton harvested in this manner can be stored in trailers, baskets, or compacted stacks for extended periods with little loss in fiber or seed quality. Thus, cotton is not normally aerated or artificially dried prior to ginning.

Cotton harvested during inclement weather and stored cotton exposed to precipitation must be dried at the cotton gin within a few days to prevent self-heating and deterioration of the fiber and seed.

Though cotton may be safely stored at moisture contents as high as 12%, moisture levels near the upper limit are too high for efficient ginning and for obtaining optimum fiber grade. The cleaning efficiency of cotton is inversely proportional to its moisture content, with the most efficient level being 5% fiber moisture content. However, fiber quality is best preserved when the fiber is separated from the seed at moisture contents between 6.5 and 8%. Therefore, if cotton comes into the system below this level, it can be cleaned, but moisture should be added prior to separating the fiber from the seed to improve the ginning quality. Dryers in the cotton gins are capable of drying the cotton to the desired moisture level.

Although several types of dryers are available commercially, the tower dryer is the most commonly used. This device operates on a parallel flow principle: 0.015 to 0.025 m^3/s of drying air per kilogram of cotton also serves as the conveying medium. As it moves through the dryer's serpentine passages, cotton impacts on the walls. This action agitates the cotton for improved drying and lengthens its exposure time. The drying time depends on many variables, but total exposure seldom exceeds 15 s. For extremely wet cotton, two stages of drying are necessary for adequate moisture control.

Wide variations in initial moisture content dictate different drying amounts for each load of cotton. Rapid changes in drying requirements are accommodated by automatically controlling drying air temperature in response to moisture measurements taken before or after drying. These control systems prevent overdrying and reduce energy requirements. For safety and to preserve fiber quality, drying air temperature should not exceed 177°C in any portion of the drying system.

If the internal cottonseed temperature does not exceed 60°C, germination is unimpaired by drying. This temperature is not exceeded in a tower dryer; however, the moisture content of the seed after drying may be above the 12% level recommended for safe long-term storage. Wet cottonseed is normally processed immediately at a cottonseed oil mill. Cottonseed under the 12% level is frequently stored for several months prior to milling or prior to delinting and treatment at a seed processing plant. The aeration that cools deep beds of stored cottonseed effectively maintains viability and prevents an increase in free fatty acid content. For aeration, ambient air is normally drawn downward through the bed at a rate of at least 0.0004 m^3/s per cubic metre of oil mill seed and 0.0021 m^3/s per cubic metre of planting seed.

PEANUTS

Peanuts normally have a moisture content of about 50% at the time of digging. Allowing the peanuts to dry on the vines in the windrow for a few days removes much of this water. However, peanuts usually contain 20 to 30% moisture when removed from the vines, and some artificial drying is necessary. Drying should begin within 6 h after harvesting to keep the peanuts from self-heating. Both the maximum temperature and the rate of drying must be carefully controlled to maintain quality.

High temperatures result in an off flavor or bitterness. Drying too rapidly without high temperatures results in blandness or nuts that do not develop flavor during roasting. High temperatures, rapid drying, or excessive drying cause the skin to slip easily and the kernels to become brittle. These conditions result in high damage rates in the shelling operation but can be avoided if the moisture removal rate does not exceed 0.5% per hour. Because of these limitations, continuous-flow drying is not usually recommended for peanuts.

Peanuts can be dried in bulk bins using unheated air or air with supplemental heat. Under poor drying conditions, unheated air may cause spoilage, so supplemental heat is preferred. Air should be heated no more than 7 to 8°C to a maximum temperature of 35°C. An airflow rate of 0.050 to 0.130 m^3/s per cubic metre of peanuts should be used, depending on the initial moisture content.

The most common method of drying peanuts is bulk wagon drying. Peanuts are dried in depths of 1.5 to 1.8 m, using airflow rates of 0.05 to 0.08 m^3/s per cubic metreof peanuts and air heated 6 to 8 K above ambient. This method retains quality and usually dries the peanuts in three to four days. Wagon drying reduces handling labor but may require additional investment in equipment.

RICE

Of all grains, rice is probably the most difficult to process without quality loss. Rice containing more than 13.5% moisture cannot be safely stored for long periods, yet the recommended harvest moisture content for best milling and germination ranges from 20 to 26%. When rice is harvested at this moisture content, drying must be started promptly to prevent souring. Normally, heated air is used in continuous-flow dryers, where large volumes of air are forced through 100 to 250 mm layers of rice. Temperatures as high as 55°C may be used, if (1) the temperature drop across the rice does not exceed 11 to 17°C, (2) the moisture reduction does not exceed two percentage points in a 0.5 h exposure, and (3) the rice temperature does not exceed 38°C. During the tempering period following drying, the rice should be aerated to ambient temperature prior to the next pass through the dryer. This removes additional moisture and eliminates one to two dryer passes. It is estimated that full use of aeration following dryer passes could increase the maximum daily drying capacity by about 14%.

Unheated air or air with a small amount of added heat (7 K above ambient, but not exceeding 35°C) should be used for deep-bed rice drying. Too much heat overdries the bottom, resulting in checking (cracking), reduced milling qualities, and possible spoilage in the top. Because unheated air drying requires less investment and attention than supplemental heat drying, it is preferred when conditions permit. In the more humid rice-growing areas, supplemental heat is desirable to ensure that the rice dries. The time required for drying varies with weather conditions, moisture content, and airflow rate. In California, the recommended airflow rate is 0.001 to 0.012 m^3/s per cubic metre. Because of less favorable drying conditions in Arkansas, Louisiana, and Texas, greater airflow rates are recommended (e.g., a minimum of 0.01 m^3/s per cubic metre is recommended in Texas). Whether unheated air or supplemental heat is used, the fan should be turned on as soon as rice uniformly covers the air distribution system. The fan should then run continuously until the moisture content in the top 300 mm of rice is reduced to about 15%. At this point, the supplemental heat should be turned off. The rice can then be dried to a safe storage level by operating the fan only when the relative humidity is below 75%.

STORAGE PROBLEMS AND PRACTICES

MOISTURE MIGRATION

Redistribution of moisture generally occurs in stored grain when grain temperature is not controlled (Figure 12). Localized spoilage can occur even when the grain is stored at a safe moisture level. Grain placed in storage in the fall at relatively high temperatures cools nonuniformly through contact with the outside surfaces of the storage bin as winter approaches. Thus, the grain near the outside walls and roof may be at cool outdoor temperatures while the grain nearer the center is still nearly the same temperature it was at harvest. These temperature differentials induce air convection currents that flow downward along the outside boundaries of the porous grain mass and upward through the center. When the cool air from the outer regions contacts the warm grain in the interior, the air is

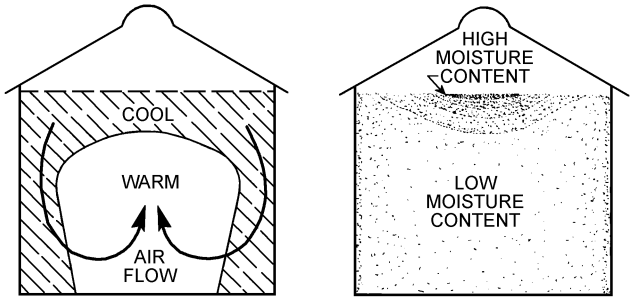

Fig. 12 Grain Storage Conditions Associated with Moisture Migration During Fall and Early Winter

heated and its relative humidity is lowered, increasing its capacity to absorb moisture from the grain. When the warm, humid air reaches the cool grain near the top of the bin, it cools again and transfers vapor to the grain. Under extreme conditions, water condenses on the grain. The moisture concentration near the center of the grain surface causes significant spoilage if moisture migration is uncontrolled. During spring and summer, the temperature gradients are reversed. The grain moisture content increases most at depths of 600 to 1200 mm below the surface. Daily variations in temperature do not cause significant moisture migration. Aside from seasonal temperature variations, the size of the grain mass is the most important factor in fall and winter moisture migration. In storages containing less than 35 m^3, there is less trouble with moisture migration. The problem becomes critical in large storages and is aggravated by in-complete cooling of artificially dried grain. Artificially dried grain should be cooled to near ambient temperature soon after drying.

GRAIN AERATION

Aeration by mechanically moving ambient air through the grain mass is the best way to control moisture migration. Aeration systems are also used to cool grain after harvest, particularly in warmer climates where grain may be placed in storage at temperatures exceeding 38°C. After the harvest heat is removed, aeration may be continued in cooler weather to bring the grain to a temperature within 11 K of the coldest average monthly temperature. The temperature must be maintained below 10°C.

Aeration systems are not a means of drying because airflow rates are too low. However, in areas where the climate is favorable, carefully controlled aeration may be used to remove small amounts of moisture. Commercial storages may have pockets of higher-moisture grain if, for example, some batches of grain are delivered after a rain shower or early in the morning. Aeration can control heating damage in the higher-moisture pockets.

Aeration Systems Design

Aeration systems include fans capable of delivering the required amount of air at the required static pressure, suitable ducts or floors to distribute the air into the grain, and controls to regulate the operation of the fan. The airflow rate determines how many hours are required to cool the crop (Table 8). Most aeration systems are designed with airflow rates between 0.0007 to 0.0027 m^3/s per cubic metre of grain.

Stored grain is aerated by forcing air up or down through the grain. Moving air up through the grain is more common because it is easier to observe when the cooling front has moved through the entire grain mass. In large, flat storages with long ducts, upward airflow results in more uniform air distribution than downdraft systems.

During aeration, a warming or cooling front moves through the crop (Figure 13); it is important to run the fan long enough to move the front completely through the crop.

Static pressure for an aeration system can be determined using the airflow resistance information in Chapter 11 of the 1997 *ASHRAE Handbook—Fundamentals*. All common types of fans are used in aeration systems. Attention should be given to noise levels with fans that are operated near residential areas or where people work for extended periods. The supply ducts connecting the fan to the distribution ducts in the grain should be designed and constructed according to the standards of good practice for any air-moving application. A maximum air velocity of 13 m/s may be used, but 8 to 10 m/s is preferred. In large systems, one large fan may be attached to a manifold duct leading to several distribution ducts in one or more storages, or smaller individual fans may serve individual distribution ducts. Where a manifold is used, valves or dampers

Table 8 Airflow Rates Corresponding to Approximate Grain Cooling Time

Airflow Rate, m^3/s per cubic metre of grain	Cooling Time, h
0.0007	240
0.0013	120
0.0027	60
0.0040	40
0.0054	30
0.0067	24
0.0080	20
0.0107	15
0.0134	12

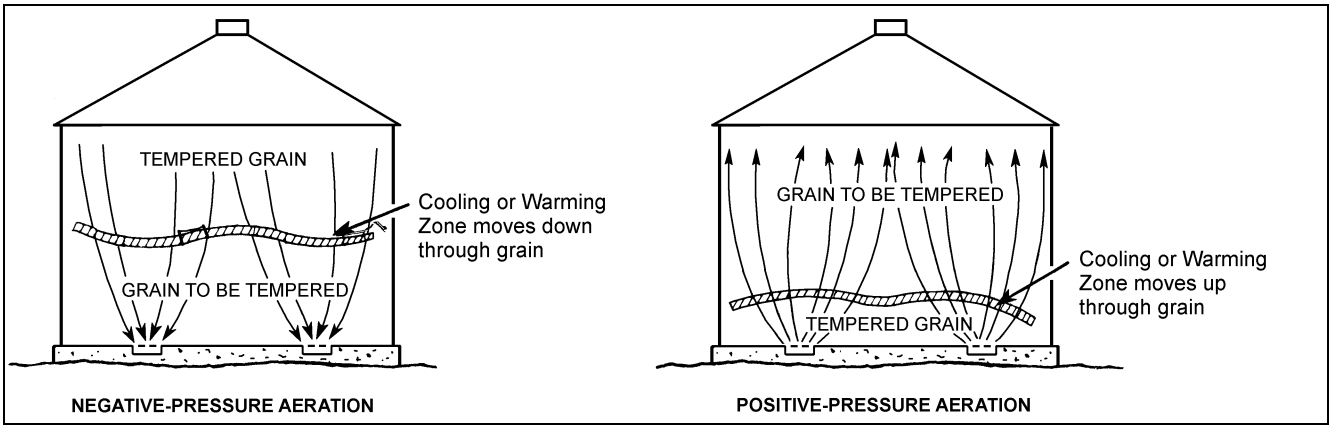

Fig. 13 Aerating to Change Grain Temperature

should be installed at each takeoff to allow adjustment or closure of airflow when part of the aerator is not needed.

Distribution ducts are usually perforated sheet metal with a circular or inverted U-shaped cross section, although many functional arrangements are possible. The area of the perforations should be at least 10% of the total duct surface. The holes should be uniformly spaced and small enough to prevent the passage of the grain into the duct (e.g., 2.5 mm holes or 2 mm wide slots do not pass wheat).

Since most problems develop in the center of the storage, and the crop cools naturally near the wall, the aeration system must provide good airflow in the center. Flush floor systems work well in storages with sweep augers and unloading equipment. Ducts should be easily removable for cleaning. Duct spacing should not exceed the depth of the crop; the distance between the duct and storage structure wall should not exceed one-half the depth of the crop for bins and flat storages. Common duct patterns for round bins are shown in Figure 14. Duct spacing for flat storages is shown in Figure 15.

When designing the distribution duct system for any type of storage, the following should be considered: (1) the cross-sectional area and length of the duct, which influences both the air velocity within the duct and the uniformity of air distribution; (2) the duct surface area, which affects the static pressure losses in the grain surrounding the duct; and (3) the distance between ducts, which influences the uniformity of airflow.

For upright storages where the distribution ducts are relatively short, distribution duct velocities up to 10 m/s are permissible. Maximum recommended air velocities in ducts for flat storages are shown in Table 9. Furthermore, these velocities should not be exceeded in the air outlets from the storage; therefore, an air outlet area at least equal to the duct cross-sectional area should be provided.

The duct surface area that is perforated or otherwise open for air distribution must be great enough that the air velocity through the grain surrounding the duct is low enough to avoid excessive pressure loss. When a semicircular perforated duct is used, the entire surface area is effective; only 80% of the area of a circular duct resting on the floor is effective. For upright storages, the air velocity through the grain near the duct (duct face velocity) should be limited to 0.15 m/s or less; in flat storages, to 0.10 m/s or less.

Duct strength and anchoring are important. If ducts placed directly on the floor are to be held in place by the crop, the crop flow should be directly on top of the ducts to prevent movement and damage. Distribution ducts buried in the grain must be strong enough to withstand the pressure the grain exerts on them. In tall, upright storages, static grain pressures may reach 70 kPa. When ducts are located in the path of the grain flow, as in a hopper, they may be subjected to many times this pressure during grain unloading.

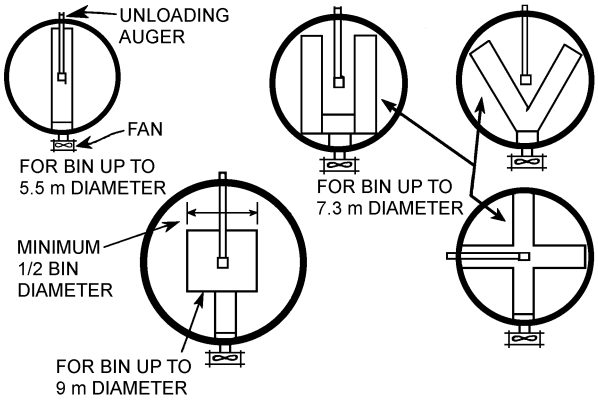

Fig. 14 Common Duct Patterns for Round Grain Bins

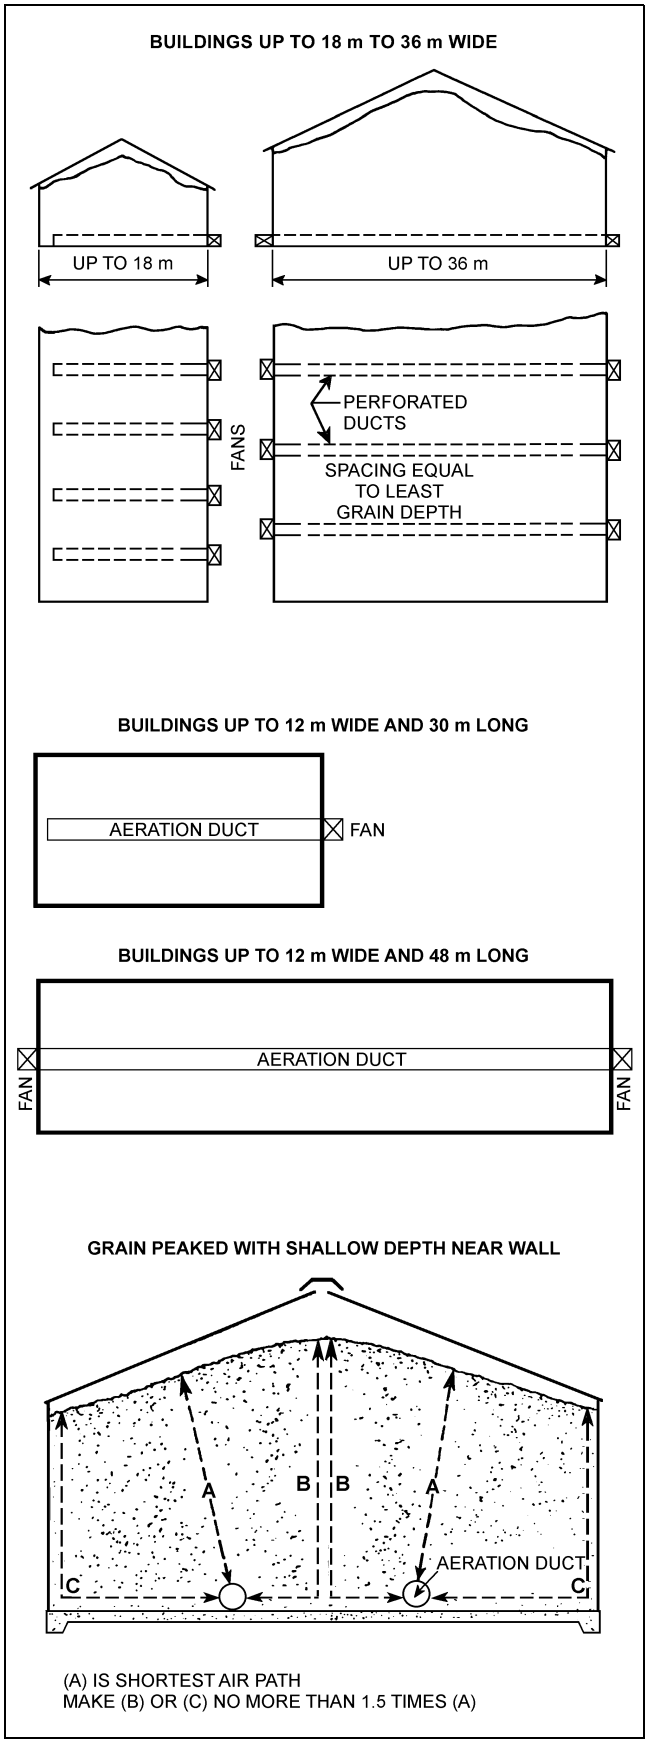

Fig. 15 Duct Arrangements for Large Flat Storages

Operating Aeration Systems

The operation of aeration systems depends largely on the objectives to be attained and the locality. In general, cooling should be carried out any time the outdoor air temperature is about 8°C cooler than the grain. Stored grain should not be aerated when the air humidity is much above the equilibrium humidity of the grain because moisture will be added. The fan should be operated long enough to cool the crop completely, but it should then be shut off and covered, thus limiting the amount of grain that is rewetted.

Aeration to cool the grain should be started as soon as the storage is filled, and cooling air temperatures are available. Aeration to prevent moisture migration should be started whenever the average air temperature is 6 to 8 K below the highest grain temperature. Aeration is usually continued as weather permits until the grain is uniformly cooled to within 11 K of the average temperature of the coldest month, or to 0 to 5°C.

Grain temperatures of about 0 to 10°C are desirable. In the northern corn belt, aeration may be resumed in the spring to equalize the grain temperature and raise it to between 5 to 10°C This reduces the risk of localized heating from moisture migration. Storage problems are the only reason to aerate when air temperatures are above 15°C. Aeration fans and ducts should be covered when not in use.

Table 9 Maximum Recommended Air Velocities Within Ducts for Flat Storages

Grain	Airflow Rate, m^3/s per cubic metre (grain)	Air Velocity (m/s) within Ducts for Grain Depths of:				
		3 m	6 m	9 m	12 m	15 m
Corn, soybeans, and other large grains	0.0007	—	3.8	5.0	6.3	6.3
	0.0013	3.8	5.0	6.3	7.6	8.8
	0.0027	5.0	6.3	—	—	—
Wheat, grain sorghum, and other small grains	0.0007	—	5.0	7.6	8.8	10.0
	0.0013	3.8	7.6	10.0	—	—
	0.0027	5.0	10.0	—	—	—

In storages where the fans are operated daily in the fall and winter months, automatic controls work well when the air is not too warm or humid. One thermostat usually prevents fan operation when the air temperature is too high, and another prevents operation when the air is too cold. A humidistat allows operation when the air is not too humid. Fan controllers are available that determine the equilibrium moisture content of the crop based on existing air conditions and regulate the fan based on entered information.

SEED STORAGE

Seed must be stored in a cool, dry environment to maintain viability. Most seed storages have refrigeration equipment to maintain a storage environment of 7 to 12°C. Seed storage conditions must be achieved before mold and insect damage occur.

CHAPTER 23

AIR CONDITIONING OF WOOD AND PAPER PRODUCT FACILITIES

General Wood Product Operations 23.1
Pulp and Paper Operations 23.1

THIS chapter covers some of the standard requirements for air conditioning of facilities that manufacture finished wood products as well as pulp and paper.

GENERAL WOOD PRODUCT OPERATIONS

Finished lumber products to be used in heated buildings should be stored in areas that are heated 6 to 11 K above ambient. This provides sufficient protection for furniture stock, interior trim, cabinet material, and stock for products such as ax handles and glue-laminated beams. Air should be circulated within the storage areas. Lumber that is kiln-dried to a moisture content of 12% or less can be kept within a given moisture content range through storage in a heated shed. The moisture content can be regulated either manually or automatically by altering the dry-bulb temperature (Figure 1).

Some special materials require close control of moisture content. For example, musical instrument stock must be dried to a given moisture level and maintained there because the moisture content of the wood affects the harmonics of most stringed wooden instruments. This control may require air conditioning with reheat and/or heating with humidification.

Process Area Air Conditioning

Temperature and humidity requirements in wood product process areas vary according to product, manufacturer, and governing code. For example, in match manufacturing, the match head must be cured (i.e., dried) after dipping. This requires careful control of the humidity and temperature to avoid a temperature near the ignition point. Any process involving the application of flammable substances should follow the ventilation recommendations of the National Fire Protection Association, the National Fire Code, and the U.S. Occupational Safety and Health Act.

Finished Product Storage

Design engineers should be familiar with the client's entire operation and should be aware of the potential for moisture regain. Finished lumber products manufactured from predried stock (moisture content of 10% or less) regain moisture if exposed to a high relative humidity for an extended period. All storage areas housing finished products such as furniture and musical instruments should be conditioned to avoid moisture regain.

PULP AND PAPER OPERATIONS

The papermaking process comprises two basic steps: (1) wood is reduced to pulp, that is, wood fibers; and (2) the pulp is converted to paper. Wood can be pulped by either mechanical action (e.g., grinding in a groundwood mill), chemical action (e.g., kraft pulping), or a combination of both.

Many different types of paper can be produced from pulp, ranging from the finest glossy finish to newsprint to bleached board to fluff pulp for disposable diapers. To make newsprint, a mixture of mechanical and chemical pulps is fed into the paper machine. To make kraft paper (e.g., grocery bags and corrugated containers), however, only unbleached chemical pulp is used. Disposable diaper material and photographic paper require bleached chemical pulp with a very low moisture content of 6 to 9%.

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

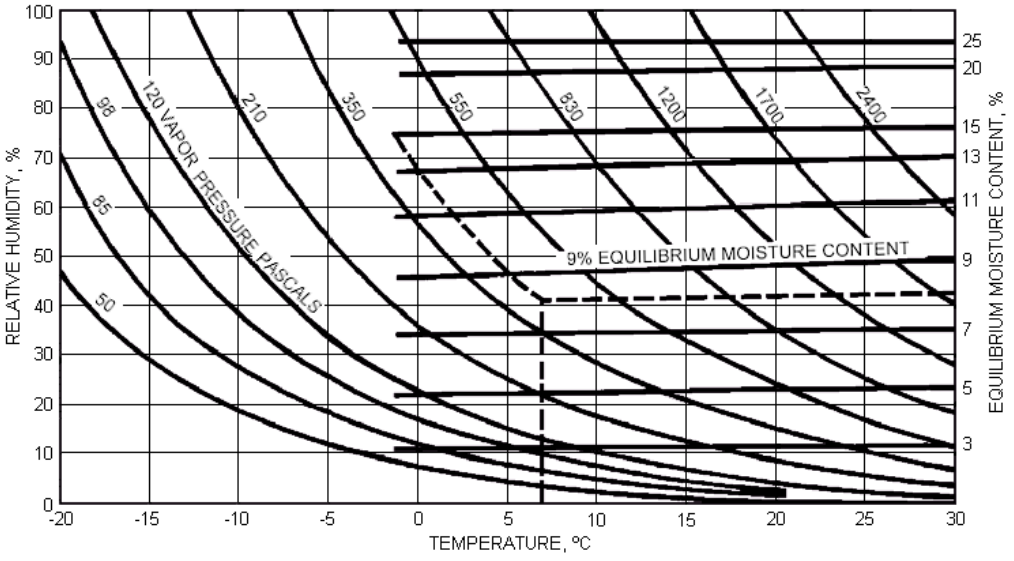

Fig. 1 Relationship of Temperature, Relative Humidity, and Vapor Pressure of Air and Equilibrium Moisture Content of Wood

Paper Machine Area

In papermaking, extensive air systems are required to support and enhance the process (e.g., by preventing condensation) and to provide reasonable comfort for operating personnel. Radiant heat from steam and hot water sources and mechanical energy dissipated as heat can result in summer temperatures in the machine room as high as 50ºC. In addition, high paper machine operating speeds of 10 to 23 m/s and a stock temperature near 50ºC produce warm vapor in the machine room.

Outside air makeup units and process exhausts absorb and remove room heat and water vapor released from the paper as it is dried (Figure 2). The makeup air is distributed to the working areas above and below the operating floor. Part of the air delivered to the basement migrates to the operating floor through hatches and stairwells. Motor cooling equipment distributes cooler basement air to the paper machine drive motors.

Wet and basement exhaust should be installed inside the room. Outside air intakes with insulated adjustable louvers should be installed on the outside wall to supplement the mechanical air supply. In facilities with no basement exterior wall, a sufficient mechanical air intake should be provided. The exhaust, adjustable louver, or mechanical air intake should be furnished with modulating control. When the ambient temperature drops to near freezing, outside airflow must be reduced to a minimum and the appropriate heater started to prevent freezing.

The most severe ventilation demand occurs in the area between the wet-end forming section and press section and the dryer section. In the forming section, the pulp slurry, which contains about 90% water, is deposited on a traveling screen. Gravity, rolls, foils, vacuum, steam boxes, and three or more press roll nips are sequentially used to remove up to 50% of the water in the forming section and press section. The wet end is very humid due to the evaporation of moisture and the mechanical generation of vapor by turning rolls and cleaning showers. Baffles and a custom-designed exhaust in the forming section help control the vapor. A drive-side exhaust in the wet end removes heat from the motor vent air and removes the process generated vapor.

To prevent condensation or accumulated fiber from falling on the traveling web, a false ceiling with ducts connected to roof exhausters remove humid air not captured at a lower point. At the wet end, heated inside air is usually circulated to scrub the underside of the roof to prevent condensation in cold weather. Additional roof exhaust may also remove accumulated heat from the dryer section and the dry end during warmer periods. Ventilation in the wet end should be predominantly by roof exhaust.

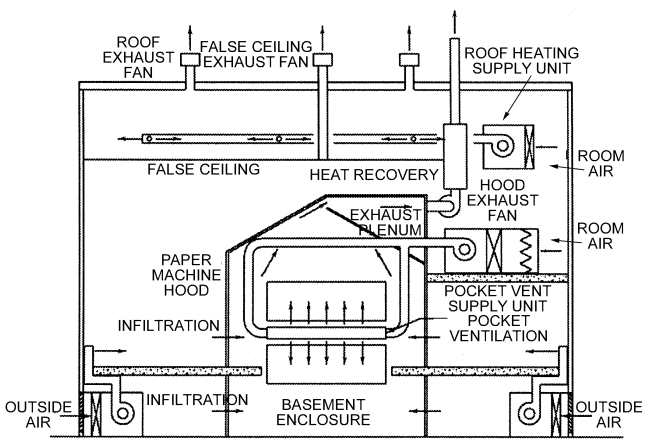

Fig. 2 Paper Machine Area

The large volume of moisture and vapor generated from the wet-end process rises and accumulates under the roof. To keep condensation from forming in winter, the roof is normally exhausted and hot air is distributed under the roof. Sufficient roof insulation should be installed to keep the inside surface temperature above the dewpoint. Heat transfer from the room to the interior surface is

$$\frac{t_r - t_{is}}{R_{r-is}} = \frac{t_{is} - t_o}{R_{is-o}} \quad (1)$$

where

t_r = room air temperature, °C
t_{is} = roof interior surface temperature, °C
t_o = outside air temperature, °C
R_{r-is} = heat transfer resistance from room air to roof interior surface. In winter, $R_{r-is} = 0.11$ m²·K/W
R_{is-o} = required total R-value from roof interior surface to outside air, m²·K/W

For a given project t_o and t_r have been determined and only t_{is} needs to be selected. For wet-end roof insulation and assuming 96% relative humidity, t_{is} can be shown on a psychrometric chart to be

$$t_{is} = t_r - 0.7°C \quad (2)$$

Then Equation (1) can be simplified to find the required roof R-value as

$$R_{is-o} = \frac{0.11}{0.7}(t_r - t_o - 0.7) \quad (3)$$

In the dryer section, the paper web is dried as it travels in a serpentine path around rotating steam-heated drums. Exhaust hoods remove heat from the dryers and moisture evaporated from the paper web. Most modern machines have enclosed hoods, which reduce the airflow required to less than 50% of that required for an open hood exhaust. The temperature inside an enclosed hood ranges from 50 to 60ºC at the operating floor to 80 to 95ºC in the hood exhaust plenum at 70 to 90% rh, with an exhaust rate generally ranging from 140 to 190 m³/s.

Where possible, pocket ventilation air (see Figure 3) and hood supply air are drawn from the upper level of the machine room to take advantage of the preheating of makeup air by process heat as it rises. The basement of the dryer section is also enclosed to control infiltration of machine room air to the enclosed hood. The hood supply and pocket ventilation air typically operate at 95ºC; however, some systems run as high as 120ºC. Enclosed hood exhaust is typically 0.16 m³/s per megagram of machine capacity. The pocket ventilation and hood supply are designed for 75 to 80% of the exhaust, with the balance infiltrated from the basement and machine room. Large volumes of air (240 to 380 m³/s) are required to balance the paper machine's exhaust with the building air balance.

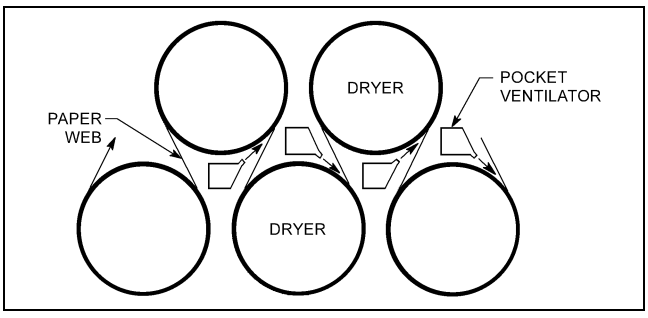

Fig. 3 Pocket Ventilation

The potential for heat recovery from the hood exhaust air should be evaluated. Most of the energy in the steam supplied to the paper dryers is converted to latent heat in the hood exhaust as water is evaporated from the paper web. Air-to-air heat exchangers are used where the air supply is located close to the exhaust. Air-to-liquid heat exchangers that recirculate water-glycol to heat remote makeup air units can also be used. Air-to-liquid systems provide more latent heat recovery, resulting in three to four times more total heat recovery than air-to-air units. Some machines use heat recovered from the exhaust air to heat process water. Ventilation in paper machine buildings in the United States ranges from 10 to 25 air changes per hour in northern mills to 20 to 50 in southern mills. In some plants, computers monitor the production rate and outside air temperature to optimize the operation and conserve energy.

After fine, bond, and cut papers have been bundled and/or packaged, they should be wrapped in a nonpermeable material. Most papers are produced with less than 10% moisture by mass, the average being 7%. Dry paper and pulp are hygroscopic and begin to swell noticeably and deform permanently when the relative humidity exceeds 38%. Therefore, finished products should be stored under controlled conditions to maintain their uniform moisture content.

Finishing Area

To produce a precisely cut paper that will stabilize at a desirable equilibrium moisture content, the finishing areas require temperature and humidity control. Further converting operations such as printing and die cutting require optimum sheet moisture content for efficient processing. Finishing room conditions range from 21 to 24ºC db and from 40 to 45% rh. The rooms should be maintained within reasonably close limits of the selected conditions. Without precise environmental control, the paper equilibrium moisture content will vary, influencing dimensional stability, the tendency to curl, and further processing.

Process and Motor Control Rooms

In most pulp and paper applications, process control, motor control, and switchgear rooms are separate from the process environment. Air conditioning removes heat generated by equipment, lights, etc., and reduces the air-cleaning requirement. (See Chapter 16 for air conditioning in control rooms that include a computer, a computer terminal, or data processing equipment.) Ceiling grilles or diffusers should be located above access aisles to avoid the risk of condensation on control consoles or electrical equipment during start-up and recovery after an air-conditioning shutdown. Electrical rooms are usually maintained in the range of 24 to 27ºC, with control rooms at 23ºC; the humidity is maintained in the range of 45 to 55% in process control rooms and is not normally controlled in electrical equipment rooms.

Electrical control rooms for distributed control and process control contain electronic equipment that is susceptible to corrosion. The typical pulp and paper mill environment contains both particulate and vapor-phase contaminants with sulfur- and chloride-based compounds. To protect the equipment, multistage particulate and adsorbent filters should be used. They should have treated activated charcoal and potassium permanganate-impregnated alumina sections for vapor-phase contaminants, as well as fiberglass and cloth media for particulates.

Switchgear and motor control centers are not as heat-sensitive as control rooms, but the moisture-laden air carries chemical residues onto the contact surfaces. Arcing, corrosion, and general deterioration can result. A minimum amount of filtered, outside air and air conditioning is used to protect these areas.

In most projects, the electric distribution control system (DCS) is energized before the room air conditioning is installed and started. If a temporary air conditioner is used in the DCS room, a condensate drain pan and temporary drain pipe should be installed to keep condensate from the cable channel beneath the DCS panels.

Paper Testing Laboratories

Design conditions in paper mill laboratories must be followed rigidly. The most recognized standard for testing environments for paper and paper products (paperboard, fiberboard, and containers) is TAPPI (the Technical Association of the Pulp and Paper Industry) *Standard* T402, Standard Conditioning and Testing Atmospheres for Paper, Board, Pulp Handsheets, and Related Products. Other standards include ASTM E 171, Standard Specification for Standard Atmospheres for Conditioning and Testing Materials, and ISO/TC 125, Enclosures and Conditions for Testing.

Standard pulp and paper testing laboratories have three environments: preconditioning, conditioning, and testing. The physical properties of a sample are different if it is brought to the testing humidity from a high humidity than if it is brought from a lower humidity. Preconditioning at lower relative humidity tends to eliminate hysteresis. For a preconditioning atmosphere, TAPPI *Standard* T402 recommends 10 to 35% rh and 22 to 40ºC db. Samples are usually conditioned in a controlled, conditioned cabinet.

Conditioning and testing atmospheres should be maintained at 50 ± 2.0% rh and 23 ± 1ºC db. However, a change of 1ºC db at 23ºC without starting a humidifier causes the relative humidity to fluctuate as much as 3%. A dry-bulb temperature tolerance of ±0.5ºC must be held to maintain a ±2% rh. A well-designed temperature and humidity control system should be provided.

Miscellaneous Areas

The pulp digester area contains many components that release heat and contribute to dusty conditions. For batch digesters, the chip feeders are a source of dust and need hooded exhaust and makeup air. The wash and screen areas have numerous components with hooded exhausts that require considerable makeup air. Good ventilation controls fumes and humidity. The lime kiln feed-end releases extremely large amounts of heat and requires high ventilation rates or air conditioning.

Recovery-boiler and power-boiler buildings have conditions similar to those of power plants; the ventilation rates are also similar. The control rooms are generally air conditioned. The grinding motor room, in which groundwood is made, contains many large motors that require ventilation to keep the humidity low.

System Selection

The system and equipment selected for air conditioning a pulp and paper mill depends on many factors, including the plant layout and atmosphere, geographic location, roof and ceiling heights (which can exceed 30 m), and degree of control desired. Chilled water systems are economical and practical for most pulp and paper operations, because they have both the large cooling capacity needed by mills and the precision of control to maintain the proper temperature and humidity in laboratories and finishing areas. In the bleach plant, the manufacture of chlorine dioxide is enhanced by using water with a temperature of 7ºC or lower; this water is often supplied by the chilled water system. If clean plant or process water is available, water-cooled chillers are satisfactory and may be supplemented by water-cooled direct-expansion package units for small, remote areas. However, if plant water is not clean enough, a separate cooling tower and condenser water system should be installed for the air conditioning.

Most manufacturers prefer water-cooled over air-cooled systems because of the gases and particulates present in most paper mills. The most prevalent contaminants are chlorine gas, caustic soda, borax, phosphates, and sulfur compounds. With efficient air cleaning, the air quality in and about most mills is adequate for properly placed air-cooled chillers or condensing units that have properly applied coil and housing coatings. Phosphor-free brazed

coil joints are recommended in areas where sulfur compounds are present.

Heat is readily available from processing operations and should be recovered whenever possible. Most plants have quality hot water and steam, which can be used for unit heater, central station, or reheat quite easily. Evaporative cooling should be considered. Newer plant air-conditioning methods using energy conservation techniques, such as temperature destratification and stratified air conditioning, have application in large structures. Absorption systems should be considered for pulp and paper mills because they provide some degree of energy recovery from the high-temperature steam processes.

CHAPTER 24

POWER PLANTS

General Design Criteria 24.1
Ventilation Approach 24.3
Steam Generator Buildings: Industrial and Power Facilities 24.4
Turbine Generator Building 24.6
Combustion Turbine Areas 24.7
Main Control Center 24.8
Oil Storage and Pump Buildings 24.8
Coal Crusher and Coal Transportation System Buildings 24.8
Heating/Cooling Systems 24.9

THIS chapter discusses heating, ventilating, and air-conditioning (HVAC) systems for industrial facilities for the production of process heat and power and for electrical generating stations. While not every type of power plant is specifically covered, the process areas addressed normally correspond to similar process areas in any plant. For example, wood-fired boilers are not specifically discussed, but the requirements for coal-fired boilers generally apply.

Aspects of HVAC system design unique to nuclear power plants are covered in Chapter 25.

GENERAL DESIGN CRITERIA

The space-conditioning systems in power plant buildings are designed to maintain an environment for the reliable operation of the power generation systems and equipment and for the convenience and safety of plant personnel. A balance is achieved between the cost of the process systems designed to operate in an environment and the cost of providing that environment.

Environmental criteria for personnel safety and comfort are governed by several sources. The U.S. Occupational Safety and Health Administration (OSHA) defines noise and air contaminant exposure limits. Chapter 11 and Chapter 28 of this volume and *Industrial Ventilation* by the American Conference of Governmental Industrial Hygienists (ACGIH 1998) also provide guidance for safety in work spaces. The degree of comfort for the worker is somewhat subjective and more difficult to quantify. The plant owner or operator ordinarily establishes the balance between cost and worker comfort.

Criteria should be clearly defined at the start of the design process because they document an understanding between the process designer and the HVAC system engineer that is fundamental to achieving the environment required for the various process areas. Typical criteria for a coal-fired power plant are outlined in Table 1. They should be reviewed for compliance with local codes, the plant operator's experience and preferences, and the overall financial objectives of the facility. Additional discussion of criteria may be found in the sections on specific areas.

Redundancy

Maintaining design operating temperatures within the power plant is essential for reliable operation. Operating electrical equipment in temperatures above its rated temperature reduces the life of the equipment. Sensitive electronic equipment, such as in the main control center, may not function reliably at high temperatures. Low temperatures also affect plant availability; for example, low temperatures in the batteries or freezing of pipes, instrument lines, or tanks could prevent normal plant operation.

HVAC systems or components essential for plant operation should be designed with redundancy to ensure plant availability. Automatic switchover to the backup system may be required in normally unoccupied areas. In areas where backup systems are impractical, temperature monitoring and alarming systems should be considered to initiate temporary corrective measures.

HVAC systems that include multiple units (indicated as **multiplicity** in Table 1) also improve the reliability of the power plant. A space ventilated by multiple fans, such as four at 1/4 capacity, may retain sufficient ventilation even if one fan is out of service.

Filtration and Space Cleanliness

Filtration of ventilation air for process areas is usually not needed because some areas are generally dirtier than the outdoor surroundings, and the process equipment is designed to accommodate a dusty environment. However, the plant may be located in an area having sources of outdoor particulate contaminants that need to be managed to protect the process equipment. Power plants in dusty or sandy areas, or where there are seasonal nuisances such as cottonwood seeds, may require filtration of ventilation air. Plants at industrial sites such as refineries and paper mills may need to address gaseous contaminants and corrosive gases as well.

Indoor air cleanliness is a concern in control room HVAC system design. Even if the control center is in an independent building remote from the boiler-turbine building, coal transportation, coal crushing, fuel/ air distribution and combustion, ash handling, fume heat recovery, fume/smoke exhaust diffusion, and so forth, may contaminate the entire plant and its surroundings.

When potential outdoor contaminants are a factor, the quality of outdoor air may need to be evaluated. This may include collection of typical particulates and the use of corrosion coupons to quantify gaseous contaminants. The U.S. Environmental Protection Agency (EPA) is a source of data. Filtration requirements may include 30% dust-spot test efficiency prefilters, 65% to 90% efficiency final filters, and gas-phase filtration units.

Air-conditioned areas for people should meet ASHRAE *Standard* 62 requirements. Air-conditioned areas for control and electrical equipment should meet the requirements of the manufacturer. Guidelines for reliability of electrical equipment are found in Instrument Society of America (ISA) *Standard* S71.04.

Temperature and Humidity

Selection of outdoor design temperatures is based on the operating expectations of the plant. If the power production facility is critical and must operate during severe conditions, then the effect of local extreme high and low temperatures on the systems should be evaluated. Electrical power consumption is usually highest under extreme outdoor conditions, so the plant should be designed to operate when needed the most. Other temperature ranges, indicated in Table 1, may be more appropriate for less critical applications.

If the equipment is enclosed, the indoor temperatures must match the specified operating temperatures of the equipment. The electrical equipment, such as switchgear, motor control centers, and motors, typically determines the design temperature limits in the plant. Common ratings are 40 or 50°C. Elevator machine room equipment may include electronics with temperature restrictions.

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

[a]See Chapter 26 of the 1997 *ASHRAE Handbook—Fundamentals* for design dry-bulb temperature data corresponding to the given annual cumulative frequency of occurrence and the specific geographic location of the plant.

[b]Multiplicity indicates that the HVAC system should have multiple units.

[c]See Figure 4 in Chapter 7 of the 1997 *ASHRAE Handbook—Fundamentals* for noise criterion curves.

In plant areas where compressed gas containers are stored, the design temperature is according to the gas supplier. Typically, the minimum temperature should be high enough that the gas volume can be effectively released from the containers. If the gas is hazardous (e.g., chlorine), the minimum temperature does not apply during personnel occupancy periods, when high dilution ventilation rates are needed.

Practical ventilation rates for fuel-fired power plants provide indoor conditions 6 to 12 K above the outdoor ambient. Therefore, ventilation design criteria establish a temperature rise above the design outdoor temperature to produce an expected indoor temperature that matches the electrical equipment ratings. For example, an outdoor extreme design temperature of 44°C with a ventilation system designed for a 6 K rise would meet the requirements of 50°C-rated plant equipment unless a new record temperature occurred. However, the environment for workers should also be considered. Velocity (spot) cooling may be necessary in some areas to support work activities in such a building.

Low temperatures affect plant reliability due to the potential for freezing. The selection of the low design temperature should be balanced by the selection of the heating design margin. If the record low temperature is used in the design, indoor design temperatures of 2 to 4°C may be used. In the heating system design, credit is generally not taken for heat generated from operating equipment.

The selection of outdoor design humidity levels affects the selection of cooling towers and evaporative cooling processes and the sizing of air-conditioning coils for outdoor air loads. When values from Chapter 26 of the 1997 *ASHRAE Handbook—Fundamentals* are used for design, the mean coincident wet bulb is appropriate. If extreme dry-bulb temperatures are selected for the design basis, the use of extreme wet bulbs is too restrictive because the extremes are not coincident. It is prudent to use the wet bulb associated with the 1% dry bulb when extreme dry-bulb temperatures are used for the design.

Indoor design humidity is not a factor in ventilated areas unless the plant is in a harsh, corrosive environment. In this case, lower humidity reduces the potential for corrosion. In air-conditioned areas for personnel or electronic equipment, ASHRAE, ISA, and manufacturers' recommendations dictate the humidity criteria.

Ventilation Rates

Ventilation within plant structures provides heat removal and dilution of potentially hazardous gases. Ventilation rates for heat removal are calculated during HVAC system design to meet summer indoor design temperatures.

The numbers shown in Table 1 for air change rates are for estimating approximate ventilation needs. Actual heat emission rates should be obtained from equipment manufacturers or from the engineer's experience.

The ventilation rate for room heat removal is

$$Q = \frac{q}{(t_r - t_o)(\rho c_p)} \quad (1)$$

where

Q = ventilation rate, m^3/s
q = room heat, kW
t_r = allowed room temperature from Table 1, °C
t_o = outside air temperature, °C
ρ = air density, kg/m^3
c_p = specific heat of air = 1.0 kJ/(kg·K)

Hazardous gases are mostly handled by the process system design functions. Natural gas and other combustible fuel gases are controlled by ignition safeties and may contain odorants for detection. Hydrogen and gases used for generator and bus cooling are monitored for leakage by pressure loss or makeup rates. Escaped gases are diluted by outside air infiltration. There are no specific ventilation rate criteria for these gases. For a building with very tight construction (i.e., very little natural infiltration), an analysis should be performed to verify that dilution rates are acceptable.

Flue gas is confined to the boiler and flue gas ductwork and generally poses no hazard. In a forced-draft boiler, however, flue gas is at a higher pressure than the surroundings and can leak into occupied areas. Also, special flue gas treatment gases such as ammonia can leak into the boiler building. In these cases, gas detection monitors should be used.

Ventilation for areas with hazardous gases (e.g., chlorine) should be designed by specific gas industry standards such as the *Chlorine Manual* or ACGIH (1998).

Infiltration

Infiltration of outside air into boiler and power generation structures is driven by the thermal buoyancy of the heated air. While this outside air is beneficial in that it dilutes fugitive fumes, it also adds to the cold weather load on the heating system.

Noise

Consideration should be given to noise levels produced by HVAC system equipment both inside and outside plant spaces. Indoor noise guidelines should be established for air-conditioned areas and ventilated areas with continuous occupancies. Outdoor noise levels are established by the environmental noise pollution concerns of adjacent areas.

Air-conditioned indoor spaces should meet the normal sound level guidelines for occupancies such as offices that are listed in Chapter 46. Special occupancies such as control rooms should follow the guidelines in Table 1.

Ventilated areas of the plant should be treated as other industrial areas following OSHA regulations. The sound levels indicated in Table 1 are suggested guidelines that may be appropriate in the absence of a specific engineered solution to meet the OSHA requirements.

HVAC system components contribute to the overall noise level outside the plant buildings either by generating noise or by having ventilation openings. HVAC designs for power plants situated in urban areas can be significantly influenced by outdoor noise level requirements. Equipment may have to include sound-absorbing materials or be located indoors in sound attenuation enclosures. Openings may require acoustical louvers.

VENTILATION APPROACH

Ventilation can be achieved by natural draft, forced mechanical supply and exhaust, or natural and mechanical combined systems. The HVAC engineer should select the approach that best suits the overall project objectives for performance and cost. **Natural-draft systems** use a combination of inlet louvers and open doors or windows and relieve warmed air through roof or high sidewall openings. **Mechanical systems** use fans, power roof ventilators (PRVs), or air-handling units to move air. A typical **combined** system would use mechanical supply fans with natural roof openings for relief. With any ventilation arrangement, consideration should be given to the physical separation of inlet and outlet openings to minimize recirculation, as discussed in Chapter 15 of the 1997 *ASHRAE Handbook—Fundamentals*.

Driving Forces

Natural ventilation uses the thermal buoyancy of the air as the motive force for air movement through a building. The equations for determining differential pressures for natural ventilation are found in Chapter 25 of the 1997 *ASHRAE Handbook—Fundamentals*. With natural ventilation, air enters the enclosed space and is heated by the plant equipment. The difference in density between the inside air and the outside air causes air to be drawn into the building at low elevations and relieved at high elevations.

Mechanical ventilation can provide the required ventilation rate regardless of the building configuration or temperature difference.

Air Distribution

With natural ventilation, small differential pressures drive air movement. Accordingly, air is drawn into the building at low velocities; it penetrates a short distance into the building and then disperses.

Mechanical ventilation supplied from the walls or from the roof can distribute air more effectively throughout the structure.

Inlet and Exhaust Areas

Due to the low differential pressure driving the air, natural ventilation requires large inlet louver and exhaust relief areas. This necessitates large wall spaces where the ventilation is needed and large roof areas for hoods, ridge vents, or gravity relief openings.

Mechanical ventilation requires fewer roof penetrations with the associated curbs, crickets, and flashing. The amount of wall louver can be reduced by a factor of four or more compared to natural ventilation.

Noise

Natural ventilation has the advantage of being noise-free. Noise can be an indirect concern, however, because the openings required for natural ventilation allow noise generated by other plant equipment to pass more easily to the outside.

Fans and PRVs generate noise directly, but the noise level can be managed by fan selection and sound treatment of PRV inlet hoods.

Impact on Plant Cleanliness

By its nature, natural ventilation creates negative pressure in the lower portions of the building. With the large openings low in the structure, the negative pressure may draw dust and fumes into the building from ground level.

Mechanical ventilation usually pressurizes the building and can draw air from relatively clean sources at higher elevations.

Economics

The primary advantage to natural ventilation is that there are no operating costs for fan power. Because natural ventilation is passive, it is more reliable and has lower maintenance costs than a mechanical system. However, natural ventilation may not always be the most economical selection. The cost of louvers and inlet openings, architectural features, and gravity relief openings to achieve an acceptable ventilation rate may be higher than the first cost for mechanical ventilation.

Another consideration is the average building temperature. Because internal heat is the driving force, the naturally ventilated building is normally warmer than the power ventilated building. This warmer average temperature may shorten the life of plant equipment such as expansion joints, seals, motors, electrical switchgear, and instrumentation. Warmer temperatures may also affect operator performance.

The large louver areas associated with natural ventilation may create greater infiltration, thereby increasing the winter heating load. This additional heating cost may offset some of the summer energy savings of natural ventilation.

STEAM GENERATOR BUILDINGS: INDUSTRIAL AND POWER FACILITIES

A steam generator is a device that uses heat energy to convert water to steam. The two basic subsystems of a steam generator are the heat energy system and the steam process system.

The heat energy system for a fueled (oil, gas, coal, etc.) steam generator includes fuel distribution piping or conveyors, preparation subsystems, and supply rate and ignition controls. Provision to supply and regulate combustion air is required at the combustion chamber; the flue gas is handled downstream of the combustion area. With ash-producing fuels, the bottom ash below the steam generator and the fly ash entrained in the flue gas must be processed. Figure 1 shows a steam generator building with typical components.

Steam process components typically found in the steam generator building include an enclosure for the fire and heat transfer surfaces and feedwater equipment such as pumps, piping, and controls. Steam lines for primary and reheat steam are typically routed from the steam drum and reheat sections of the steam generator to the steam turbine or process systems.

The heat energy and steam process systems impose requirements on the HVAC systems for specific areas of the steam generator building.

Burner Areas

Fuel (gas, oil, coal, etc.) is transferred to the furnace, mixed with combustion air, and ignited in the burner area of the steam generator. Instrumentation must modulate the fuel in response to combustion needs. View ports typically allow operators to monitor the combustion processes.

The burner area requires special attention for the steam generator building ventilation system. This area is often occupied by plant operators who monitor and inspect the controls and the combustion process. Heat is radiated and conducted to the adjacent spaces from inspection ports, penetrations, and the steam generator. Leakage of fumes and combustion gases is also possible.

Both the burner area operator and the controls require ventilation with outdoor air. Outdoor air also provides dilution for the fugitive fumes. Outdoor air can be ducted to burner areas and discharged by supply registers or blown directly into the area with wall-mounted fans, depending on the building arrangement. The flow rate is difficult to quantify; generally, 60 air changes per hour supplied to an area 4 to 6 m around the steam generator provide adequate ventilation. Consideration should be given to providing velocity cooling of personnel workstations. In cold climates, outdoor air may need to be tempered with indoor air.

Steam Drum Instrumentation Area

A typical steam generator has a steam drum at the top of the boiler that provides the water-to-steam interface. The water level in the drum is monitored to regulate the flow of steam and feedwater. This is a critical steam generator control function, so accurate and reliable process flow measurement is important.

The steam drum instrumentation area may include sections of uninsulated furnace surface, which conducts and radiates heat to the surrounding area. The ventilation system should remove this heat to ensure that area temperatures are within instrumentation temperature limits. Instrumentation may need to be shielded from hot surfaces. Velocity cooling may be needed at operator workstations.

Wall-mounted panel fans in the outside walls are an option for providing ventilation air during warm weather. Heating is generally not a concern unless the steam generator is expected to be out of service during cold weather.

Local Control and Instrumentation Areas

In addition to the drum and burners, the steam generator building may house local control areas for such functions as fuel supply, draft fans, or ash handling. Because areas around a steam generator may be hot and dirty, the location and selection of the control equipment should be coordinated between the electrical system engineer and the HVAC system engineer.

The alternatives are (1) to locate the control equipment remotely from the steam generator, (2) to use electrical components that can withstand the environment, or (3) to provide a local environmentally controlled enclosure. The first alternative requires additional cable and raceway and perhaps additional signal boosters and conditioners. The second alternative requires increased cost for electrical equipment that can tolerate the extremely hot or dirty areas.

When the electrical and control system design dictates that the equipment be located near the steam generator, a dedicated enclosure with a supporting environmental control system may be necessary. A typical environmental control system may

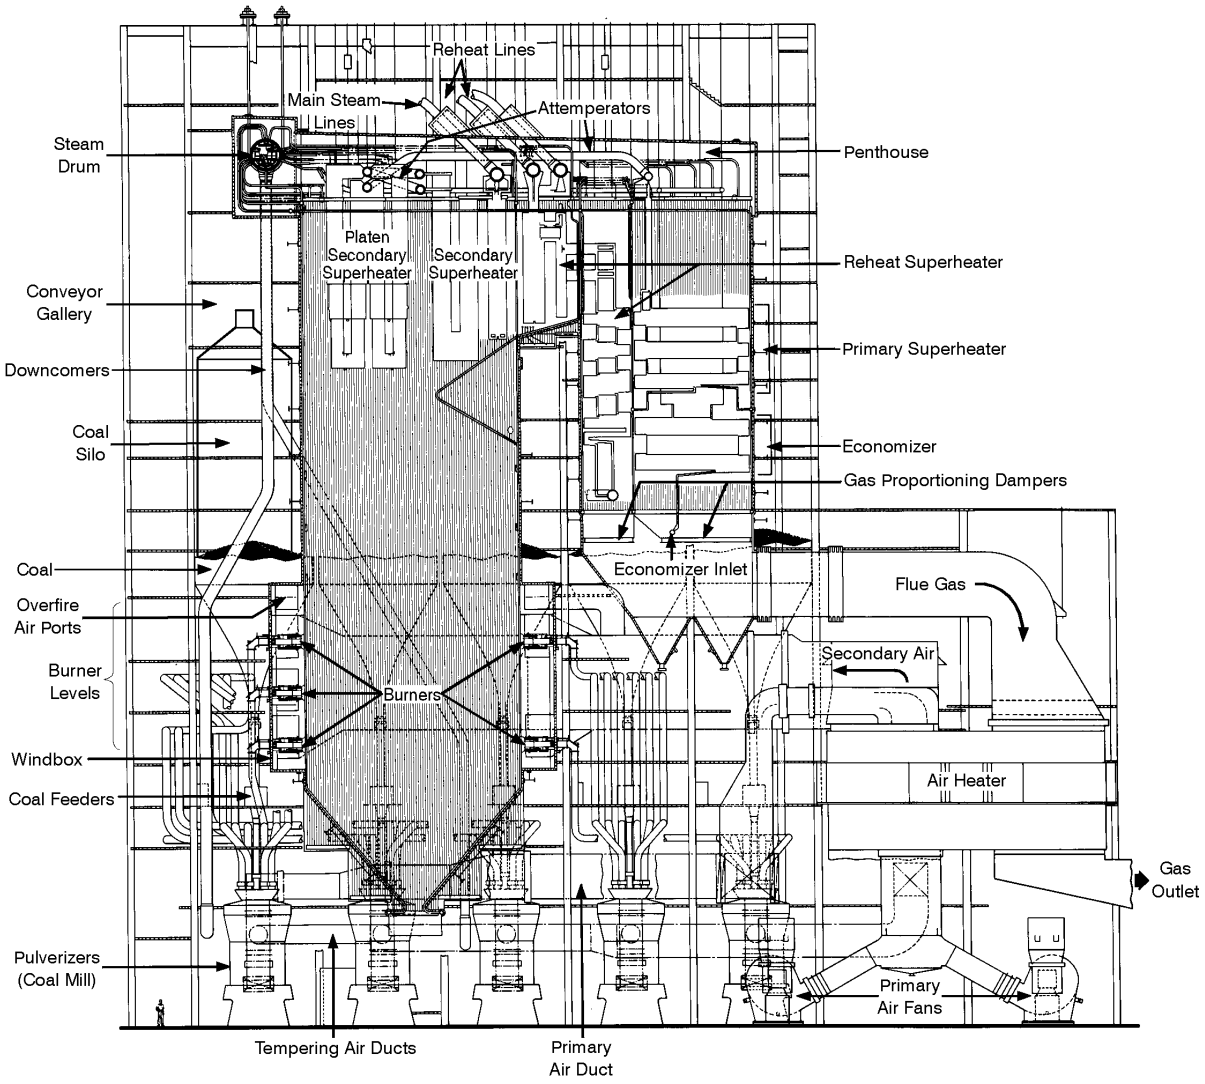

Fig. 1 Steam Generator Building
Courtesy Babcock and Wilcox

control an air-handling unit capable of providing adequate filtration, pressurization, and temperature control. The temperature control may be obtained with a chilled-water or direct-expansion coil with a remote condensing unit. An air-cooled condensing unit may be used if it is rated to match the surroundings.

Coal- and Ash-Handling Areas

Coal is typically stored on-site, either in piles or in storage structures. Material-handling equipment moves the coal to conveyors for transportation to preconditioning equipment (e.g., a crusher). The processed coal is conveyed to the steam generator building storage silos. Coal feed equipment regulates the supply of coal from the silos either to the burner or to final processing equipment such as pulverizing mills.

The coal-handling areas in the steam generator building that require special ventilation system consideration are the conveyor, silo, feeder, mill, and ash-handling areas.

Conveyor Areas. The primary concerns are dust control, outgassing from the coal, freezing of the coal and personnel access areas, and fire protection. Dust can be a concern due to the potential for environmental emission and also as a personnel and/or explosive hazard. Dust may be controlled by water-based spray systems or by air induction pickups at the point of generation. Some types of coal may outgas small quantities of methane, which could accumulate in the conveyor and storage structures.

Natural or forced ventilation must remove heat from conveyor motors, other equipment, and envelope loads. Ventilation air can also remove outgassed fumes. Generally, the ventilation requirements are low, on the order of 2 to 5 air changes per hour. If air entrainment dust collection equipment is used, provisions for makeup should be included in the design. If natural openings are not sufficient for makeup air, supply ventilation fans may need to be electrically interlocked to operate with the dust suppression/collection equipment. The makeup air may have to be heated if freeze protection is a design criterion. Unit heaters are generally used for spot heating. The unit heater should be specified to the hazard classification for the area it serves. Because coal dust can produce acids when wet, consideration should be give to specifying noncorrosive materials and coatings.

Silo and Feeder Areas. Coal is generally fully contained by feeders and silos, so no special ventilation is needed. Occasionally, the coal systems include an inert gas purge system for fire prevention. Ventilation may be needed for life safety dilution ventilation of purge gases.

Coal Mill Areas. Coal mills require large power motors for the grinding process. These motors may have their own ventilation system, or the motor heat may be rejected directly to the surrounding space.

The challenge for the ventilation system is to provide enough ventilation to remove the heat without creating high air velocities that blow the accumulated dust around. Blowing dust can pose health risks to operators and create a dust ignition hazard. While dust ignition air-to-dust ratios are possible, this area is generally not classified as hazardous. The dust ignition risk is managed by housekeeping, maintenance of the seals on the mill equipment, and other dust-control measures.

Forced supply ventilation is generally required for equipment cooling. Sidewall propeller fans work well if the mills are arranged near outside walls. Mills located in the interior of the building may require ducted supply air. Supply air velocities at the coal-handling equipment must be lower than the particulate entrainment velocity for the expected dust size. The maximum air velocity is established using the particle size distribution spectrum and the associated air settling velocities indicated in Figure 1 in Chapter 12 of the 1997 *ASHRAE Handbook—Fundamentals*.

Ash-Handling Areas. Ash is generated when coal or heavy fuel oil is burned. Fine ash particles carried by the flue gas from the top of the steam generator are called **fly ash**. Ash that accumulates as slag in the bottom of the steam generator is called **bottom ash**.

Ash-handling equipment generally demands no special HVAC system consideration. Although fly ash is captured in the flue gas stream by a baghouse or electrostatic precipitator, uncaptured (fugitive) fly ash can create problems in equipment mechanisms due to its abrasiveness. If fugitive fly ash is expected to be in the air, HVAC equipment in the ash-handling areas should include filters to capture the ash before it enters building areas.

Stack Effect

One of the considerations in the HVAC system design for a steam generator building is the stack effect caused by the buoyancy of the heated air. A 90 m tall steam generator building with −18°C outdoor air temperature and 38°C indoor air temperature may have 125 Pa (gage) negative internal pressure at ground level. This high level of negative pressure would cause abnormally large forces on doors, creating a hazard for operators.

Sources of Combustion Air

Large-draft fans supply the combustion air for the steam generator. A positive pressure steam generator is supplied by forced-draft fans, and a negative pressure steam generator uses induced-draft fans. A balanced-draft steam generator, typical for a larger unit, uses both forced- and induced-draft fans. Because the air is heated to furnace temperatures in the combustion process, part of the fuel energy is used to heat the air. The forced-draft fans on a large steam generator can supply 50 m^3/s or more to the combustion process. A significant amount of energy is needed to preheat the combustion air.

Two prevailing methods of preheating combustion air are used. One method is to draw the air in from outdoors and heat it via steam or hot water coils using energy directly from the power cycle.

Another method is to use the heat rejected from the steam generator surfaces to the building space to heat combustion air; this method provides energy savings over heating outdoor air. Temperatures in the higher levels of the generator building can be 38°C or higher. The heat recovery is accomplished by locating the intake to the draft fan high in the building. Although the potential for savings is large in a cold climate, the total effect on the building heating and ventilation systems should be evaluated. One effect is that drawing the air from the building makes the building pressure more negative; this increases infiltration and adds to the building heating system load, possibly offsetting the potential power cycle thermal efficiency advantage. The increase in negative pressure also contributes to the stack effect problems associated with negative pressure low in the building. The draft fan can also be used to supplement ventilation during warm outdoor conditions.

TURBINE GENERATOR BUILDING

As indicated in Figure 2, a turbine generator building usually includes a high-bay operating level, a deaerator mezzanine, and a suboperating level. Typically, the steam and combustion turbines and electric generators are located along the centerline of the building between operating level and suboperating level and are the major heat sources in the building. Deaerators are another significant heat contributor; the deaerator mezzanine is commonly open to the turbine operating level. Other room heat sources are steam, steam condensate and hot water piping, heat exchangers, steam valve stations and traps, motors, electric transformers, and other electrical equipment.

Local Control and Instrumentation Areas

Some power plants include a local turbine-generator control panel on the operating floor. Although one alternative is to provide an enclosure for the local control panel area of the turbine generator, an open arrangement may also be used. For the enclosed arrangement, the environmental requirements are the same as those given in the section on Main Control Center.

For an open arrangement, velocity cooling with conditioned air improves the operator's working environment. Because the area may be directly exposed to high-temperature surroundings, the recommended velocity of the conditioned air discharge is 1.5 to 3 m/s. The air distribution should be furnished with manually adjustable air deflectors for operator comfort. In addition, the control panel may need a separate cooling source.

Deaerator Mezzanine

The deaerator area may be ventilated or air conditioned. The ventilation source should be relatively free from dust. The HVAC system should provide the necessary cooling or ventilating capacity, adjusted for seasonal variations.

Bridge Crane Operating Rooms

Outside air entering the building is heated by the process heat, rises toward higher elevation, and is relieved through openings. The bridge crane operating room is as high as the roof beam and within the building exhaust airstream. If the outside air temperature is35°C, the crane operating room may be surrounded by 40°C or hotter air. Hence, the bridge crane operating room is normally furnished with a cooled air supply.

Because the bridge crane operating room moves around in the building during its operation, through-the-wall mounted air conditioners are commonly used.To simplify the electrical work, an additional power plug in the crane for the air conditioner should be provided by the crane supplier. Provisions for the cooling coil condensate drain should be included in the design.

Suboperating Level

The turbine generator is located on the operating floor, which is a large deck surface that is open to the turbine building roof. The deck may be 70% or more of the turbine building area. Below the operating level are one or more suboperating levels. Ventilation supply air should be provided to the suboperating levels and at the lower elevations of the operating floor. The air rising through the operating levels brings room heat to the roof area, where it is relieved through high-elevation openings or exhausted by PRVs.

The major heat sources in the suboperating level are high-temperature mechanical and piping systems. Other heat contributors

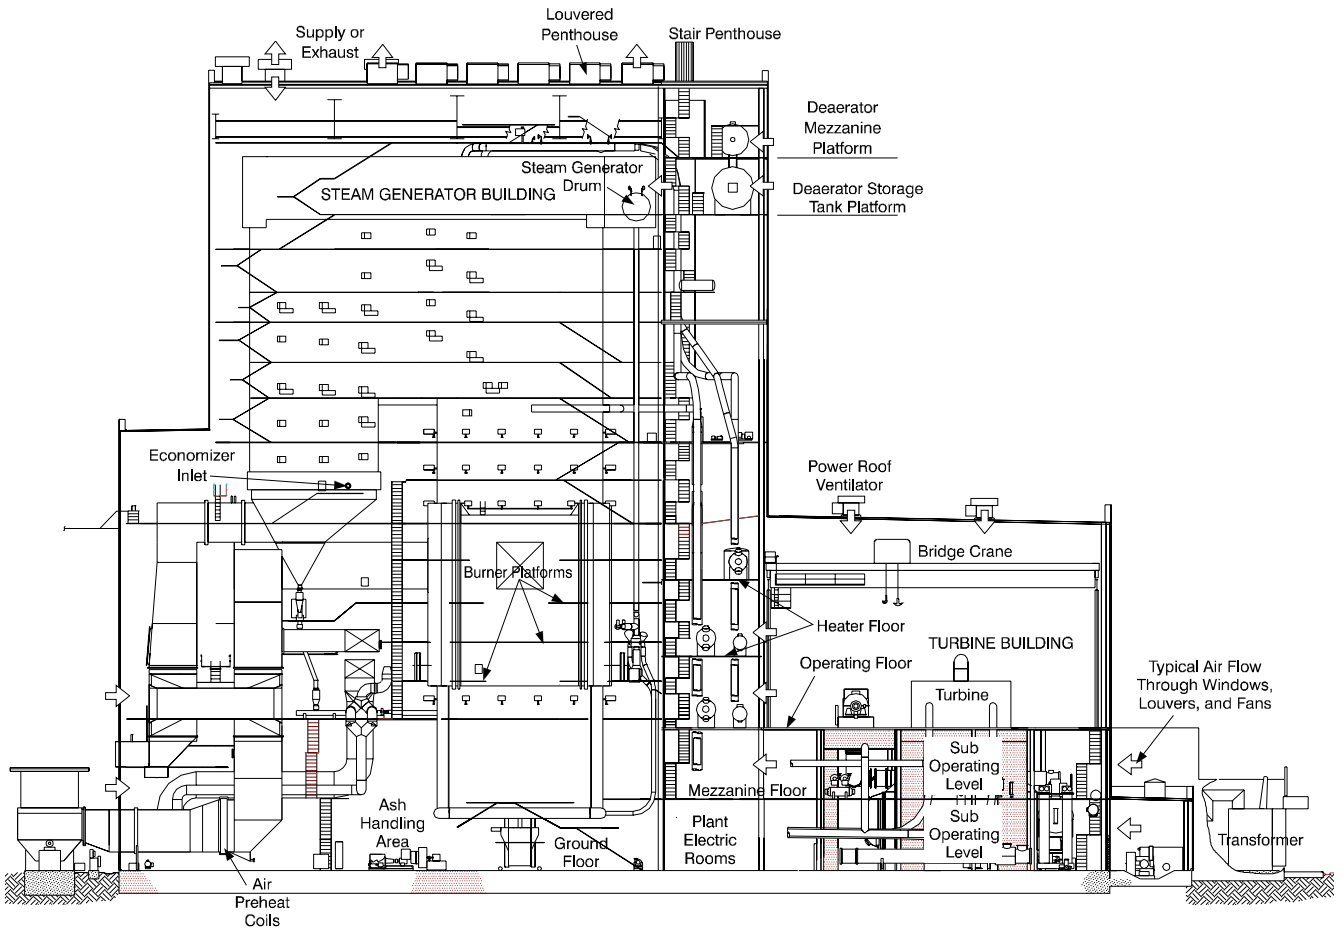

Fig. 2 Generation Building Arrangement
Courtesy Black & Veatch LLP

are electric transformer room exhaust, switchgear room exhaust, electric reactor room exhaust, electrical motor heat, etc. The electrical equipment exhaust heat in the turbine generator building is small compared to the heat emitted from mechanical and piping systems. Accordingly, ventilation air from the plant distribution electric room can generally be exhausted directly into the turbine building without ducting to the outside. Conditioned air from an air-conditioning system may be supplied to local instrumentation panel areas.

For plants in cold climates (temperatures below freezing), the engineer should consider spot heating and/or exterior door heated air curtains. Consideration should also be given to freeze protection of piping close to building walls because of the stack effect and wind-driven infiltration. This can increase local heating requirements at the building perimeter. This problem can be addressed by adding capacity to the installed heating systems or by providing mobile, temporary heating.

Electric Transformer Rooms

Transformer rooms are typically at a suboperating level between the turbine building and steam generator buildings. For the isolation of dust, the transformer rooms should not have inlet openings to the steam generator building.

The transformer room exhaust air temperature should not exceed the design limit of the transformers. Typically, air intake is from the turbine building suboperating floor level or from outdoors, and exhaust air discharges at the higher level of the transformer room toward the turbine building.

Plant Electrical Distribution Equipment and Switchgear/MCC Rooms

Air for the main station switchgear and motor control center (MCC) rooms should be relatively clean. Supply air from outdoors should be filtered with 30% efficiency air filters. Air can be relieved through louvers into the plant or to the outside.

A similar approach is used for the ventilation system for an electric reactor room. If the reactors have ducted connections for the exhausts, a removable section may be required so that the ducts can be disassembled when the reactor is lifted during maintenance.

COMBUSTION TURBINE AREAS

The heating and ventilation design issues unique to combustion turbines are combustion air intakes, ventilation of the equipment compartments, the high-temperature exhaust duct, fuel supply piping, inlet air cooling, and noise.

Airflows requirements associated with combustion air and separately ventilated compartments should be provided by the manufacturer and accommodated in the heating and ventilation system design.

High-temperature combustion turbine exhaust ductwork can create a significant heat load on the ventilation system. The duct should be insulated and arranged to allow air movement over its surfaces to minimize hot spots. Provisions should be made to isolate the hot duct wall and roof materials.

One method of addressing the high stack surface temperatures is the induction of room air into the stack to lower the exhaust

temperature. The induced air must be included in the heating and ventilation system design.

Systems delivering fuel gas through the building to the combustion turbine should be designed to prevent gas release. Minimum ventilation rates should provide dilution of gases at their expected design leakage and detection rates.

Combustion turbine power increases as inlet air temperature decreases due to the increased mass flow throughput. Several methods are available to cool the inlet air, including chilled-water coils and both direct and indirect evaporative cooling coils. These power cycle enhancements can be considered alone or in conjunction with thermal storage.

Noise from combustion turbines is generally managed by a combination of sound-attenuating enclosures over the turbine components and acoustical treatments on building ventilation openings.

MAIN CONTROL CENTER

The main control center usually comprises a control room, a battery room, a communication equipment room, electronic and electric control panel rooms, and associated administration areas.

Because the control center usually contains temperature-sensitive electronic equipment critical to plant operation, it is generally provided with redundant air-handling units and refrigeration equipment. A backup power supply may also be required. Passive components such as distribution ductwork and piping do not have to be duplicated. Controls should be designed so that the failure of a component common to both the primary and backup systems does not cause the failure of both systems. A manual changeover is a simple solution to this problem.

Control Rooms

The control room houses the computerized microprocessor, printer, electronic and emergency response controls, fire protection controls, communication and security systems, regional system networks, accessories, and relevant wiring and tubing systems.

An air-conditioning system typical for office occupancy, with features to meet overall design requirements for reliability and the specific environmental needs of the control equipment, is generally appropriate.

Battery Rooms

The optimum temperature for battery rooms balances battery life against battery performance. Temperatures higher than the optimum reduce battery life, while lower temperatures reduce battery performance. The typical optimum temperature for wet cell battery rooms is approximately 25°C.

Another consideration in battery room design is the hydrogen gas generated during the charging process. The amount of hydrogen generated depends on the charging current and the duration of the charging process. Hydrogen generation rates vary among the different types of batteries. The battery manufacturer should be contacted for pertinent design-related information, and the guidelines of National Fire Protection Association (NFPA) *Standard* 70, the *National Electrical Code*, should be followed. The recommended hydrogen concentration in the battery room is 2% or less of the room volume. When no battery design information is available, a general ventilation exhaust rate of 2 to 4 air changes per hour may be adequate for preventing the hydrogen concentration in the battery room from reaching explosive limits. If dilution ventilation air is provided, the room does not have to be rated as hazardous. Standard HVAC materials should be used, and in the unlikely event of a spill, the room and the ventilation equipment should be cleaned.

OIL STORAGE AND PUMP BUILDINGS

At a power plant, fuel oil may be the main source of energy for the steam generator, combustion turbine, or diesel generator. It may also be a backup or supplemental fuel. Coal-fueled plants usually use oil or gas as the initial light-off fuel or for operation of an auxiliary steam generator. Auxiliary steam generators provide initial plant warm-up and building heating.

Oil for combustion is generally a light oil such as No. 2 fuel oil or a heavy oil such as No. 6. Light oils can be pumped at normal temperatures, but heavy oils are highly viscous and may need to be heated for pumping. Oils are usually received by rail or truck, transported by pipeline, and stored in tanks.

Enclosures for pumps, valves, heat exchangers, and associated equipment should be heated and ventilated to remove heat and to dilute hydrocarbon fumes. Tank ventilation is an integral part of the tank and piping system design, which is separate from the enclosure ventilation design. Fuel oils are classified in NFPA *Standard* 30 as either combustible or flammable depending on their vapor pressure at the indoor design temperature. Flammable liquids are hazardous; combustible liquids are not.

The design of HVAC systems for areas containing combustible fuels involves following the ventilation principles for removal of heat and good air mixing. Ventilation rates should dilute fumes expected from the evaporation of spilled or leaking fuel, following ACGIH (1998) guidelines and material safety data sheets (MSDSs) provided by the material manufacturer. For fuel handling confined to piping systems, the expected leakage is nearly zero, so very low fresh air rates are required for ventilation—generally less than 1 air change per hour. If fuel is handled in open containers or hoses, higher rates are prudent.

If the fuel is flammable at temperatures expected in the room, NFPA *Standard* 30 and other safety and building codes should be followed. Electrical systems may need to be classified as hazardous.

COAL CRUSHER AND COAL TRANSPORTATION SYSTEM BUILDINGS

The coal-handling facilities at a power plant receive and prepare coal and then transport it from the initial delivery point to the burners. Intermediate steps in the process may include long- or short-term storage, cleaning, and crushing. Receipt may include barge, railcar, or truck unloading. Storage may be in piles on the ground, underground, or in barns or silos. On-site, the coal is handled by mobile equipment or conveyor systems.

Regardless of the specifics, the following general HVAC issues apply for the structures involved.

Potential for Dust Ignition Explosion

Most types of coal readily break down into dust particles when handled or conveyed. The dust can become fine enough and occur in the right particle size distribution and concentration to create a dust explosion. The design engineer should review and apply the referenced NFPA standards and guidelines to determine the dust ignition potential for each ventilation system application.

Ventilation of Conveyor and Crusher Motors in a Coal Dust Environment

Heat from motors and process equipment should be removed through ventilation. The options are to use ducted, ventilated motors or to ventilate the building enclosures. Ventilation in enclosures containing coal should keep the velocity below the entrainment velocities of the expected particle sizes. Figure 1 in Chapter 12 of the 1997 *ASHRAE Handbook—Fundamentals* has information on settling velocity. Generally, air should be mechanically exhausted to allow ventilation air to enter the building through louvers at low velocities.

Cooling or Ventilation of Electrical and Control Equipment

Electrical and control equipment may be located near coal piles or other coal-handling facilities. Air-conditioned control rooms should be pressurized with filtered outdoor air. Ventilated motor control or switchgear areas should also be pressurized with filtered air. Due to the high dust concentrations in coal yards, ordinary filter media have a short life; a solution is the use of inertial filters. For air-conditioned areas, the inertial filters can be followed by higher efficiency media filters.

For electrical equipment rooms adjacent to an area with the potential for a dust ignition explosion, NFPA *Standard* 496 should be followed. This standard recommends the flow of clean air away from the electrical equipment into the dusty area.

Ventilation of Methane Fumes

Methane and other hydrocarbons are present in the coal both as free gas in the cracks and voids and as adsorbents within the coal. Although most of the methane is released from the interstitial coal structure during the mining and handling process, some methane or other potentially flammable gases may remain in the coal. Thus, flammable concentrations of methane can accumulate when large amounts of coal are stored. The design engineer should identify the potential for methane accumulation when designing for structures associated with silos or coal storage buildings. At the mine or mine mouth, methane gas emission rates as high as 150 L/mg are possible. At locations removed from the mine mouth, the rate is usually less than 30 L/mg Dust collection air exhaust or natural ventilation is often sufficient to prevent the methane level from reaching the 1% explosion limit. The design engineer should apply guidelines from NFPA *Standards* 120, 123, 850, 8503, 8504, and 8505.

Underground Tunnels and Conveyors

Enclosed conveyors are generally of loose construction and require no ventilation. Smoke or gases in underground conveyor tunnels, hoppers, or conveyor transfer points could cause a personnel safety hazard. Ventilation systems should be coordinated with escape route passages to move fresh air from the direction of the egress. Ventilation rates in the range of 2 to 5 air changes per hour are generally appropriate for normal system operation.

Makeup of Dust Collection Air

Coal dust can be controlled by high-velocity air pickup at locations where coal is transferred. The volumetric airflow associated with these pickup points may be sufficient to meet the ventilation requirements. Air inlets must be provided. If additional ventilation is needed, the ventilation fan must coordinate with the dust collection system. For heated structures, makeup air may need to be heated.

HEATING/COOLING SYSTEMS

Selection of the heating and cooling systems in a power plant depends on several variables, including the geographical location and orientation of the plant and the type of fuel used. Most plants are ventilated with outdoor air, but it is customary in hot climates to air condition many plant areas. Steam, hot water, gas, and electricity are alternative heating methods to be evaluated for the most economical choice. Electricity is the primary energy source for general-purpose cooling of the various areas of the plant. Areas such as the main control room, office areas, and electrical switchgear/MCC rooms are air conditioned for continuous human occupancy or for maintaining the operability of the electrical equipment and controls.

Cooling

The cooling source may be either a centrally located chilled-water system providing chilled water to various area coolers or individual direct-expansion area coolers with either air-cooled or water-cooled condensing units. Selection depends on the layout of the various areas to be cooled and the comparative costs of the two options. The condensing system of the water chiller may be either air cooled or water cooled with available water from the plant service water system. Air-cooled chillers are used when the air near the proposed chiller location is moderately clean and no fly ash or coal dust problem is anticipated. For a water-cooled system, a closed-loop cooling tower is sometimes used if service water is poor or unavailable (e.g., during start-up or plant outages). To protect the chillers from the fouling and corrosion effects of the service water, a heat exchanger is sometimes used between the chiller condenser and the service water source. In a power plant with several operating units and individual self-supporting chilled-water systems, the chilled-water systems of each unit are sometimes interconnected to provide backup and redundancy.

Heating

Heating in various areas of the power plant is usually provided by electric, steam, or hot water unit heaters or heating coils in air-handling units. In a hot water distribution system, glycol is usually added into the system for protection against freezing. Because the stack effect in the building induces large quantities of infiltration air, heating requirements in the lower levels of the steam generator building may increase when the steam generator is operating. Pressurization fans directing cooler, outside air into the warmer upper elevations of the plant can offset this infiltration. Also, the design engineer may evaluate redistribution of hotter air from higher to lower elevations.

An alternative to heating the open areas of the plant is to use pipeline heat tracing and spot heating at personnel workstations. For this approach, the design engineer should consider all components that may require heat tracing, such as instrument lines, small and large pipes, traps, pumps, tanks and other surfaces that may be subject to the freezing temperatures. Often the large number of components and surfaces to be heat traced and insulated makes this impractical.

Laboratories 25.7
Decommissioning of Nuclear Facilities 25.8
Codes and Standards 25.8

THE HVAC requirements for facilities using radioactive materials are discussed in this chapter. Such facilities include nuclear power plants, fuel fabrication and processing plants, plutonium processing plants, hospitals, corporate and academic research facilities, and other facilities housing nuclear operations or materials. The information presented here should serve as a guide; however, careful and individual analysis of each facility is required.

BASIC TECHNOLOGY

Criticality, radiation fields, and regulation are three issues that are more important in the design of nuclear-related HVAC systems than in that of other special HVAC systems.

Criticality. Criticality considerations are unique to nuclear facilities. Criticality is the condition reached when the chain reaction of fissionable material, which produces extreme radiation and heat, becomes self-sustaining. Unexpected or uncontrolled conditions of criticality must be prevented at all cost. In the United States, only a limited number of facilities—including fuel plants, weapons facilities, and some national laboratories—handle **special nuclear material** (SNM) subject to criticality concerns.

Radiation Fields. Radiation fields are found in all facilities using nuclear materials. They pose problems of material degradation and personnel exposure. Although material degradation is usually addressed by regulation, it must be considered in all designs. The personnel exposure hazard is more difficult to measure than the amount of material degradation because a radiation field cannot be detected without special instruments. It is the responsibility of the designer and of the end user to monitor radiation fields and limit personnel exposure.

Regulation. In the United States, the Department of Energy (DOE) regulates weapons-related facilities and national laboratories; the Nuclear Regulatory Commission (NRC) controls civil, industrial, and power facilities. Further complicating the issue are other government regulations at the local, state, and federal levels. For example, meeting an NRC requirement does not relieve the designer or operator of the responsibility of meeting Occupational Safety and Health Administration (OSHA) requirements. The design of an HVAC system to be used near radioactive materials must follow all guidelines set by these agencies and by the local, state, and federal governments. For facilities outside the United States, the specific national and local regulations apply.

As Low as Reasonably Achievable

As low as reasonably achievable (ALARA) means that all aspects of a nuclear facility are designed to limit worker exposure to the minimum amount of radiation that is reasonably achievable. This refers not to meeting legal requirements, but rather to attaining the lowest cost-effective below-legal levels.

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

Design

HVAC requirements for a facility using or associated with radioactive materials depend on the type of facility and the specific service required. The following are design considerations:

- Physical layout of the HVAC system that minimizes the accumulation of material within piping and ductwork
- Control of the system so that portions can be safely shut down for maintenance and testing or in the case of any event, accident, or natural catastrophe that may cause radioactivity to be released
- Modular design for facilities that change operations regularly
- Preservation of confinement integrity to limit the spread of radioactive contamination in the physical plant and surrounding areas

The design basis in most nuclear facilities requires that safety-class systems and their components have active control during and after any event, accident, or natural catastrophe that causes radioactivity to be released.

Normal or Power Design Basis

The normal or power design basis for nuclear power plants covers normal plant operation, including normal operation mode and normal shutdown mode. This design basis imposes no requirements more stringent than those specified for standard indoor conditions.

Safety Design Basis

The safety design basis establishes special requirements necessary for a safe work environment and public protection from exposure to radiation. Any system designated **essential** or **safety-class** must mitigate the effect of any event, accident, or natural catastrophe that may cause the release of radioactivity into the surroundings or the plant atmosphere. These safety systems must be operative at all times. Safety analysis reports (SARs) determine which components must function during and after a **design basis accident** (DBA) or the simultaneous occurrence of such events as a safe shutdown earthquake (SSE), a tornado, a loss of coolant accident (LOCA), and loss of off-site electrical power (LOEP). Non-safety-related equipment should not adversely affect safety-related equipment.

System Redundancy. Systems important to safety must be redundant so that their function is performed even if a component of one system fails. Such a failure should not cause a failure in the backup system. For additional redundancy requirements, refer to the section on Nuclear Regulatory Commission Facilities.

Seismic Qualification. All safety-class components, including equipment, pipe, duct, and conduit, must be seismically qualified by testing or calculation to withstand and perform under the shock and vibration caused by an SSE or an operating basis earthquake (the largest earthquake postulated for the region). This qualification also covers any amplification by the building structure. In addition, any HVAC component, the failure of which could jeopardize the essential function of a safety-related component, must be seismically qualified or restrained to prevent such failure.

Environmental Qualification. Safety-class components must be environmentally qualified; that is, the useful life of the component in the environment in which it operates must be determined through a program of accelerated aging. Environmental factors such as temperature, humidity, pressure, acidity, and accumulated radioactivity must be considered.

Quality Assurance. All designs and components of safety-class systems must comply with the requirements of a quality assurance (QA) program for design control, inspection, documentation, and traceability of material. Refer to Appendix B of Title 10 of the *Code of Federal Regulations*, Part 50 (10 CFR 50) or ASME *Standard* NQA-1 for quality assurance program requirements.

Emergency Power. All safety-class systems must have a backup power source such as an emergency diesel generator.

Outdoor Conditions

Chapters 26 and 29 of the 1997 *ASHRAE Handbook—Fundamentals*, the National Oceanic and Atmospheric Administration, and site meteorology can provide information on outdoor conditions, temperature, humidity, solar load, altitude, and wind. DOE *Order* 6430.1A may specify outdoor conditions.

Nuclear facilities generally consist of heavy structures having high thermal inertia. Time lag should be considered in determining solar loads. For some applications, such as diesel generator buildings or safety-related pumphouses in nuclear power plants, 24 h averages suffice.

Indoor Conditions

Indoor temperatures are dictated by occupancy, equipment or process requirements, and personnel activities. HVAC system temperatures are dictated by the environmental qualification of the safety-class equipment located in the space and by ambient conditions during the different operating modes of the equipment.

Indoor Pressures

Where control of airflow pattern is required, a specific pressure relative to the outside atmosphere or to adjacent areas must be maintained. For process facilities having pressure zones, the pressure relationships are specified in the section on Confinement Systems.

In facilities where zoning is different from that in process facilities, and in cases where any airborne radioactivity must not spread to rooms within the same zone, this airborne radioactivity must be controlled by airflow.

Airborne Radioactivity

The level of airborne radioactivity within a facility and the amount released to the surroundings must be controlled to meet the requirements of DOE *Orders* 5400.5 and N 441.1, 10 CFR 20, 10 CFR 50, 10 CFR 61, and 10 CFR 100, or equivalent national regulations of the site country.

Tornado/Wind Protection

Protection from tornados and the objects or missiles launched by tornados or design basis wind is normally required to prevent the release of radioactive material to the atmosphere. A tornado passing over a facility causes a sharp drop in ambient pressure. If exposed to this transient pressure, ducts and filter housings could collapse because the pressure inside the structure would still be that of the environment prior to the pressure drop. Protection is usually provided by tornado dampers and missile barriers in all appropriate openings to the outside. Tornado dampers are heavy-duty, low-leakage dampers designed for pressure differences in excess of 20 kPa. They are normally considered safety-class and are environmentally and seismically qualified.

Fire Protection

Fire protection for the HVAC and filtration systems must comply with the applicable requirements of Appendix R of 10 CFR 50 and NFPA, UL, and ANSI or equivalent standards. Design criteria should be developed for all building fire protection systems, including secondary sources, filter plenum protection, fire dampers, and detection/suppression systems. Fire protection systems may consist of a combination of building sprays, hoses and standpipes, and gaseous or foam suppression. The type of fire postulated in the SAR determines which kind of system is used.

Secondary sources may include one or more of the following: (1) a water tower with a diesel-powered or electric water pump, (2) a pressurized water tank, or (3) a second water main. These systems are not unique to nuclear facilities.

A requirement specific to nuclear facilities is protection of the filter plenums and the ventilation ductwork. Water sprays (window nozzles, fog nozzles, or standard dry pipe/wet pipe system spray heads) are usually used to protect the filters in filter plenums. In the case of metal filters, fire protection equipment may also be used for cleansing. Sprinkler location, system balancing, and spray patterns should be designed for maximum effect. Flow requirements should be consistent with the design criteria for the facility. Performance of the room ventilation system in response to fire scenarios must be analyzed to determine the operational requirements and optimum location of fire dampers. Various codes may limit alternatives.

Heat detectors and fire suppression systems should be considered for special equipment such as glove boxes. Application of the two systems in combination allows the shutdown of one system at a time for repairs, modifications, or maintenance. Smoke control criteria can be found in NFPA *Standards* 801 and 901.

Control Room Habitability Zone

The HVAC system in a control room is a safety-related system that must fulfill the following requirements during all normal and postulated accident conditions:

1. Maintain conditions comfortable to personnel, and ensure the continuous functioning of control room equipment.
2. Protect personnel from exposure to airborne radioactivity or toxic chemicals potentially present in the outside atmosphere or surrounding plant areas.
3. Protect personnel from the effects of breaks in high-energy lines in the surrounding plant areas.
4. Protect personnel from combustion products emitted from onsite fires.

Filtration

HVAC filtration systems can be designed to remove either radioactive particles or radioactive gaseous iodine from the airstream. They filter potentially contaminated exhaust air prior to discharge to the environment and may also filter potentially contaminated makeup air for power plant control rooms and technical support centers.

The composition of the filter train is dictated by the type and concentration of the contaminant, the process air conditions, and the filtration levels required by the applicable regulations (e.g., RG 1.52, RG 1.140, ASME AG-1, ASME N509, 10 CFR 20, and 10 CFR 100). Filter trains may consist of one or more of the following components: prefilters, high-efficiency particulate air (HEPA) filters, charcoal filters (adsorbers), sand filters, heaters, and demisters.

Dust Filters/Prefilters. Dust filters are selected for the efficiency required by the particular application. High-efficiency dust filters are often used as prefilters for the special filters listed below to prevent them from being loaded with atmospheric dust and to minimize replacement costs.

HEPA Filters. Nuclear HEPA filters are used where there is a risk of particulate airborne radioactivity. The construction and

preuse quality assurance testing of HEPA filters is specified in DOE *Standards* NE F 3-43 and 3020. Filter performance requirements are based on penetration at a specified airflow and static pressure. For a 0.3 µm particle, the penetration at rated airflow must not exceed 0.03%. The construction and QA testing of HEPA filters for use in nuclear power plants is specified in ASME *Standards* N509, N510, and AG-1. HEPA filters are in-place tested and inspected when first installed, and then tested every 12 to 18 months thereafter. One or both of the following two methods may be used for in-place testing of a stage of filtration: (1) mass flow testing of the stage as a whole or (2) testing of the individual filters and frame that make up the stage. In both preuse and in-place tests, an approved challenge agent such as the aerosol dioctyl phthalate (DOP) or a similar agent must be used.

Sand Filters. Sand filters consist of multiple beds of sand and gravel through which air is drawn. The air enters an inlet tunnel that runs the entire length of the filter. Smaller cross-sectional laterals running perpendicular to the inlet tunnel distribute the air across the base of the sand. The air rises through several layers of various sizes of sand and gravel, typically at a rate of 25 mm/s. It is then collected in the outlet tunnel for discharge to the atmosphere.

Charcoal Filters. Activated charcoal adsorbers are used mainly to remove radioactive iodine, which is a vapor or gas. Bed depths are typically 50 or 100 mm but may be deeper. These filters have an efficiency of 99.9% for elemental iodine and 95 to 99% for organic iodine. Charcoal filters lose efficiency rapidly as the relative humidity increases. They are preceded by a heating element to keep the relative humidity of the entering air below 70%.

To control the argon content in the primary coolant, argon is adsorbed on charcoal at extremely low (cryogenic) temperatures. In a high-temperature gas-cooled reactor or in the off-gas system of a boiling water reactor, helium is similarly adsorbed.

Heaters. Electric heating coils and/or demisters may be used to meet the relative humidity conditions requisite for charcoal filters. For safety-class systems, electric heating coils should be connected to the emergency power supply. Interlocks should be provided to prevent heater operation when the exhaust fan is deenergized.

Demisters (Mist Eliminators). Demisters are required to protect HEPA and charcoal filters if entrained moisture droplets are expected in the airstream. They should be fire resistant.

DEPARTMENT OF ENERGY FACILITIES

Nonreactor nuclear HVAC systems must be designed in accordance with DOE *Order* 6430.1A. Critical items and systems in plutonium processing facilities are designed to confine radioactive materials under both normal and DBA conditions, as required by 10 CFR 100.

CONFINEMENT SYSTEMS

Zoning

Typical process facility confinement systems are shown in Figure 1. Process facilities comprise several zones.

Primary Confinement Zone. This zone includes the interior of the hot cell, canyon, glove box, or other means of containing radioactive material. Containment must prevent the spread of radioactivity within or from the building under both normal conditions and upset conditions up to and including a facility DBA. Complete isolation from neighboring facilities is necessary. Multistage HEPA and/or sand filtration of the exhaust is required

Secondary Confinement Zone. This zone is bounded by the walls, floors, roofs, and associated ventilation exhaust systems of the cell or enclosure surrounding the primary confinement zone. Except for glove box operations, this zone is usually unoccupied.

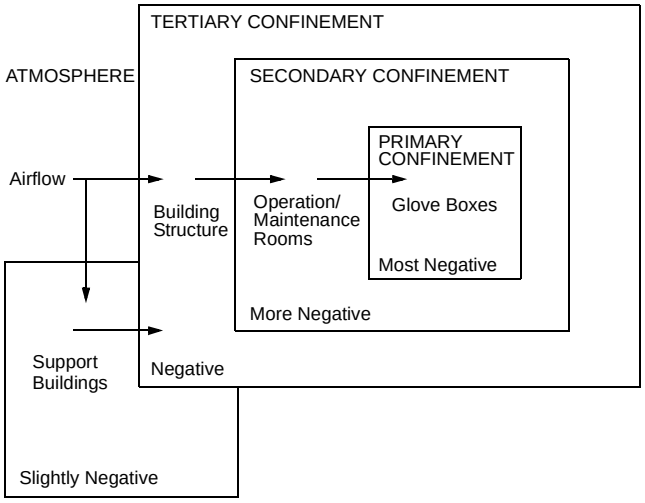

Fig. 1 Typical Process Facility Confinement Categories

Tertiary Confinement Zone. This zone is bounded by the walls, floors, roofs, and associated ventilation exhaust systems of the facility. They provide a final barrier against the release of hazardous material to the environment. Radiation monitoring may be required at exit points.

Uncontaminated Zone. This zone includes offices and cold shop areas.

Air Locks

Air locks in nuclear facilities are used as safety devices to maintain a negative differential pressure when a confinement zone is accessed. They are used for placing items in primary confinement areas and for personnel entry into secondary and tertiary confinement areas. Administrative controls ensure proper operation of the air lock doors.

There are three methods of ventilating personnel air locks (ventilated vestibules):

1. The clean conditioned supply (CCS) air method, where the air lock is at positive pressure with respect to the adjacent zones. For this method to be effective, the air lock must remain uncontaminated at all times.
2. The flow-through ventilation (FTV) air method, where no conditioned air is supplied to the air lock and the air lock stays at negative pressure with respect to the less contaminated zone.
3. The combined ventilation (CV) air method, which is a combination of the CCS and FTV methods. Testing has shown that this is the most effective method, when properly designed.

Zone Pressure Control

Negative static pressure increases (becomes more negative) from the uncontaminated zone to the primary confinement zone, causing any air leakage to be inward, toward areas of higher potential contamination. All zones should be maintained negative with respect to atmospheric pressure. Zone pressure control cannot be achieved through the ventilation system alone; confinement barrier construction must meet all applicable specifications.

Differential Pressures

Differential pressures help ensure that air flows in the proper direction in the event of a breach in a confinement zone barrier. The design engineer must incorporate the desired magnitudes of the differential pressures into the design early to avoid later operational problems. These magnitudes are normally specified in the design

basis document of the SAR. The following are approximate values for differential pressures between the three confinement zones.

Primary Confinement. With respect to the secondary confinement area, air-ventilated glove boxes are typically maintained at pressures of –175 to –250 Pa, inert gas glove boxes at –175 to –375 Pa, and canyons and cells at a minimum of –250 Pa.

Secondary Confinement. Differential pressures of –7 to –37 Pa with respect to the tertiary confinement area are typical.

Tertiary Confinement. Differential pressures of –2 to –37 Pa with respect to the atmosphere are typical.

VENTILATION

Ventilation systems are designed to confine radioactive materials under normal and DBA conditions and to limit radioactive discharges to the required minimum. They ensure that airflows are, under all normal conditions, toward areas (zones) of progressively higher potential radioactive contamination. Air-handling equipment should be sized conservatively so that upsets in the airflow balance do not cause the airflow to reverse direction. Examples of upsets include improper use of an air lock, a credible breach in the confinement barrier, or excessive loading of HEPA filters.

HEPA filters at the ventilation inlets in all primary confinement zone barriers prevent movement of contamination toward zones of lower potential contamination in the event of an airflow reversal. Ventilation system balancing helps ensure that the building air pressure is always negative with respect to the outside atmosphere.

Recirculating refers to the reuse of air in a particular zone or area. Room air recirculated from a space or zone may be returned to the primary air-handling unit for reconditioning and then, with the approval of health personnel, be returned to the same space (zone) or to a zone of greater potential contamination. All air recirculated from secondary and tertiary zones must be HEPA-filtered prior to reintroduction to the same space. Recirculating air is not permitted in primary confinement areas, except those with inert atmospheres.

A safety analysis is necessary to establish minimum acceptable response requirements for the ventilation system and its components, instruments, and controls under normal, abnormal, and accident conditions.

Analysis determines the number of exhaust filtration stages required in different areas of the facility to limit (in conformance with the applicable standards, policies, and guidelines) the amount of radioactive or toxic material released to the environment during normal and accident conditions. Consult DOE *Order* 6430.1A for air-cleaning system criteria.

Ventilation Requirements

A partial recirculating ventilation system may be considered for economic reasons. However, it must be designed to prevent contaminated exhaust from entering the room air-recirculating systems.

The exhaust system is designed to (1) clean radioactive contamination from the discharge air, (2) safely handle combustion products, and (3) maintain the building under negative pressure relative to the outside.

Provisions may be made for independent shutdown of ventilation systems or isolation of portions of the systems to facilitate operations, filter change, maintenance, or emergency procedures such as fire fighting. All possible effects of partial shutdown on the airflows in interfacing ventilation systems should be considered. Positive means must be provided to control the backflow of air that might transport contamination. A HEPA filter installed at the interface between the enclosure and the ventilation system minimizes contamination in the ductwork; a prefilter reduces HEPA filter loading. These HEPA filters should not be considered the first stage of an airborne contamination cleaning system.

Ventilation Systems

The following is a partial list of elements that may be included in the overall air filtration and air-conditioning system:

- Air-sampling devices
- Carbon bed adsorbers
- Prefilters and absorption, HEPA, sand, and glass fiber filters
- Scrubbers
- Demisters
- Process vessel vent systems
- Condensers
- Distribution baffles
- Fire suppression systems
- Fire and smoke dampers
- Exhaust stacks
- Fans
- Coils
- Heat removal systems
- Pressure- and flow-measuring devices
- Duct test ports
- Radiation-measuring devices
- Critically safe drain systems
- Tornado dampers

The ventilation system and associated fire suppression system are designed for fail-safe operation. The ventilation system is equipped with alarms and instruments that report and record its behavior through readouts in control areas and utility service areas.

Control Systems

Control systems for HVAC systems in nuclear facilities have some unique safety-related features. Because the exhaust system is to remain in operation during both normal and accident-related conditions, redundancy in the form of standby fans is often provided. These standby fans and their associated isolation dampers energize automatically upon a set reduction in either airflow rate or specific location pressure, as applicable. For DOE facilities, maintaining exhaust airflow is important, so fire dampers are excluded from all potentially contaminated exhaust ducts.

Pressure control in the facility interior maintains zones of increasing negative pressure in areas of increasing contamination potential. Care must be taken to prevent windy conditions from unduly effecting the atmospheric control reference. Pulsations can cause the pressure control system to oscillate strongly, resulting in potential reversal of relative pressures. One alternative is to use a variety of balancing and barometric dampers to establish an air balance at the desired differential pressures, lock the dampers in place, and then control the exhaust air to a constant flow rate.

Air and Gaseous Effluents Containing Radioactivity

Air and all other gaseous effluents are exhausted through a ventilation system designed to remove radioactive particulates. Exhaust ducts or stacks located downstream of final filtration that may contain radioactive contaminants should have two monitors, one a continuous air monitor (CAM) and the other a fixed sampler. These monitors may be a combination unit. Exhaust stacks from nuclear facilities are usually equipped with an isokinetic sampling system that relies on a relatively constant airflow rate. The isokinetic sensing probe is a symmetrically arranged series of pickup tubes connected through sweeping bends to a common tube, usually stainless steel, that leads to a nearby CAM. Typically, an exhaust system flow controller modulates the exhaust fan inlet dampers or motor speed to hold the exhaust airflow rate steady while the HEPA filters load.

Continuous air monitors can also be located in specific ducts where a potential for radiological contamination has been detected. These CAMs are generally placed beyond the final stage of HEPA

filtration, as specified in ANSI *Standard* N13.1. Each monitoring system is connected to an emergency power supply.

The following are design considerations for CAM systems:

- Maintain fully developed turbulent flow near isokinetic sampler.
- For accurate CAM operation, heat tracing on the sampling air tubing may be required.
- Keep the ratio of the sample airflow rate to the total discharge airflow rate constant.

NUCLEAR REGULATORY COMMISSION FACILITIES

NUCLEAR POWER PLANTS

The two kinds of commercial light-water power reactors used in the United States today are the **pressurized water reactor** (PWR) and the **boiling water reactor** (BWR). For both types, the main objective of the HVAC systems, in addition to ensuring personnel comfort and reliable equipment operation, is protecting operating personnel and the general public from airborne radioactive contamination during all normal and emergency modes of plant operation. 10 CFR 20 sets forth the requirements for keeping radiation exposure as low as reasonably achievable (ALARA). The ALARA concept is the design objective of the HVAC system. In no case is the radiological dose allowed to exceed the limits as defined in 10 CFR 50 and 10 CFR 100.

The NRC has developed **regulatory guides** (RGs) that delineate techniques of evaluating specific problems and provide guidance to licensed applicants concerning information needed by the NRC for its review of the facility. Four regulatory guides that relate directly to HVAC system design are RG 1.52, RG 1.78, RG 1.95, and RG 1.140. Deviations from RG criteria must be justified by the owner and approved by the NRC.

The design of the HVAC systems for a nuclear power generating station must ultimately be approved by the NRC staff in accordance with Appendix A of 10 CFR 50. The NRC developed **standard review plans** (SRPs) as part of *Regulatory Report* NUREG-0800 to provide an orderly and thorough review. The SRP provides a good basis or checklist for the preparation of a **safety analysis report** (SAR). The **safety review plan** is based primarily on the information provided by an applicant in an SAR as required by Section 50.34 of 10 CFR 50. Technical specifications for nuclear power plant systems are developed by the owner and approved by the NRC as outlined in Section 50.36 of 10 CFR 50. Technical specifications define safety limits, limiting conditions for operation, and surveillance requirements for all systems important to plant safety.

Minimum requirements for the performance, design, construction, acceptance testing, and quality assurance of equipment used in safety-related air and gas treatment systems in nuclear facilities are found in ASME *Standard* AG-1.

PRESSURIZED WATER REACTORS

Reactor Containment Building

The containment building houses the reactor in a nuclear power plant. The temperature and humidity conditions are dictated by the **nuclear steam supply system** (NSSS). These conditions are generally specified for three modes of operation: normal operation, refueling operation, and loss of coolant accident (LOCA) condition. General design requirements are contained in ANS *Standard* 56.6.

Normal Operating Condition. Nuclear steam supply system temperature and humidity requirements are specified by the NSSS supplier. Some power plants require recirculation filtration trains in the containment building to control the level of airborne radioactivity. Cooling is provided by a reactor containment cooling system.

Refueling Condition. The maximum allowable temperature during refueling is determined by the refueling personnel. Because they work in protective clothing, their activities are slowed by discomfort, and the refueling outage is prolonged. Cooling can be by normal cooling units because the cooling load is low when the reactor is shut down. Ventilation with outdoor air is necessary.

Loss of Coolant Accident Condition. In the event of a LOCA (breakage of the primary cooling loop), circulating water at high pressure and temperature flashes and fills the containment building with radioactive steam. The major source of radioactivity is iodine in the water. The primary measures taken are directed at reducing the pressure in the containment building and lowering the amount of radioactive products in the containment atmosphere. Pressure is reduced by the reactor containment cooling units and/or sprays, which cool the atmosphere and condense the steam.

Containment Cooling. The following systems are typical for containment cooling:

Reactor containment coolers. These units remove most of the heat load. Distribution of the air supply depends on the containment layout and the location of the major heat sources.

Reactor cavity air-handling units or fans. These units are usually transfer fans without coils that provide cool air to the reactor cavity.

Control rod or control element drive mechanism (CRDM or CEDM) air-handling units. The CRDM and CEDM are usually cooled by induced-draft using exhaust fans. Because the flow rates, pressure drops, and heat loads are generally high, the air should be cooled before it is returned to the containment atmosphere.

Essential reactor containment cooling units. The containment air-cooling system, or a part of it, is normally designed to provide cooling after a postulated accident. The system must be able to perform at high temperature, pressure, humidity, and levels of radioactivity. Cooling coils are provided with essential service water.

System design must accommodate both normal and accident conditions. The ductwork must be able to endure the rapid pressure buildup associated with accident conditions, and fan motors must be sized to handle the high-density air.

Radioactivity Control. Airborne radioactivity is controlled by the following means:

Essential containment air filtration units. Some older power plants rely on redundant filter units powered by two Class 1E buses to reduce the amount of post-LOCA airborne radioactivity. The typical system consists of a demister, a heater, a HEPA filter bank, and a charcoal adsorber, possibly followed by a second filter. The electric heater is designed to reduce the relative humidity from 100% to less than 70% at the design inlet air temperature. All the components must be designed and manufactured to meet the requirements of a LOCA environment.

In the case of a LOCA and the subsequent operation of the filter train, the charcoal becomes loaded with radioactive iodine such that the decay heat could cause the charcoal to self-ignite if the airflow stops. If the primary fan stops, a secondary fan maintains a minimum airflow through the charcoal bed to remove the heat generated by the radioactive decay. The decay heat fan is powered by a Class 1E power supply. The filtration units are located inside the containment.

Containment power access purge or minipurge. Ventilation is needed during normal operation, when the reactor is under pressure, to control containment pressure or the level of airborne radioactivity within the containment. The maximum opening size allowed in the containment boundary during normal operation is 200 mm.

The system consists of a supply fan, double containment isolation valves in each of the containment wall penetrations (supply and exhaust), and an exhaust filtration unit with a fan. The typical filtration unit contains a HEPA filter and a charcoal adsorber, possibly followed by a second filter.

This system should not be connected to any duct system inside the containment. It should include a debris screen within the containment over the inlet and outlet ducts, so that the containment isolation valves can close even if blocked by debris or collapsed ducts.

Containment refueling purge. Ventilation is required to control the level of airborne radioactivity during refueling. Because the reactor is not under pressure during refueling, there are no restrictions on the size of the penetrations through the containment boundary. Large openings of 1 to 1.2 m, each protected by double containment isolation valves, may be provided. The required ventilation rate is typically based on 1 air change per hour.

The system consists of a supply air-handling unit, double containment isolation valves at each supply and exhaust containment penetration, and an exhaust fan. Filters are recommended.

Containment combustible gas control. In the case of a LOCA, when a strong solution of sodium hydroxide or boric acid is sprayed into the containment, various metals react and produce hydrogen. Also, if some of the fuel rods are not covered with water, the fuel rod cladding can react with steam at elevated temperatures to release hydrogen into the containment. Therefore, redundant hydrogen recombiners are needed to remove the air from the containment atmosphere, recombine the hydrogen with the oxygen, and return the air to the containment. The recombiners may be backed up by special exhaust filtration trains.

BOILING WATER REACTORS

Primary Containment

The boiling water reactor (BWR) primary containment is a low-leakage, pressure-retaining structure that surrounds the reactor pressure vessel and related piping. Also known as the **drywell**, it is designed to withstand, with minimum leakage, the high temperature and pressure caused by a major break in the reactor coolant line. General design requirements are in ANS *Standard* 56.7.

The primary containment HVAC system consists of recirculating cooler units. It normally recirculates and cools the primary containment air to maintain the environmental conditions specified by the NSSS supplier. In an accident, the system performs the safety-related function of recirculating the air to prevent stratification of any hydrogen that may be generated. The cooling function may or may not be safety related, depending on the specific plant design.

Temperature problems have been experienced in many BWR primary containments due to temperature stratification and underestimation of heat loads. The ductwork should adequately mix the air to prevent stratification. Heat load calculations should include a safety factor sufficient to allow for deficiencies in insulation installation. In addition, a temperature monitoring system should be installed in the primary containment to ensure that bulk average temperature limits are not exceeded.

Reactor Building

The reactor building completely encloses the primary containment, auxiliary equipment, and refueling area. Under normal conditions, the reactor building HVAC system maintains the design space conditions and minimizes the release of radioactivity to the environment. The HVAC system consists of a 100% outside air cooling system. Outside air is filtered, heated, or cooled as required prior to being distributed throughout the various building areas. The exhaust air flows from areas with the least potential contamination to areas of most potential contamination. Prior to exhausting to the environment, potentially contaminated air is filtered with HEPA filters and charcoal adsorbers; all exhaust air is monitored for radioactivity. To ensure that no unmonitored exfiltration occurs during normal operations, the ventilation systems maintain the reactor building at a negative pressure relative to the atmosphere.

Upon detection of abnormal plant conditions, such as a line break, high radiation in the ventilation exhaust, or loss of negative pressure, the HVAC system's safety-related function is to isolate the reactor building. Once isolated via fast-closing, gastight isolation valves, the reactor building serves as a secondary containment boundary. This boundary is designed to contain any leakage from the primary containment or refueling area following an accident.

Once the secondary containment is isolated, pressure rises due to the loss of the normal ventilation system and the thermal expansion of the confined air. A safety-related exhaust system, the **standby gas treatment system** (SGTS), is started to reduce pressure and maintain the building's negative pressure. The SGTS exhausts air from the secondary containment to the environment through HEPA filters and charcoal adsorbers. The capacity of the SGTS is based on the amount of exhaust air needed to reduce the pressure in the secondary containment and maintain it at the design level, given the containment leakage rates and required drawdown times.

In addition to the SGTS, some designs include safety-related recirculating air systems within the secondary containment to mix, cool, and/or treat the air during accident conditions. These recirculation systems use portions of the normal ventilation system ductwork; therefore, the ductwork must be classified as safety related.

If the isolated secondary containment area is not to be cooled during accident conditions, it is necessary to determine the maximum temperature that could be reached during an accident. All safety-related components in the secondary containment must be environmentally qualified to operate at this temperature. In most plant designs, safety-related unit coolers handle the high heat release with **emergency core cooling system** (ECCS) pumps.

Turbine Building

Only a BWR supplies radioactive steam directly to the turbine, which could cause a release of airborne radioactivity to the surroundings. Therefore, areas of the BWR turbine building in which release of airborne radioactivity is possible should be enclosed. These areas must be ventilated and the exhaust filtered to ensure that no radioactivity is released to the surrounding atmosphere. Filtration trains typically consist of a prefilter, a HEPA filter, and a charcoal adsorber, possibly followed by a second filter. Filtration requirements are based on the plant and site configuration.

AREAS OUTSIDE PRIMARY CONTAINMENT

All areas located outside the primary containment are designed to the general requirements contained in ANS *Standard* 59.2. These areas are common to both PWRs and BWRs.

Auxiliary Building

The auxiliary building contains a large amount of support equipment, much of which handles potentially radioactive material. The building is air conditioned for equipment protection, and the exhaust is filtered to prevent the release of potential airborne radioactivity. The filtration trains typically consist of a prefilter, a HEPA filter, and a charcoal adsorber, possibly followed by a second filter.

The HVAC system is a once-through system, as needed for general cooling. Ventilation is augmented by local recirculation air-handling units in the individual equipment rooms requiring additional cooling due to localized heat loads. The building is maintained at negative pressure relative to the outside.

If the equipment in these rooms is not safety related, the area is cooled by normal air-conditioning units. If it is safety related, the area is cooled by safety-related or essential air-handling units powered from the same Class 1E (according to IEEE *Standard* 323) power supply as the equipment in the room.

The normal and essential functions may be performed by one unit having both a normal and an essential cooling coil and a safety-related fan served from a Class 1E bus. The normal coil is served

with chilled water from a normal chilled water system, and the essential coil operates with chilled water from a safety-related chilled water system.

Control Room

The control room HVAC system serves the control room habitability zone—those spaces that must be habitable following a postulated accident to allow the orderly shutdown of the reactor—and performs the following functions:

- Control indoor environmental conditions
- Provide pressurization to prevent infiltration
- Reduce the radioactivity of the influent
- Protect the zone from hazardous chemical fume intrusion
- Protect the zone from fire
- Remove noxious fumes, such as smoke

The design requirements are described in detail in SRP 6.4 and SRP 9.4.1. Regulatory guides that directly affect control room design are RG 1.52, RG 1.78, and RG 1.95. NUREG-CR-3786 provides a summary of the documents affecting control room system design. ASME *Standards* N509 and AG-1 also provide guidance for the design of control room habitability systems and methods of analyzing pressure boundary leakage effects.

Control Cable Spreading Rooms

These rooms are located directly above and below the control room. They are usually served by the air-handling units that serve the electric switchgear room or the control room.

Diesel Generator Building

Nuclear power plants have auxiliary power plants to generate electric power for all essential and safety-related equipment in the event of loss of off-site electrical power. The auxiliary power plant consists of at least two independent diesel generators, each sized to meet the emergency power load. The heat released by the diesel generator and associated auxiliary systems is normally removed through outside air ventilation.

Emergency Electrical Switchgear Rooms

These rooms house the electrical switchgear that controls essential or safety-related equipment. The switchgear located in these rooms must be protected from excessive temperatures (1) to ensure that its useful life, as determined by environmental qualification, is not cut short and (2) to preserve power circuits required for proper operation of the plant, especially its safety-related equipment.

Battery Rooms

Battery rooms should be maintained at 25°C with a temperature gradient of not more than 3 K, according to IEEE *Standard* 484. The minimum room design temperature should be taken into account in determining battery size. Because batteries produce hydrogen gas during charging periods, the HVAC system must be designed to limit the hydrogen concentration to the lowest of the levels specified by IEEE *Standard* 484, OSHA, and the lower explosive limit (LEL). The minimum number of room air changes per hour is 5. Because hydrogen is lighter than air, the system exhaust duct inlet openings should be located on the top side of the duct to prevent hydrogen pockets from forming at the ceiling. If the ceiling is supported by structural beams, there should be an exhaust air opening in each beam pocket.

Fuel-Handling Building

New and spent fuel is stored in the fuel-handling building. The building is air conditioned for equipment protection and ventilated with a once-through air system to control potential airborne radioactivity. Normally, the level of airborne radioactivity is so low that the exhaust need not be filtered, although it should be monitored. If significant airborne radioactivity is detected, the building is sealed and kept under negative pressure by exhaust through filtration trains powered by Class 1E buses.

Personnel Facilities

For nuclear power plants, this area usually includes decontamination facilities, laboratories, and medical treatment rooms.

Pumphouses

Cooling water pumps are protected by houses that are often ventilated by fans to remove the heat from the pump motors. If the pumps are essential or safety related, the ventilation equipment must also be considered safety related.

Radioactive Waste Building

Radioactive waste other than spent fuel is stored, shredded, baled, or packaged for disposal in this building. The building is air conditioned for equipment protection and ventilated to control potential airborne radioactivity. The air may require filtration through HEPA filters and/or charcoal adsorbers prior to release to the atmosphere.

Technical Support Center

The technical support center (TSC) is an outside facility located close to the control room; it is used by plant management and technical support personnel to provide assistance to control room operators under accident conditions.

In case of an accident, the TSC HVAC system must provide the same comfort and radiological habitability conditions maintained in the control room. The system is generally designed to commercial HVAC standards. An outside air filtration system (HEPA-charcoal-HEPA) pressurizes the facility with filtered outside air during emergency conditions. The TSC HVAC system must be designed to safety-related standards.

NONPOWER MEDICAL AND RESEARCH REACTORS

The requirements for HVAC and filtration systems for nuclear nonpower medical and research reactors are set by the NRC. The criteria depend on the type of reactor (ranging from a nonpressurized swimming pool type to a 10 MW or more pressurized reactor), the type of fuel, the degree of enrichment, and the type of facility and environment. Many of the requirements discussed in the sections on various nuclear power plants apply to a certain degree to these reactors. It is therefore imperative for the designer to be familiar with the NRC requirements for the reactor under design.

LABORATORIES

Requirements for HVAC and filtration systems for laboratories using radioactive materials are set by the DOE and/or the NRC. Laboratories located at DOE facilities are governed by DOE regulations. All other laboratories using radioactive materials are regulated by the NRC. Other agencies may be responsible for regulating other toxic and carcinogenic material present in the facility.

Laboratory containment equipment for nuclear processing facilities is treated as a primary, secondary, or tertiary containment zone, depending on the level of radioactivity anticipated for the area and on the materials to be handled. For additional information see Chapter 13, Laboratories.

Glove Boxes

Glove boxes are windowed enclosures equipped with one or more flexible gloves for handling material inside the enclosure from the outside. The gloves are attached to a porthole in the enclosure

and seal the enclosure from the surrounding environment. Glove boxes permit hazardous materials to be manipulated without being released to the environment.

Because the glove box is usually used to handle hazardous materials, the exhaust is HEPA filtered before leaving the box and prior to entering the main exhaust duct. In nuclear processing facilities, a glove box is considered primary confinement (Figure 1), and is therefore subject to the regulations governing those areas. For nonnuclear processing facilities, the designer should know the designated application of the glove box and design the system according to the regulations governing that particular application.

Laboratory Fume Hoods

Nuclear laboratory fume hoods are similar to those used in nonnuclear applications. Air velocity across the hood opening must be sufficient to capture and contain all contaminants in the hood. Excessive hood face velocities should be avoided because they cause contaminants to escape when an obstruction (e.g., an operator) is positioned at the hood face. For information on fume hood testing, refer to ASHRAE *Standard* 110.

Radiobenches

A radiobench has the same shape as a glove box except that in lieu of the panel for the gloves, there is an open area. Air velocity across the opening is generally the same as for laboratory hoods. The level of radioactive contamination handled in a radiobench is much lower than that handled in a glove box.

DECOMMISSIONING OF NUCLEAR FACILITIES

The exhaust air filtration system for decontamination and decommissioning (D&D) activities in nuclear facilities depends on the type and level of radioactive material expected to be found during the D&D operation. The exhaust system should be engineered to accommodate the increase in dust loading and more radioactive contamination than is generally anticipated because the D&D activities dislodge previously fixed materials, making them airborne. Good housekeeping measures include chemical fixing and vacuuming the D&D area as frequently as necessary.

The following are some design considerations for the ventilation systems required to protect the health and safety of the public and the D&D personnel:

- Maintain a higher negative pressure in the areas where D&D activities are being performed than in any of the adjacent areas.
- Provide an adequate capture velocity and transport velocity in the exhaust system from each D&D operation to capture and transport fine dust particles and gases to the exhaust filtration system.
- Exhaust system inlets should be as close to the D&D activity as possible to enhance the capture of contaminated materials and to minimize the amount of ductwork that is contaminated. Movable inlet capability is desirable.
- With portable enclosures, filtration of the enclosure inlet and exhaust air must maintain the correct negative internal pressure.

Low-Level Radioactive Waste (LLRW)

Requirements for the HVAC and filtration systems of LLRW facilities are governed by 10 CFR 61. Each facility must have a ventilation system to control airborne radioactivity. The exhaust air is drawn through a filtration system that typically includes a demister, heater, prefilter, HEPA filter, and charcoal adsorber, which may be followed by a second filter. Ventilation systems and their CAMs should be designed for the specific characteristics of the facility.

CHAPTER 26

MINE AIR CONDITIONING AND VENTILATION

Worker Heat Stress 26.1
Sources of Heat Entering Mine Air 26.1
Wall Rock Heat Flow 26.2
Air Cooling and Dehumidification 26.3
Equipment and Applications 26.3
Mechanical Refrigeration Plants 26.5
Underground Heat Exchangers 26.5
Water Sprays and Evaporative Cooling 26.7

IN underground mines, excess humidity, high temperature, and inadequate oxygen have always been points of concern because they lower worker efficiency and productivity and can cause illness and death. Air cooling and ventilation are needed in deep underground mines to minimize heat stress. As mines have become deeper, heat removal and ventilation problems have become more difficult to solve.

WORKER HEAT STRESS

Mine air must be conditioned to maintain a temperature and humidity that ensures the health and comfort of miners so they can work safely and productively. Chapter 8 of the 1997 *ASHRAE Handbook—Fundamentals* addresses human response to heat and humidity. The upper temperature limit for humans at rest in still, saturated air is about 32°C. If the air is moving at 1 m/s the upper limit is 35°C. In a hot mine, a relative humidity of less than 80% is desirable.

Hot, humid environments are improved by providing air movement of 0.8 to 2.5 m/s. Although a greater air volume lowers the mine temperature, air velocity has a limited range in which it improves worker comfort.

Indices for defining acceptable temperature limits include the following:

- **Effective temperature scale.** An effective temperature of 26.7°C is the upper limit for ensuring worker comfort and productivity.
- **Wet-bulb globe temperature (WBGT) index.** A WBGT of 26.7°C is the permissible temperature exposure limit for moderate continuous work; a WBGT of 25°C is the limit for heavy continuous work.

See Figure 1 in Chapter 28 for recommended heat stress exposure limits.

SOURCES OF HEAT ENTERING MINE AIR

Adiabatic Compression

Air descending a shaft increases in pressure (due to the weight of air above it) and temperature. As air flows down a shaft, it is heated as if compressed in a compressor, even if there is no heat interchange with the shaft and no evaporation of moisture.

One kilojoule is added to each kilogram of air for every 102 m decrease in elevation or is removed for the same elevation increase. For dry air, the specific heat is 1.006 kJ/(kg·K), and the dry-bulb temperature change is $1/(1.006 \times 102 \times 1) = 0.00975$ K per m or 1 K per 102 m of elevation. For constant air-vapor mixtures, the change in dry-bulb temperatures is $(1 + W)/(1.006 + 1.84W)$ per 102 m of elevation, where W is the humidity ratio in kilograms of water per kilogram of dry air.

Theoretically, when 50 m^3/s of standard air (density = 1.204 kg/m^3) is delivered underground via an inlet airway, the heat of autocompression for every 100 m of depth is calculated as follows:

$$50\ \text{m}^3 \times 1.204 \text{kg/m}^3 \times \frac{1\ \text{kJ/kg}}{102\ \text{m}} \times 100\ \text{m}$$

$$= 59\ \text{kW of heat to be removed}$$

Autocompression of air may be masked by the presence of other heating or cooling sources, such as shaft wall rock, groundwater, air and water lines, or electrical facilities. The actual temperature increase for air descending a shaft does not usually match the theoretical adiabatic temperature increase, due to the following:

- Effect of night cool air temperature on the rock or shaft lining
- Temperature gradient of ground rock related to depth
- Evaporation of moisture within the shaft, which decreases the temperature while increasing the moisture content of the air

The seasonal variation in surface air temperature has a major effect on the temperature of air descending a shaft. When the surface air temperature is high, much of its heat is absorbed by the shaft walls; thus, the temperature rise for the descending air may not reach the adiabatic prediction. When the surface temperature is low, heat is absorbed from the shaft walls, and the temperature increases more than predicted adiabatically. Similar diurnal variations may occur. As air flows down a shaft and increases in temperature and density, its cooling ability and volume decrease. Additionally, the mine ventilation requirements increase with depth. Fan static pressures up to 2.5 kPa (gage) are common in mine ventilation and raise the temperature of the air about 1 K/kPa.

Electromechanical Equipment

Power-operated equipment transfers heat to the air. In mines, systems are commonly powered by electricity, diesel fuel, and compressed air.

For underground diesel equipment, about 90% of the heat value of the fuel consumed, or 35 MJ/L, is dissipated to the air as heat. If exhaust gases are bubbled through a wet scrubber, the gases are cooled by adiabatic saturation, and both the sensible heat and the moisture content of the air are increased.

Vehicles with electric drives or electric-hydraulic systems release one-third to one-half the heat released by diesel equipment.

All energy used in a horizontal plane appears as heat added to the mine air. Energy required to elevate a load gives potential energy to the material and does not appear as heat.

Groundwater

Transport of heat by groundwater is the largest variable in mine ventilation. Groundwater usually has the same temperature as the virgin rock. If there is an uncovered ditch containing hot water, ventilation cooling air can pick up more heat from the ditch water than from the hot wall rock. Thus, hot drainage water should be contained in pipelines or in a covered ditch.

Heat release from open ditches becomes more significant as airways get older and the flow of heat from the surrounding rock decreases. In one Montana mine, water in open ditches was 22 K cooler than when it issued from the wall rock; the heat was transferred to the air. Evaporation of water from wall rock surfaces lowers the surface temperature of the rock, which increases the

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

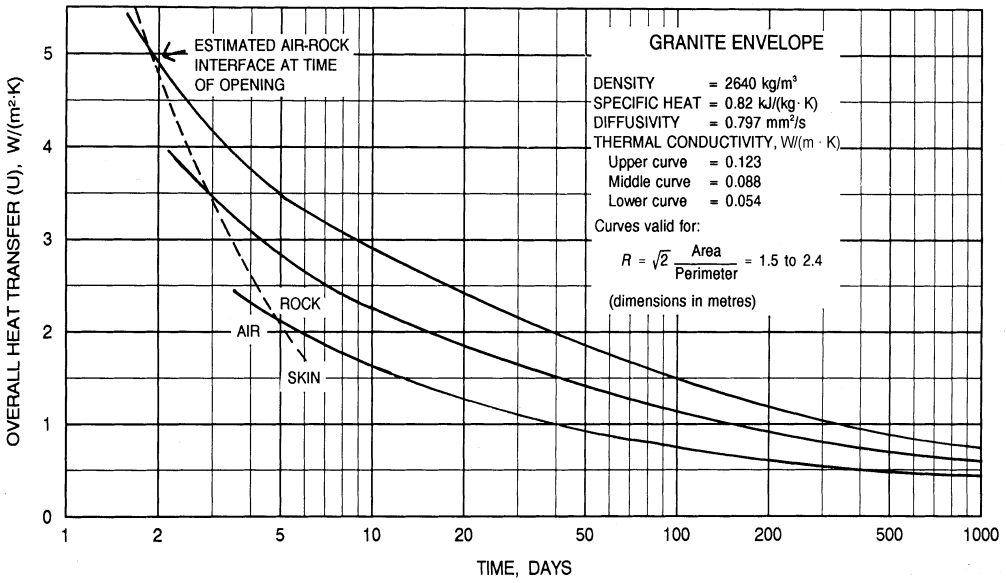

Fig. 1 Heat Flow for Salt Envelope Mine

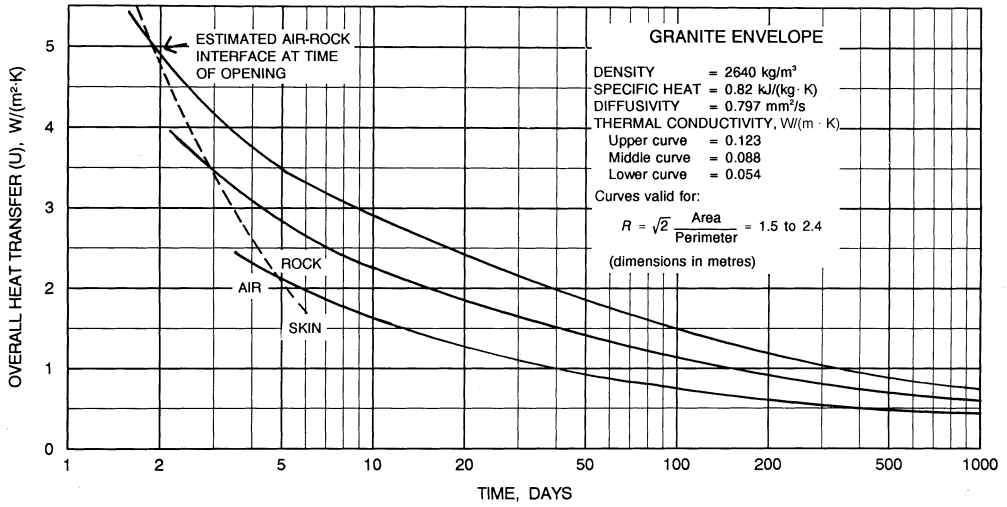

Fig. 2 Heat Flow for a Granite Envelope Mine

temperature gradient of the rock, depresses the dry-bulb temperature of the air, and allows more heat to flow from the rock. Most of this extra heat is expended in evaporation.

WALL ROCK HEAT FLOW

Wall rock is a major heat source in mines. The heat flow from wall rock with constant thermal conductivity is considerably higher when a mine is first excavated and transient heat flow applies than it is several years later, when steady-state conditions have developed. Heat flow from wall rock to air can be calculated using the steady-state heat transfer equation:

$$Q = UA\Delta t \quad (1)$$

where

Q = heat flow, kW
U = overall coefficient of heat transfer, W/(m^2·K) (from Figure 1 or 2)
A = area, m^2
Δt = temperature difference between virgin rock and dry-bulb air temperature, K

Equation (1) can be used with mine ventilation rates, virgin rock temperatures, and the age of airways to calculate rock heat flow throughout a mine.

In young mining areas, heat inflow must be computed by transient heat flow techniques. Figures 1 and 2 show heat flow from wall rock to air over 1000 days in two types of mines: a salt envelope mine and a granite envelope mine. The temperature difference between wall rock and air is not constant along the entire length of an airway, so the airway can be treated as a series of consecutive lengths. Figures 1 and 2 are based on the following:

- The cross-sectional areas of the mine openings range from 21 to 42 m^2
- The heat transfer coefficient decreases from the time the heading is excavated and ventilated.
- Steady-state heat transfer coefficients are approximately 0.57 to 0.85 W/(m^2·K) for salt or granite envelopes.

The Starfield and Goch-Patterson methods of calculating heat flow rates from underground exposed rock surfaces are often used. The Starfield method (Starfield 1966), which is theoretically more accurate, is frequently difficult to apply because it depends on air

Table 1 Maximum Virgin Rock Temperatures

Mining District	Depth, m	Temperature, °C

velocity criteria. The errors in measuring or estimating air velocities and the length and cross-sectional dimensions of the rock surfaces are often greater than the error introduced by the Starfield method.

The Goch-Patterson method (Goch and Patterson 1940), which assumes that the rock face temperature is the same as that of the air, is widely used. Heat load calculated for airways is overestimated by 10 to 20%, so a contingency is normally not added to the heat load. When using the Goch-Patterson tables, the correct value of instantaneous versus average heat load data should be used used for shafts and older connecting airways. Time-average heat load data should be used for excavations that are continuous and active.

The rate of heat release from wall rock can be accurately estimated horizontally and vertically. The **virgin rock temperature (VRT)** should be measured at various elevations throughout the mine.

Before constructing a gradient to estimate the temperatures at various elevations, a base point for measurement must be selected. The VRT 15 m below the earth's surface is often used; it is usually equal to the mean of surface air temperatures (dry-bulb) recorded over a number of years.

Table 1 lists maximum VRTs at the bottom of various mines.

Heat from Blasting

The heat produced by blasting can be appreciable. Virtually all the explosive energy is converted to heat. The typical heat potential in various types of explosives is similar to that of 60% dynamite, about 4.2 MJ/kg.

AIR COOLING AND DEHUMIDIFICATION

Sources of heat in mines include wall rock, hot water issuing from underground sources, adiabatic compression of the inlet air down deep shafts, electromechanical equipment, hot compressed air lines and lines draining hot mine water, oxidation of timber and sulfide minerals, blasting, friction and shock losses from moving air, body metabolism, friction from rock movement, and internal combustion engines (Fenton 1972).

Thermal gradients of the world's major mining districts vary from approximately 0.9 K to over 7.3 K per 100 m of elevation.

When air is cooled underground, the heat extracted must be removed. If enough cool, uncontaminated air is available, the warmed air can be mixed with it and removed from the mine. In a water heat exchanger, the water is warmed while the air is cooled. The warm water is returned in a closed circuit to the cooling plant (cooling tower, underground mechanical refrigeration unit, or heat exchanger), discharged to the mine drainage system, or sprayed into the mine exhaust air system.

The high heat capacity of water makes it a better heat transfer medium than air. For water, a relatively small pipeline can remove as much heat as would be removed by a large volume of air through a large shaft and inlet airways.

EQUIPMENT AND APPLICATIONS

Air-Conditioning Components and Practices

Figures 3 through 6 show components normally used in underground air-conditioning systems.

Cooling Surface Air

If cold air is available on the surface, as in far northern and far southern hemisphere winters, it can be forced into the mine. In deep mines with small cross-sectional airways, this supply of cold air may be insufficient for adequate cooling and may need to be supplemented by cooled air. In winter, it may even be necessary to heat the intake air.

Cooling air on the surface is the least expensive method of cooling. Factors favoring surface cooling are (1) low adiabatic compression (which applies to shafts that are not too deep) and (2) low heat gain in the shaft and intake airways. Cooling inlet air on the surface rather than in an underground cooling plant saves energy because the cooling water does not need to be returned to the surface.

In a surface plant installation, air is chilled using cold water or brine cooled by mechanical refrigeration units. The chilled air is then delivered to the intake shaft to be taken underground. Condenser water is usually cooled in towers or spray ponds. Such installations have been used in Morro Velho, Brazil; Robinson Deep Mine, Rand, South Africa; Kolar, India; and Rieu du Coeur, Belgium.

There are serious disadvantages to surface air cooling. By the time the chilled air reaches the working headings, it has been warmed considerably by autocompression and heat from the wall rock. Furthermore, a plant of sufficient size for peak load has an annual load factor as low as 60%. For these reasons, surface plant systems are no longer being installed. The trend is to install air-cooling plants underground with the cooling coils as close to the working areas of the mine as possible. If a large supply of cold water is available, it can be piped underground to the air-conditioning plants.

Cooling Surface Water

Surface-made ice or ice slurry in 0°C water can be delivered down a pipeline and used for activities such as drilling and wetting down muckpiles. The use of chilled water at 0°C reduces the required circulated flow rate to 50 to 70% of that in chilled water air-conditioning plants using warmer water. However, ice-making machines have a lower coefficient of performance and higher capital costs than do normal mechanical refrigeration units used to chill mine water.

In one Canadian mine, large, cold, mined-out areas are sprayed with water during the winter months, allowing ice to form in the openings. During the summer, intake air is cooled by drawing it over this ice.

Evaporative Cooling of Mine Chilled Water

Geographic areas with both low average winter temperatures and low relative humidity during the summer have a natural cooling capacity that is adaptable to mine air-cooling methods. A system in such an area cools water or brine on the surface, carries it through closed-circuit piping to an underground air-cooling plant near the working zone, and returns it to the cooling tower through a second pipeline. At the mine underground air-cooling plant, heat is absorbed

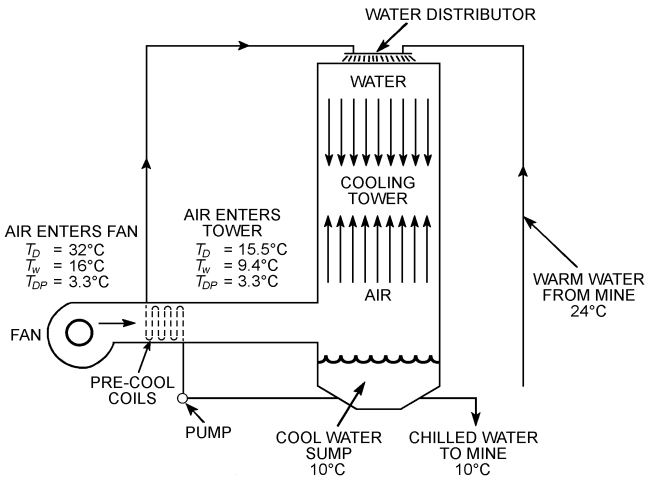

Fig. 3 Evaporative Cooling Tower System
(Richardson 1950)

by circulating water and is dissipated to the surface atmosphere in the surface cooling tower. The closed-circuit piping balances the hydrostatic pressure, so pumping power must only overcome frictional resistance.

An evaporative cooling tower was installed at a mine in the northwestern United States. This "dew-point" cooling system reduces the temperature of the cooling medium to below the wet-bulb temperature of the surface atmosphere (Figure 3). Precooling coils were installed between the fan and the cooling tower. Some cool water from the sump at the base of the cooling tower is pumped through the coils to the top of the cooling tower, where this heated flow joins the warm return water from the airflow; the moisture content in the airstream passing over the coils is unchanged, so that the dew-point temperature remains constant. The heat content of the air is reduced, and the equivalent heat is added to the water circulating in coil adsorbers. The dry- and wet-bulb temperature of the air entering the bottom of the cooling tower is less than the temperature of the air entering the fan. The temperature of the water leaving the tower approaches the wet-bulb temperature of the surface atmosphere.

Evaporative Cooling Plus Mechanical Refrigeration

On humid summer days, the wet-bulb temperature may increase over extended periods, severely hampering the effectiveness of evaporative cooling. This factor, plus warming of the air entering the mine, may necessitate the series installation of a mechanical refrigeration unit to chill the water delivered underground.

Performance characteristics at one northern United States mine on a spring day were as follows:

Evaporative cooling tower	4305 kW
Mechanical refrigeration unit (in series)	2870 kW
Water volume circulated	110 L/s
Water temperature entering mine	4.5°C
Water temperature leaving mine	20°C

Combination Systems

Components may be arranged in various ways for the greatest efficiency. For example, air-cooling towers may be used to cool water during the cool months of the year as well as to supplement a mechanical refrigerator during the warm months of the year.

Surface-installed mechanical refrigeration units provide the bulk of cooling in summer. In winter, much of the cooling comes from the precooling tower when the ambient wet-bulb temperature is usually lower than the temperature of water entering the tower. The precooling tower is normally located above the return water storage reservoir. An evaporative cooling tower is more cost-effective (capital and operating costs) than mechanical refrigeration with comparable capacity.

Reducing Water Pressure

The use of underground refrigerated water chillers is increasing because they are efficient and can be located close to the work. Transfer of heat from the condensers is the major problem with these systems. If hot mine water is used to cool the condenser, efficiency is lost due to the high condensing temperature, the possibility of corrosion, and fouling. If surface water is used, it must be piped both in and out of the mine. If water is noncorrosive and nonfouling, fairly good chiller efficiencies can be obtained for entering condenser water with temperatures up to 52°C.

Surface water being delivered in a vertical pipe is usually allowed to flow into tanks located at different levels in the shaft to break the high water pressure that develops. In this process, energy is wasted, and the water temperature rises about 1.8 K for every 1000 m of drop. The water pressure can be reduced for use at the mine level and after use, the water can be discharged to the drainage system. Although low-pressure mine cooling is convenient, the costs for pumping the water to the surface are high.

If a pipe 1000 m high were filled with water (density = 998 kg/m^3), the pressure would be $998 \times 1000 \times 9.807$ m/s^2 = 9.8 MPa. In an open piping system, the pressure at the bottom is further increased by the pressure necessary to raise the water up the

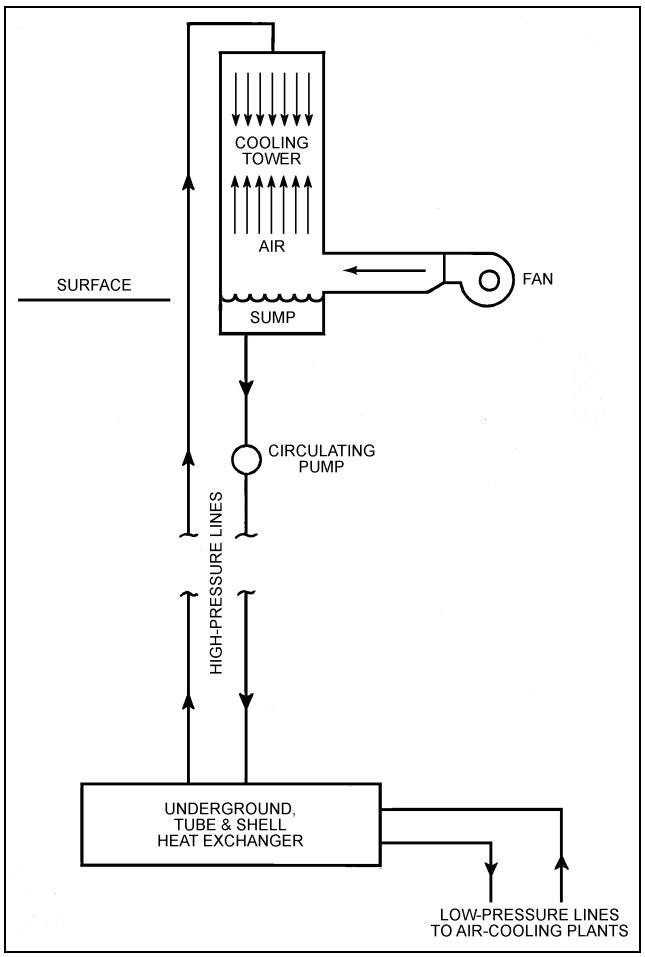

Fig. 4 Underground Heat Exchanger, Pressure Reduction System

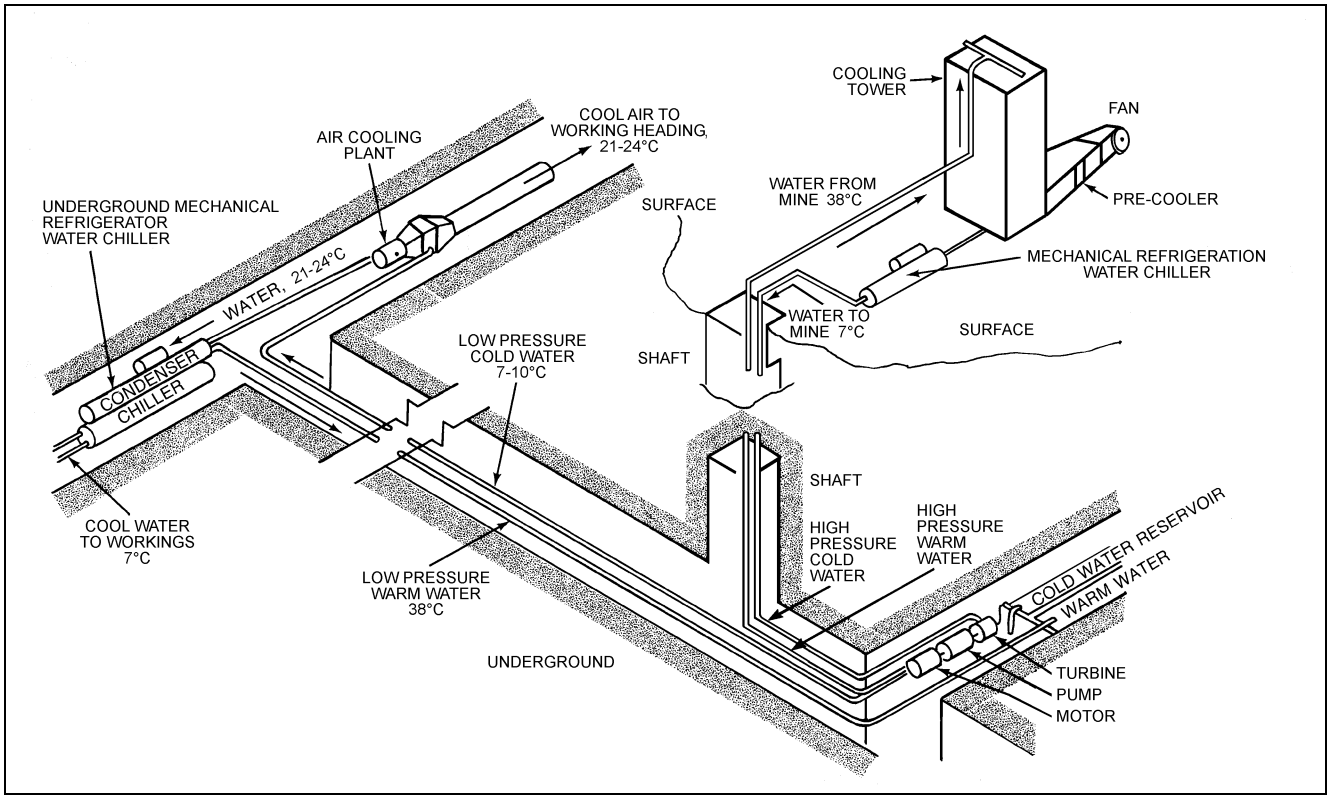

Fig. 5 Layout for Turbine-Pump-Motor Unit with Air-Cooling Plants and Mechanical Refrigeration

pipe and out of the mine. Water pipes and coils in deep mines must be able to withstand this high pressure. Fittings and pipe specialties for high-pressure equipment are costly. Safety precautions and care must be taken when operating high-pressure equipment. Closed-circuit piping has the same static pressures, but pumps must only overcome pipe friction.

Frequent movement of surface cooling towers, a desired feature for shifting mining operations, results in high construction costs. Closed-circuit systems have been used in various mines in the United States to overcome the cost of pumping brine or cooling water out of the mine.

To take advantage of both low-pressure and closed-circuit systems, the Magma mine in Arizona installed heat exchangers underground at the mining horizon. Shell-and-tube heat exchangers convert surface chilled water in a high-pressure closed circuit to a low-pressure chilled water system on mine production levels. Air-cooling plants and chilled water lines can be constructed of standard materials, permitting frequent relocation (Figure 4). Although desirable, this system has not been widely used.

Energy-Recovery Systems

Pumping costs can be reduced by combining a water turbine with the pump. The energy of high-pressure water flowing to a lower pressure drives the pump needed for the low-pressure water circuit. Rotary-type water pumps have been developed to pump against 15 MPa, and water turbines are also available to operate under pressure. Figure 5 shows a turbine pump-motor combination. Only the shaft and the pipe and fittings to the unit on the working level need strong pipes. The system connects to underground refrigeration water-chilling units; the return chilled water is used for condensing before being pumped out.

Two types of turbines are suitable for mine use—the Pelton wheel and a pump in reverse. The Pelton wheel has a high-duty efficiency of about 80%, is simply constructed, and is readily controlled. A pump in reverse is only 10 to 15% efficient, but mine maintenance and operating personnel are familiar with this equipment. Turbine energy recovery may encounter difficulties when operating on chilled mine service water because mine demands fluctuate widely, often outside the operating range of the turbine. Operating experience shows that coupling a Pelton wheel to an electric generator is the best approach.

South African mines have mechanical refrigeration units, surface heat-recovery systems, and turbine pumps incorporated into their air-cooling plants in a closed circuit.

A surface-sited plant has two disadvantages: (1) chilled water delivered underground at low operating pressure heats up at a rate of 1.8 K per 1000 m of shaft, and (2) pumping this water back to the surface is expensive. Energy-recovery turbines underground and a heat-recovery system on the surface help offset pumping costs.

Descending chilled water is fed through a turbine mechanically linked to pumps operating in the return chilled water line. The energy recovery turbine reduces the rate of temperature increase in the descending chilled water column to about 0.5 K per 1000 m of shaft.

Precooling towers on the surface reduce the water temperature a few degrees before it enters the refrigeration plant. Because of the unlimited supply of relatively cool ambient air for heat rejection, the operating cost of a surface refrigeration plant is about one-half that of a comparable underground plant.

In a uranium mine in South Africa, condensing water from surface refrigeration units is the heat source for a high condensing temperature heat pump, which discharges 55°C water. This water can be used as service hot water or as preheated feedwater for steam generation in the uranium plant. The total additional cost of a heat pump over a conventional refrigeration plant has a simple payback of about 18 months.

Pelton turbines are used by the South African gold-mining industry to recover energy from chilled water flowing down the shafts. About 1000 kW can be recovered at a typical installation;

this partially offsets the power requirements for pumping return water to the surface.

One mining company in the United States installed an energy-recovery system that includes two separate units, one at the 750 m level and one at the 1500 m level. Each installation consists of turbines directly connected to 150 kW, 3600 rpm induction motors operating as generators. Rated output is 144 kW at 35 L/s water flow at approximately 7.5 MPa.

A surface-level installation chills the service water used throughout the mining operation. A 150 mm line feeds chilled water to the turbine through a pneumatically controlled valve. The water level in an adjacent discharge reservoir is monitored to modulate the position of this valve proportional to the water demand in the reservoir. When the system is shut down, spring pressure slowly closes the inlet valve to the turbine. Simultaneously, the bypass valve opens slowly and water is discharged into the sump. Typical operating data are as follows:

Bypass discharge temperature	6.5°C
Turbine inlet temperature	4.5°C
Turbine discharge temperature	4.9°C
Turbine output	144 kW
Volume through turbine	35 L/s

MECHANICAL REFRIGERATION PLANTS

In most underground applications, mechanical refrigeration plants (Figure 5) provide chilled water for delivery underground, where some or all may be supplied condensed to direct-expansion air-to-air cooling systems. Air that passes over direct-expansion evaporator coils is cooled and delivered to working headings.

Underground mechanical refrigeration plants avoid the additional heat due to the autocompression of air coming down the shafts. The main disadvantage of these units is the disposal of heat from the condensers. The condenser discharge water can either be run into the mine drainage system, returned to the surface for cooling, or sprayed into the mine discharge air system.

Hot water discharged from the condensers of underground refrigeration units may be ejected into sumps of the mine water-pumping system. This procedure requires a constant resupply of condenser water from freshwater lines or mine drainage sources and increases mine pumping costs. Underground cooling towers are seldom used because they encounter air shortages, which result in higher condensing temperatures than those on the surface. It is difficult to predict the performance of underground cooling towers and the condensing temperatures of equipment over the life of a mine. High condenser temperatures cause excessive power consumption. In addition, water is often contaminated with dust and fumes, which cause fouling, scaling, and corrosion of the piping and condenser tubes. These problems make placing mechanical refrigeration units on the surface more favorable.

Spot Cooling

Spot cooling permits the driving of long headings for exploration or extended development prior to the installation of primary ventilation equipment. Using mechanical refrigeration systems with direct-expansion air coolers, spot cooling services a single heading or localized mining area. Spot coolers allow development headings to be advanced more rapidly and under more comfortable conditions. Development headings where rock temperatures exceed 38°C may also use spot cooling.

UNDERGROUND HEAT EXCHANGERS

Two types of heat exchangers are used underground: air-to-water and water-to-water. Air-to-water exchangers include those with (1) water sprays in the airstream and (2) finned tubes.

Air Cooling Versus Working Place Cooling

Figure 6 shows a typical underground central plant that provides a large area in a mine with air cooled by chilled water. Air flows through ventilation ducts or headings from the chiller to the working headings. When working headings are distant, the air warms and, in some cases, picks up moisture in transit. This limits the cooled air in the production area. The performance characteristics of one plant are as follows:

Air volume cooled	47 m^3/s
Entering air temperature	
Dry-bulb	26.9°C
Wet-bulb	23.5°C
Discharge air temperature	13.6°C
Entering water temperature	5.6°C
Discharge water temperature	19.4°C
Heat extracted from air	1790 kW

If one of the air-conditioning plants from the workings is not operating, it is preferable to pump chilled water in closed circuit to cooling plants close to or serving individual productive headings.

Another underground cooling plant arrangement (Figure 6A) at a mine in Wallace, Idaho, comprises a light, portable unit that attaches to the normal ventilation system and requires no extra excavation. No separate spray or dust-collection system is used, and the condensed water drips from the duct. The fan gives good service downstream from the cooler. A mechanical refrigeration unit located on the same, or a nearby, level chills water to cool the air; potable water is used in the condenser and discharged to the mine sumping system.

This underground system avoids the central plant problem of cooled air being heated as it travels down a shaft. The cooling coils are normally located within 90 m of the working place and reduce overall air-cooling plant requirements. Table 2 shows typical performance characteristics.

Cooling Coils and Fan Position

The fan may be upstream or downstream of the cooling coils in underground cooling plants. An upstream fan provides a discharge temperature that is a few degrees lower, but a downstream fan distributes air more efficiently over the coils.

WATER SPRAYS AND EVAPORATIVE COOLING

Finned-tube heat exchangers need periodic cleaning, especially when they are upstream from the fan. Downstream exchangers have spray water, which helps to wash away some of the dirt.

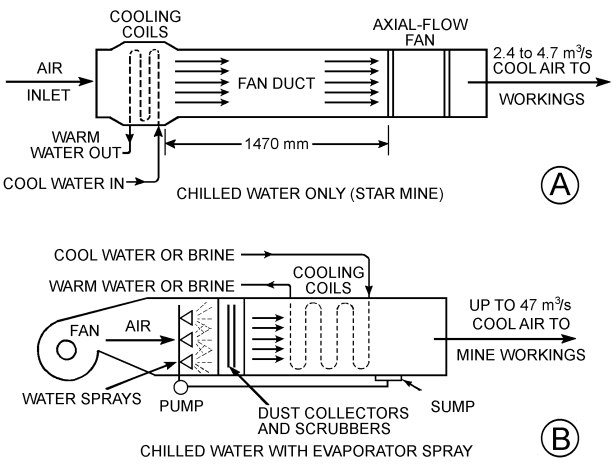

Fig. 6 Underground Air-Cooling Plants

Table 2 Typical Performance of Portable, Underground Cooling Units

Size Rating	760 by 1220 mm (141 kW)		610 by 910 mm (70 kW)	
Location	Drift	Shaft	Stope	Stope
Entering air temperature	27°C sat.	27°C sat.	27°C sat.	27°C sat.
Discharge air temperature	21°C sat.	18°C sat.	20°C sat.	27°C sat.
Volume, m^3/s	5.7	5.7	2.8	2.8
Calculated kW	158	211	79	91

Another type of bulk-spraying cooling plant in South Africa consists of a spray chamber serving a section of isolated drift up to 120 m long. Chilled water is introduced through a manifold of spray nozzles. Warm, mild air flows countercurrent to the various stages of water sprays. Air cooled by this direct air-to-water cooling system is delivered to active mine workings by the primary and secondary ventilation system. These bulk-spray coolers are efficient and economical.

At one uranium mine, a portable bulk-spray cooling plant was developed that can be advanced with the working faces to overcome the high heat load between a stationary spray chamber and the production heading.

The 1060 kW capacity plant has a stainless steel chamber 2060 mm long, 2210 mm wide, and 2590 mm high that contains two stages of spray nozzles and a demister baffle. The skid-mounted unit has a mass of about 1000 kg and is divided into four components (spray chamber, demister assembly, and two sump halves).

Portable bulk-spray coolers have a wide range of cooling capacity and are cost-effective. A smaller portable spray cooling plant has been developed to cool mine air adjacent to the workplace. It cools and cleans the air through direct air-to-water contact. The cooler is tube-shaped and is normally mounted in a remote location. The mine inlet and discharge air ventilation ducts are connected to duct transitions from the unit. Chilled water is piped to an exposed manifold, and warm water is discharged from the unit into a sump drain.

Hot, humid air enters the cooler at the bottom; it then slows down and flows through egg crate flow straighteners. Initial heat exchange occurs as the air passes through plastic mesh and contacts suspended water droplets. Vertically sprayed water in a spray chamber then directly contacts the ascending warm air. The air passes through the mist eliminator, which removes suspended water droplets. Cool, dehumidified air exits from the cooler through the top outlet transition. The warmed spray water drops to the sump and is discharged through a drainpipe.

CHAPTER 27

INDUSTRIAL DRYING SYSTEMS

Mechanism of Drying 27.1
Applying Hygrometry to Drying 27.1
Determining Drying Time 27.1
Drying System Selection 27.3
Types of Drying Systems 27.3

DRYING removes water and other liquids from gases, liquids, and solids. The term is most commonly used, however, to describe the removal of water or solvent from solids by thermal means. **Dehumidification** refers to the drying of a gas, usually by condensation or by absorption with a drying agent (see Chapter 21 of the 1997 *ASHRAE Handbook—Fundamentals*). **Distillation**, particularly **fractional distillation**, is used to dry liquids.

It is cost-effective to separate as much water as possible from a solid using mechanical methods *before* drying using thermal methods. Mechanical methods such as filtration, screening, pressing, centrifuging, or settling require less power and less capital outlay per unit mass of water removed.

This chapter describes systems used for industrial drying and their advantages, disadvantages, relative energy consumption, and applications.

MECHANISM OF DRYING

When a solid dries, two processes occur simultaneously: (1) the transfer of heat to evaporate the liquid and (2) the transfer of mass as vapor and internal liquid. Factors governing the rate of each process determine the drying rate.

The principal objective in commercial drying is to supply the required heat efficiently. Heat transfer can occur by convection, conduction, radiation, or a combination of these. Industrial dryers differ in their methods of transferring heat to the solid. In general, heat must flow first to the outer surface of the solid and then into the interior. An exception is drying with high-frequency electrical currents, where heat is generated within the solid, producing a higher temperature at the interior than at the surface and causing heat to flow from inside the solid to the outer surfaces.

APPLYING HYGROMETRY TO DRYING

In many applications, recirculating the drying medium improves thermal efficiency. The optimum proportion of recycled air balances the lower heat loss associated with more recirculation against the higher drying rate associated with less recirculation.

Because the humidity of drying air is affected by the recycle ratio, the air humidity throughout the dryer must be analyzed to determine whether the predicted moisture pickup of the air is physically attainable. The maximum ability of air to absorb moisture corresponds to the difference between saturation moisture content at wet-bulb (or adiabatic cooling) temperature and moisture content at supply air dew point. The actual moisture pickup of air is determined by heat and mass transfer rates and is always less than the maximum attainable.

ASHRAE psychrometric charts for normal and high temperatures (No. 1 and No. 3) can be used for most drying calculations. The process will not exactly follow the adiabatic cooling lines because some heat is transferred to the material by direct radiation or by conduction from the metal tray or conveyor.

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

Example 1. A dryer has a capacity of 41 kg of bone-dry gelatin per hour. Initial moisture content is 228% bone-dry basis, and final moisture content is 32% bone-dry basis. For optimum drying, the supply air is at 50°C dry bulb and 30°C wet bulb in sufficient quantity that the condition of exhaust air is 40°C dry bulb and 29.5°C wet bulb. Makeup air is available at 27°C dry bulb and 18.6°C wet bulb.

Find (1) the required amount of makeup and exhaust air and (2) the percentage of recirculated air.

Solution: In this example, the humidity in each of the three airstreams is fixed; hence, the recycle ratio is also determined. Refer to ASHRAE Psychrometric Chart No. 1 to obtain the humidity ratio of makeup air and exhaust air. To maintain a steady-state condition in the dryer, water evaporated from the material must be carried away by exhaust air. Therefore, the pickup (the difference in humidity ratio between exhaust air and makeup air) is equal to the rate at which water is evaporated from the material divided by the mass of dry air exhausted per hour.

Step 1. From ASHRAE Psychrometric Chart No. 1, the humidity ratios are as follows:

	Dry bulb, °C	Wet bulb, °C	Humidity ratio, g/kg dry air
Supply air	50	30	18.7
Exhaust air	40	29.5	22
Makeup air	27	18.6	10

Moisture pickup is 22 − 10 = 12 g/kg (dry air). The rate of evaporation in the dryer is

$$41[(228 - 32)/100] = 80.36 \text{ kg/h} = 22.3 \text{ g/s}$$

The dry air required to remove the evaporated water is 22.3/12 = 1.86 kg/s.

Step 2. Assume x = percentage of recirculated air and $(100 - x)$ = percentage of makeup air. Then

Humidity ratio of supply air =
(Humidity ratio of exhaust and recirculated air) $(x/100)$
+ (Humidity ratio of makeup air)$(100 - x)/100$

Hence,

$$18.7 = 22(x/100) + 10(100 - x)/100$$

x = 72.5% recirculated air
$100 - x$ = 27.5% makeup air

DETERMINING DRYING TIME

The following are three methods of finding drying time, listed in order of preference:

1. Conduct tests in a laboratory dryer simulating conditions for the commercial machine, or obtain performance data using the commercial machine.
2. If the specific material is not available, obtain drying data on similar material by either of the above methods. This is subject to the investigator's experience and judgment.
3. Estimate drying time from theoretical equations (see the section on Bibliography). Care should be taken in using the approximate values obtained by this method.

When designing commercial equipment, tests are conducted in a laboratory dryer that simulates commercial operating conditions. Sample materials used in the laboratory tests should be identical to the material found in the commercial operation. Results from several tested samples should be compared for consistency. Otherwise, the test results may not reflect the drying characteristics of the commercial material accurately.

When laboratory testing is impractical, commercial drying data can be based on the equipment manufacturer's experience.

Commercial Drying Time

When selecting a commercial dryer, the estimated drying time determines what size machine is needed for a given capacity. If the drying time has been derived from laboratory tests, the following should be considered:

- In a laboratory dryer, considerable drying may be the result of radiation and heat conduction. In a commercial dryer, these factors are usually negligible.
- In a commercial dryer, humidity conditions may be higher than in a laboratory dryer. In drying operations with controlled humidity, this factor can be eliminated by duplicating the commercial humidity condition in the laboratory dryer.
- Operating conditions are not as uniform in a commercial dryer as in a laboratory dryer.
- Because of the small sample used, the test material may not be representative of the commercial material.

Thus, the designer must use experience and judgment to modify the test drying time to suit the commercial conditions.

Dryer Calculations

To estimate preliminary cost for a commercial dryer, the circulating airflow rate, the makeup and exhaust airflow rate, and the heat balance must be determined.

Circulating Air. The required circulating or supply airflow rate is established by the optimum air velocity relative to the material. This can be obtained from laboratory tests or previous experience, keeping in mind that the air also has an optimum moisture pickup. (See the section on Applying Hygrometry to Drying.)

Makeup and Exhaust Air. The makeup and exhaust airflow rate required for steady-state conditions within the dryer is also discussed in the section on Applying Hygrometry to Drying. In a **continuously operating dryer**, the relationship between the moisture content of the material and the quantity of makeup air is given by

$$G_T(W_2 - W_1) = M(w_1 - w_2) \quad (1)$$

where

G_T = dry air supplied as makeup air to the dryer, kg/s
M = stock dried in a continuous dryer, kg/s
W_1 = humidity ratio of entering air, kg (water vapor) per kg (dry air)
W_2 = humidity ratio of leaving air, kg water vapor per kg (dry air) (In a continuously operating dryer, W_2 is constant; in a batch dryer, W_2 varies during a portion of the cycle.)
w_1 = dry basis moisture content of entering material, kg/kg
w_2 = dry basis moisture content of leaving material, kg/kg

In **batch dryers**, the drying operation is given as

$$G_T(W_2 - W_1) = (M_1)\frac{dw}{d\theta} \quad (2)$$

where

M_1 = mass of material charged in a discontinuous dryer, kg per batch
$dw/d\theta$ = instantaneous time rate of evaporation corresponding to w

The makeup air quantity is constant and is based on the average evaporation rate. Equation (2) then becomes identical to Equation (1), where $M = M_1/\theta$. Under this condition, the humidity in the batch dryer varies from a maximum to a minimum during the drying cycle, whereas in the continuous dryer, the humidity is constant with constant load.

Heat Balance. To estimate the fuel requirements of a dryer, a heat balance consisting of the following is needed:

- Radiation and convection losses from the dryer
- Heating of the commercial dry material to the leaving temperature (usually estimated)
- Vaporization of the water being removed from the material (usually considered to take place at the wet-bulb temperature)
- Heating of the vapor from the wet-bulb temperature in the dryer to the exhaust temperature
- Heating of the total water in the material from the entering temperature to the wet-bulb temperature in the dryer
- Heating of the makeup air from its initial temperature to the exhaust temperature

The energy absorbed must be supplied by the fuel. The selection and design of the heating equipment is an essential part of the overall design of the dryer.

Example 2. Magnesium hydroxide is dried from 82% to 4% moisture content (wet basis) in a continuous conveyor dryer with a fin-drum feed (see Figure 7). The desired production rate is 0.4 kg/s. The optimum circulating air temperature for drying is 71°C, which is not limited by the existing steam pressure of the dryer.

Step 1. Laboratory tests indicate the following:

Specific heats
- air (c_a) = 1.00 kJ/(kg·K)
- material (c_m) = 1.25 kJ/(kg·K)
- water (c_w) = 4.18 kJ/(kg·K)
- water vapor (c_v) = 1.84 kJ/(kg·K)

Temperature of material entering dryer = 15°C

Temperature of makeup air
- dry bulb = 21°C
- wet bulb = 15.5°C

Temperature of circulating air
- dry bulb = 71°C
- wet bulb = 38°C

Air velocity through drying bed = 1.3 m/s

Dryer bed loading = 33.3 kg/m^2

Test drying time = 25 min

Step 2. Previous experience indicates that the commercial drying time is 70% greater than the time obtained in the laboratory test. Therefore, the commercial drying time is estimated to be $1.7 \times 25 = 42.5$ min.

Step 3. The holding capacity of the dryer bed can be calculated as follows:

$$0.4(42.5 \times 60) = 1020 \text{ kg at 4\% (wet basis)}$$

The required conveyor area is 1020/33.3 = 30.6 m^2. Assuming the conveyor is 2.4 m wide, the length of the drying zone is 30.6/2.4 = 12.8 m.

Step 4. The amount of water in the material entering the dryer is

$$0.4[82/(100 + 4)] = 0.315 \text{ kg/s}$$

The amount of water in the material leaving is

$$0.4[4/(100 + 4)] = 0.015 \text{ kg/s}$$

Thus, the moisture removal rate is $0.315 - 0.015 = 0.300$ kg/s.

Step 5. The air circulates perpendicular to the perforated plate conveyor, so the air volume is the face velocity times the conveyor area:

$$\text{Air volume} = 1.3 \times 30.6 = 39.8 \text{ m}^3/\text{s}$$

ASHRAE Psychrometric Charts 1 and 3 show the following air properties:

Supply air (71°C db, 38°C wb)
- Humidity ratio = 29.0 g/kg (dry air)
- Specific volume = 1.02 m^3/kg (dry air)

Makeup air (21°C db, 15.5°C wb)
- Humidity ratio W_1 = 8.7 g/kg (dry air)

The mass flow rate of dry air is

$$39.8/1.02 = 39.0 \text{ kg/s}$$

Step 6. The amount of moisture pickup is

$$0.300/39.0 = 7.7 \text{ g/kg (dry air)}$$

The humidity ratio of the exhaust air is

$$W_2 = 29.0 + 7.7 = 36.7 \text{ g/kg (dry air)}$$

Substitute in Equation (1) and calculate G_T as follows:

$$G_T(36.7 - 8.7)(1 \text{ kg}/1000 \text{ g}) = (0.4/1.04)(82 - 4)/100$$

$$G_T = 10.7 \text{ kg (dry air)/s}$$

Therefore,

Makeup air = $100 \times 10.7/39.0 = 27.4\%$
Recirculated air = 72.6%

Step 7. Heat Balance

Sensible heat of material = $M(t_{m2} - t_{m1})c_m$
= $(0.4/1.04)(38 - 15)1.25$
= 11.1 kW

Sensible heat of water = $M_{w1}(t_w - t_{m1})c_w$
= $0.315(38 - 15)4.18$
= 30.2 kW

Latent heat of evaporation = $M(w_1 - w_2)H$
= 0.300 kg/s × 2411 kJ/(kg·K)
= 723.3 kW

Sensible heat of vapor = $M(t_2 - t_w)c_v$
= $0.300(71 - 38)1.84$
= 18.2 kW

Required heat for material = 782.8 kW

The temperature drop $(t_2 - t_3)$ through the bed is

$$\frac{\text{Required heat}}{\text{Supplied air, kg/s} \times c_a} = \frac{782.8}{39.0 \times 1.00} = 20 \text{ K}$$

Therefore, the exhaust air temperature is $71 - 20 = 51°C$

Required heat for makeup air = $G_T(t_3 - t_1)c_a$
= $10.7(51 - 21)1.00$
= 321 kW

The total heat required for material and makeup air is

$$782.8 + 321 = 1100 \text{ kW}$$

Additional heat that must be provided to compensate for radiation and convection losses can be calculated from the known construction of the dryer surfaces.

DRYING SYSTEM SELECTION

A general procedure for selecting a drying system consists of the following:

1. Survey of suitable dryers.
2. Preliminary cost estimates of various types.
   (a) Initial investment
   (b) Operating cost
3. Drying tests conducted in prototype or laboratory units, preferably using the most promising equipment available. Sometimes a pilot plant is justified.
4. Summary of tests evaluating quality of samples of the dried products.

Factors that can overshadow the operating or investment cost include the following:

- Product quality, which should not be sacrificed
- Dusting, solvent, or other product losses
- Space limitation
- Bulk density of the product, which can affect packaging cost

Friedman (1951) and Parker (1963) discuss additional aids to dryer selection.

TYPES OF DRYING SYSTEMS

Radiant Infrared Drying

Thermal radiation may be applied by infrared lamps, gas-heated incandescent refractories, steam-heated sources, and, most often, electrically heated surfaces. Infrared heats only near the surface of a material, so it is best used to dry thin sheets.

The use of infrared heating to dry webs such as uncoated materials has been relatively unsuccessful because of process control problems. Thermal efficiency can be low; heat transfer depends on the emitter's characteristics and configuration, and on the properties of the material to be dried.

Radiant heating is used for drying ink and other coatings on paper, textile fabrics, paint films, and lacquers. Inks have been specifically formulated for curing with tuned or narrow wavelength infrared radiation.

Ultraviolet Radiation Drying

Ultraviolet (UV) drying uses electromagnetic radiation. Inks and other coatings based on monomers are cure dried when exposed to UV radiation. This method has superior properties (Chatterjee and Ramaswamy 1975): the print resists scuff, scratch, acid, alkali, and some solvents. Printing can also be done at higher speeds without damage to the web.

Major barriers to wider acceptance of UV drying include the high capital installation cost and the increased cost of inks. The cost and frequency of replacing UV lamps are greater than for infrared ovens.

Overexposure to radiation and ozone, which is formed by UV radiation's effect on atmospheric oxygen, can cause severe sunburn and possibly blood and eye damage. Safety measures include fitting the lamp housings with screens, shutters, and exhausts.

Conduction Drying

Drying rolls or drums (Figure 1), flat surfaces, open kettles, and immersion heaters are examples of direct-contact drying. The heating surface must have close contact with the material, and agitation may increase uniform heating or prevent overheating.

Conduction drying is used to manufacture and dry paper products. It (1) does not provide a high drying rate, (2) does not furnish uniform heat and mass transfer conditions, (3) usually results in a poor moisture profile across the web, (4) lacks proper control, (5) is costly to operate and install, and (6) usually creates undesirable working conditions in areas surrounding the machine. Despite these disadvantages, replacing existing systems with other forms of drying is expensive. For example, Joas and Chance (1975) report that RF (dielectric) drying of paper requires approximately four times the capital cost, six times the operating (heat) cost, and five times the maintenance cost of steam cylinder conduction drying.

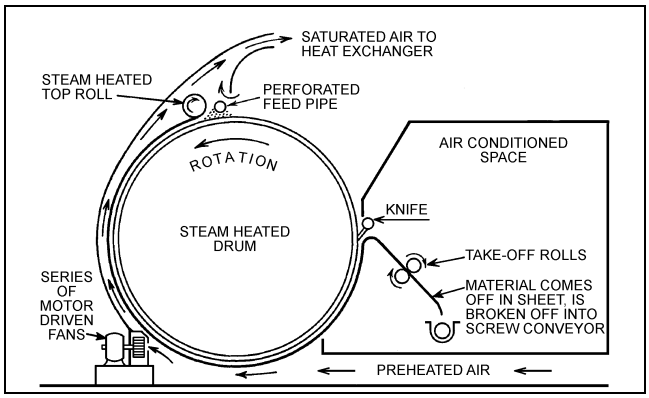

Fig. 1 Drum Dryer

However, augmenting conduction drying with dielectric drying sections offsets the high cost of RF drying and may produce savings and increased profits from greater production and higher final moisture content.

Further use of large conduction drying systems depends on reducing heat losses from the dryer, improving heat recovery, and incorporating other drying techniques to maintain quality.

Dielectric Drying

When wet material is placed in a strong, high-frequency (2 to 100 MHz) electrostatic field, heat is generated within the material. More heat is developed in the wetter areas than in the drier areas, resulting in automatic moisture profile correction. Water is evaporated without unduly heating the substrate. Therefore, in addition to its leveling properties, dielectric drying provides uniform heating throughout the web thickness.

Dielectric drying is controlled by varying field or frequency strength; varying field strength is easier and more effective. Response to this variation is quick, with neither time lag nor thermal lag in heating. The dielectric heater is a sensitive moisture meter.

Several electrode configurations are used. The platen type (Figure 2) is used for drying and baking foundry cores, heating plastic preforms, and drying glue lines in furniture. The rod or stray field types (Figure 3) are used for thin web materials such as paper and textile products. The double-rod types (over and under material) are used for thicker webs or flat stock, such as plywood.

Dielectric drying is popular in the textile industry. Because air is entrained between fibers, convection drying is slow and uneven. This can be overcome by dielectric drying after yarn drying. Because the yarn is usually transferred to large packages immediately after drying, even and correct moisture content can be obtained by dielectric drying. Knitting wool seems to benefit from internal steaming in hanks.

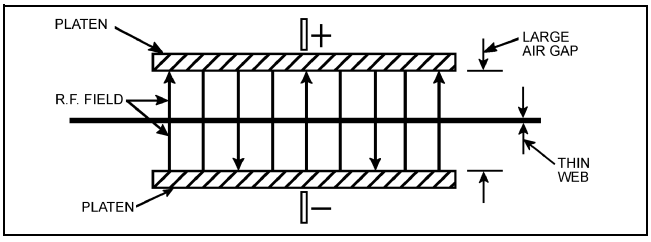

Fig. 2 Platen-Type Dielectric Dryer

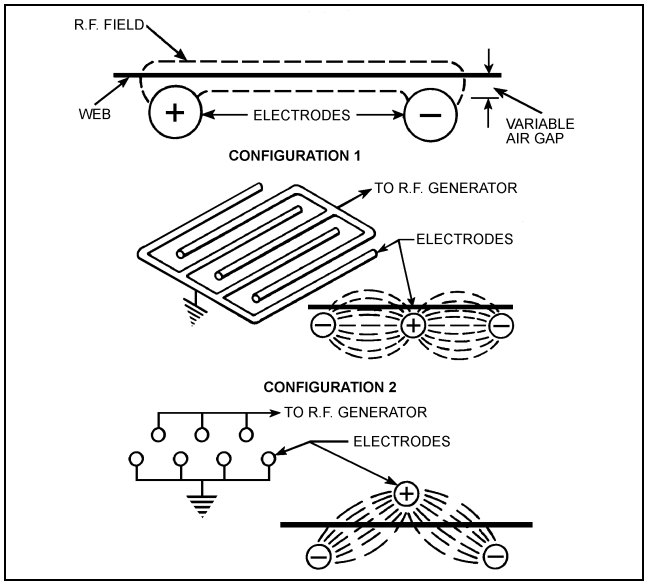

Fig. 3 Rod-Type Dielectric Dryers

Warping caused by nonuniform drying is a serious problem for plywood and linerboard. Dielectric drying yields warp-free products.

Dielectric drying is not cost-effective for overall paper drying but has advantages when used at the dry end of a conventional steam drum dryer. It corrects moisture profile problems in the web without overdrying. This combination of conventional and dielectric drying is synergistic; the drying effect of the combination is greater than the sum of the two types of drying. This is more pronounced in thicker web materials, accounting for as much as a 16% line speed increase and a corresponding 2% energy input increase.

Microwave Drying

Microwave drying or heating uses ultrahigh-frequency (900 to 5000 MHz) radiation. It is a form of dielectric heating and is used for heating nonconductors. Because of its high frequency, microwave equipment is capable of generating extreme power densities.

Microwave drying is applied to thin materials in strip form by passing the strip through the gap of a split waveguide. Entry and exit shielding make continuous process applications difficult. Its many safety concerns make microwave drying more expensive than dielectric drying. Control is also difficult because microwave drying lacks the self-compensating properties of dielectrics.

Convection Drying (Direct Dryers)

Some convection drying occurs in almost all dryers. True convection dryers, however, use circulated hot air or other gases as the principal heat source. Each means of mechanically circulating air or gases has its advantages.

Rotary Dryers. These cylindrical drums cascade the material being dried through the airstream (Figure 4). The dryers are heated directly or indirectly, and air circulation is parallel or counterflow. A variation is the rotating-louver dryer, which introduces air beneath the flights to provide close contact.

Cabinet and Compartment Dryers. These batch dryers range from the heated loft (with only natural convection and usually poor and nonuniform drying) to self-contained units with forced draft and properly designed baffles. Several systems may be evacuated to dry delicate or hygroscopic materials at low temperatures. Material is usually spread in trays to increase the exposed surface. Figure 5 shows a dryer that can dry water-saturated products.

When designing dryers to process products saturated with solvents, special features must be included to prevent explosive gases from forming. Safe operation requires exhausting 100% of the air circulated during the initial drying period or during any part of the drying cycle when the solvent is evaporating at a high rate. At the end of the purge cycle, the air is recirculated and heat is gradually applied. To prevent explosions, laboratory dryers can be used to determine the amount of air circulated, the cycle lengths, and the rate that heat is applied for each product. In the drying cycle, dehumidified air, which is costly, should be recirculated as soon possible. The air *must not* be recirculated when cross-contamination of products is prohibited.

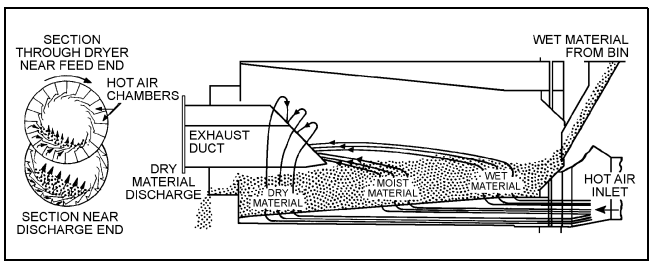

Fig. 4 Cross Section and Longitudinal Section of Rotary Dryer

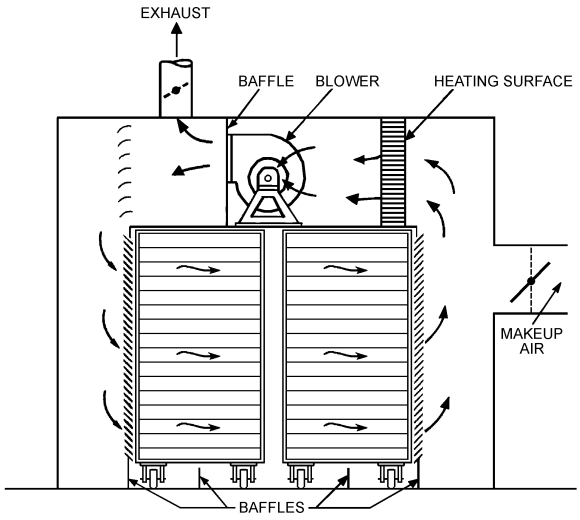

Fig. 5 Compartment Dryer Showing Trucks with Air Circulation

Dryers must have special safety features in case any part of the drying cycle fails. The following are some of the safety design features described in *Industrial Ovens and Driers* (FMEA 1990):

1. Each compartment must have separate supply and exhaust fans and an explosion-relief panel.
2. The exhaust fan blade tip speed should be 25 m/s for a forward-inclined blade, 35 m/s for a radial-tip blade, and 38 m/s for a backward-inclined blade. These speeds produce high static pressures at the fan, ensuring constant air exhaust volumes under conditions such as negative pressures in the building or downdrafts in the exhaust stacks.
3. An airflow failure switch in the exhaust duct must shut off fans and the heating coil and must sound an alarm.
4. An airflow failure switch in the air supply system must shut off fans and the heating coil and must sound an alarm.
5. A high-temperature limit controller in the supply duct must shut off the heat to the heating coil and must sound an alarm.
6. An electric interlock on the dryer door must interrupt the drying cycle if the door is opened beyond a set point, such as that wide enough for a person to enter for product inspection.

Tunnel Dryers. Tunnel dryers are modified compartment dryers that operate continuously or semicontinuously. Heated air or combustion gas is circulated by fans. The material is handled on trays or racks on trucks and moves through the dryer either intermittently or continuously. The airflow may be parallel, counterflow, or a combination obtained by center exhaust (Figure 6). Air may also flow across the tray surface, vertically through the bed, or in any combination of directions. By reheating the air in the dryer or recirculating it, a high degree of saturation is reached before the air is exhausted, thus reducing the sensible heat loss.

The following problems with tunnel dryers have been experienced and should be considered in future designs:

- Operators may overload product trays to increase output, but this can overtax the system and increase the drying time.
- Sometimes air from the drying tunnel is discharged into the production area, increasing the humidity. Air from the drying tunnel should be discharged to the drying system return or outside.
- Overloaded product trays add pressure drop, which decreases flow through the tunnel dryer. The control panel should indicate validated flow through the tunnel. High and low flow and high moisture levels should trigger alarms.
- Cycle times can be reduced by designing dryers for cross-flow rather than end-to-end flow.

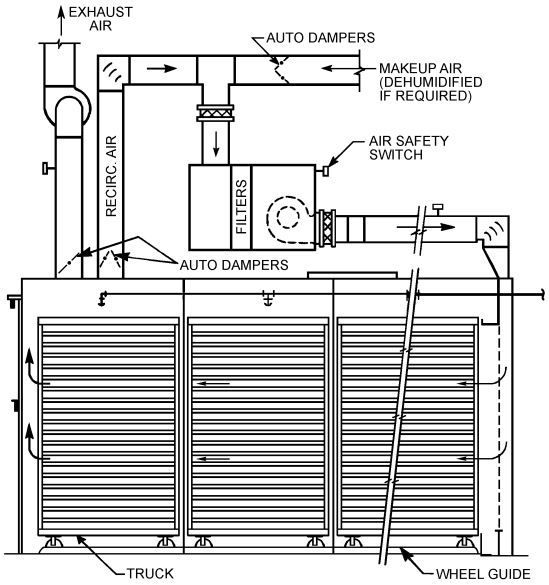

Fig. 6 Explosionproof Truck Dryer Showing Air Circulation and Safety Features

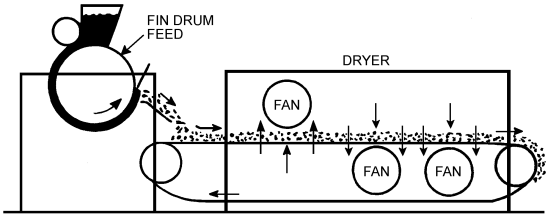

Fig. 7 Section of Blow-Through-Type Continuous Dryer

A variation of the tunnel dryer is the strictly continuous dryer, which has one or more mesh belts that carry the product through it, as shown in Figure 7. Many combinations of temperature, humidity, air direction, and velocity are possible. Hot air leaks at the entrance and exit can be minimized by baffles or inclined ends, with the material entering and leaving from the bottom.

High-Velocity Dryers. High-velocity hoods or dryers have been used as supplements to conventional cylinder dryers for drying paper. When used with conventional cylinder dryers, web instability and lack of process control result. Where internal diffusion is not the controlling factor in the drying rate, applications such as thin permeable webs offer more promise.

Spray Dryers. Spray dryers have been used in the production of dried milk, coffee, soaps, and detergents. Because the dried product (in the form of small beads) is uniform and the drying time is short (5 to 15 s), this drying method has become more important. When a liquid or slurry is dried, the spray dryer has high production rates.

Spray drying involves the atomization of a liquid feed in a hot-gas drying medium. The spray can be produced by a two-fluid nozzle, a high-pressure nozzle, or a rotating disk. Inlet gas temperatures range from 93 to 760°C, with the high temperatures requiring special construction materials. Because thermal efficiency increases with the inlet gas temperature, high inlet temperatures are desirable. Even heat-sensitive products can be dried at higher temperatures because of the short drying time. Hot gas flow may be either concurrent or countercurrent to the falling droplets. Dried particles settle out by gravity. Fine material in the exhaust air is collected in cyclone separators or bag filters. Figure 8 shows a typical spray drying system.

The physical properties of the dried product (such as particle size, bulk density, and dustiness) are affected by atomization characteristics and the temperature and direction of flow of the drying

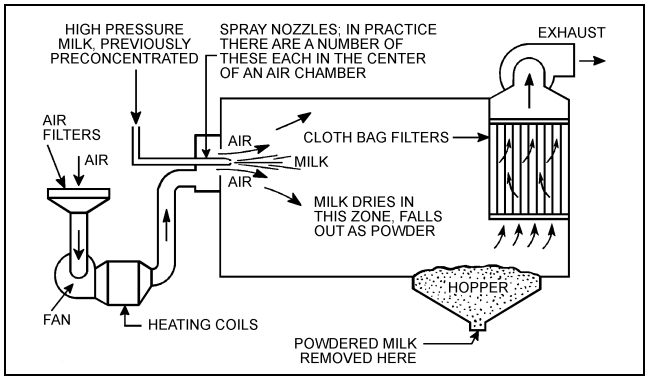

Fig. 8 Pressure-Spray Rotary-Type Spray Dryer

gas. The product's final moisture content is controlled by the humidity and temperature of the exhaust gas stream.

Currently, pilot-plant or full-scale production operating data are required for design purposes. The drying chamber design is determined by the nozzle's spray characteristics and heat and mass transfer rates. There are empirical expressions that approximate mean particle diameter, drying time, chamber volume, and inlet and outlet gas temperatures.

Freeze Drying

Freeze drying has been applied to pharmaceuticals, serums, bacterial and viral cultures, vaccines, fruit juices, vegetables, coffee and tea extracts, seafoods, meats, and milk.

The material is frozen, then placed in a high-vacuum chamber connected to a low-temperature condenser or chemical desiccant. Heat is slowly applied to the frozen material by conduction or infrared radiation, allowing the volatile constituent, usually water, to sublime and condense or be absorbed by the desiccant. Most freeze-drying operations occur between −10 and −40°C under minimal pressure. While this process is expensive and slow, it has advantages for heat-sensitive materials (see Chapter 15 of the 1998 *ASHRAE Handbook—Refrigeration*).

Vacuum Drying

Vacuum drying takes advantage of the decrease in the boiling point of water that occurs as the pressure is lowered. Vacuum drying of paper has been partially investigated. Serious complications arise if the paper breaks, and massive sections must be removed. Vacuum drying is used successfully for pulp drying, where lower speeds and higher masses make breakage relatively infrequent.

Fluidized-Bed Drying

A fluidized-bed system contains solid particles through which a gas flows with a velocity higher than the incipient fluidizing velocity but lower than the entrainment velocity. Heat transfer between the individual particles and the drying air is efficient because there is close contact between powdery or granular material and the fluidizing gas. This contact makes it possible to dry sensitive materials without danger of large temperature differences.

The dried material is free-flowing and, unlike that from convection-type dryers, is not encrusted on trays or other heat-exchanging surfaces. Automatic charging and discharging are possible, but the greatest advantage is reduced process time. Only simple controls are important (i.e., control over fluidizing air or gas temperatures and the drying time of the material).

All fluidized-bed dryers should have explosion relief flaps. Both the pressure and the flames of an explosion are dangerous. Also, when toxic materials are used, uncontrolled venting to the atmosphere is prohibited. Explosion suppression systems, such as pressure-actuated ammonium-phosphate extinguishers, have been used instead of relief venting. An inert dryer atmosphere is preferable to suppression systems because it prevents explosive mixtures from forming.

When organic and inflammable solvents are used in the fluidized-bed system, the closed system offers advantages other than explosion protection. A portion of the fluidizing gas is continuously run through a condenser, which strips the solvent vapors and greatly reduces air pollution problems, thus making solvent recovery convenient.

Materials dried in fluidized-bed installations include coal, limestone, cement rock, shales, foundry sand, phosphate rock, plastics, medicinal tablets, and foodstuffs. Leva (1959) and Othmer (1956) discuss the theory and methods of fluidization of solids. Clark (1967) and Vanecek et al. (1966) developed design equations and cost estimates.

Agitated-Bed Drying

Uniform drying is ensured by periodically or continually agitating a bed of preformed solids with a vibrating tray, a conveyor, or a vibrating mechanically operated rake, or, in some cases, by partial fluidization of the bed on a perforated tray or conveyor through which recycled drying air is directed. Drying and toasting cereals is an important application.

Drying in Superheated Vapor Atmospheres

When drying solids with air or another gas, the vaporized solvent (water or organic liquid) must diffuse through a stagnant gas film to reach the bulk gas stream. Because this film is the main resistance to mass transfer, the drying rate depends on the solvent vapor diffusion rate. If the gas is replaced by solvent vapor, resistance to mass transfer in the vapor phase is eliminated, and the drying rate depends only on the heat transfer rate. Drying rates in solvent vapor, such as superheated steam, are greater than those in air for equal temperatures and mass flow of the drying media.

This method also has higher thermal efficiency, easier solvent recovery, and a lower tendency to overdry, and it eliminates oxidation or other chemical reactions that occur when air is present. In drying cloth, superheated steam reduces the migration tendency of resins and dyes. Superheated vapor drying cannot be applied to heat-sensitive materials because of the high temperatures.

Commercial drying equipment with recycled solvent vapor as the drying medium is available. Installations have been built to dry textile sheeting and organic chemicals.

Flash Drying

Finely divided solid particles that are dispersed in a hot gas stream can be dried by flash drying, which is rapid and uniform. Commercial applications include drying pigments, synthetic resins, food products, hydrated compounds, gypsum, clays, and wood pulp.

CHAPTER 28

VENTILATION OF THE INDUSTRIAL ENVIRONMENT

Heat Control in Industrial Work Areas 28.1
Heat Exposure Control 28.5
Ventilation Design Principles 28.5
General Comfort and Dilution Ventilation 28.8
Natural Ventilation 28.17
Air Curtains 28.18
Roof Ventilators 28.20
Heat Conservation and Recovery 28.21

GENERAL ventilation controls heat, odors, and hazardous chemical contaminants that could affect the health and safety of industrial workers. For better control, heat and contaminants should be exhausted at their sources by local exhaust systems, which require lower airflows than general (dilution) ventilation (Goldfield 1980). Chapter 29, Industrial Local Exhaust Systems, supplements this chapter.

General ventilation can be provided by mechanical systems, by natural draft, or by a combination of the two. Examples of combination systems include (1) mechanical supply with air relief through louvers and/or other types of vents and (2) mechanical exhaust with air replacement inlet louvers and/or doors.

As a rule, mechanical supply systems provide the best control and the most comfortable environment. They consist of an inlet section, a filter, heating and/or cooling equipment, a fan, ducts, and air diffusers for distributing air within the building. When toxic gases and particles are not present, air that is cleaned in the general exhaust system or in free-hanging filter units can be recirculated via a return duct. Air recirculation can reduce heating costs in winter.

A general exhaust system, which removes air contaminated by gases or particles not captured by local exhausts, usually consists of inlets, ducts, an air cleaner, and a fan. After air passes through the filters, cleaned air is discharged outside or part is returned to the building. The cleaning efficiency of an air filter should conform to environmental regulations and depends on factors such as building location, background contaminant concentrations in the atmosphere, nature of the contaminants, and height and velocity of the discharge. In some cases, for example when the industrial zone is located away from residential areas, a general exhaust system may not have an air cleaner.

Many industrial ventilation systems must handle simultaneous exposures to heat and hazardous substances. In these cases, ventilation can be provided by a combination of local exhaust, general supply, and general exhaust systems. The ventilation engineer must carefully analyze supply and exhaust air requirements to determine the optimum balance between them. For example, air supply makeup for hood exhaust may be insufficient for control of heat exposure. It is also important to consider seasonal effects on the performance of ventilation systems.

In specifying acceptable design toxic chemical and heat exposure levels, the industrial hygienist or industrial hygiene engineer must consult the appropriate government standards and guidelines given either in this chapter or in reference materials. The standard levels for most chemical and heat exposures are time-weighted averages that allow excursions above the limit as long as they are balanced by equivalent excursions below the limit during the workday. However, exposure level standards for heat and contaminants are not lines of demarcation between safe and unsafe exposures. Rather, they represent conditions to which, it is believed, nearly all workers may be exposed day after day without adverse effects (ACGIH 1998b). Because a small percentage of workers may be overly stressed at exposure levels below the standards, it is prudent for the ventilation engineer to design for exposure levels below the limits.

The preparation of this chapter is assigned to TC 5.8, Industrial Ventilation.

In the case of exposure to toxic chemicals, the number of contaminant sources, their generation rates, and the effectiveness of exhaust hoods are rarely known. Consequently, the ventilation engineer must rely on common ventilation/industrial hygiene practice when designing toxic chemical controls. Close cooperation among the industrial hygienist, the process engineer, and the ventilation engineer is required (Schroy 1986).

This chapter describes principles of good ventilation practice and includes other information on hygiene in the industrial environment. Various publications from the U.S. National Institute for Occupational Safety and Health (NIOSH 1986), the British Occupational Hygiene Society (1987), the National Safety Council (1988), and the U.S. Department of Health and Human Services (1986) provide in-depth coverage of industrial hygiene principles and their application.

Ventilation control alone is frequently inadequate for meeting heat stress standards. Optimum solutions may involve additional controls, such as spot air cooling, changes in work-rest patterns, and radiation shielding. Goodfellow and Smith (1982) summarized the technical progress being made in the industrial ventilation field by different investigators throughout the world. Proceedings from international symposiums (e.g., Ventilation '85, '88, '91, '94, and '97) are also valuable sources of information on ventilation technology.

Supplemental information can be found in Chapters 16 through 21, 23, 24, and 25 of the 2000 *ASHRAE Handbook—Systems and Equipment*. Chapters 11 through 30 of this volume include ventilation requirements for specific applications, and Chapter 44 covers control of gaseous contaminants. Fundamentals of space air diffusion are covered in Chapter 31 of the 1997 *ASHRAE Handbook—Fundamentals*.

HEAT CONTROL IN INDUSTRIAL WORK AREAS

Ventilation for Heat Relief

Many industrial work situations involve processes that release large amounts of heat and moisture to the environment. In such environments, it may not be economically feasible to maintain comfort conditions (ASHRAE *Standard* 55), particularly during the hot summer months. Comfortable conditions are not physiologically necessary; the body must be in thermal balance with the environment, but this can occur at temperature and humidity conditions well above the comfort zone. In areas where heat and moisture gains from a process are low to moderate, comfort conditions may not be provided simply because personnel exposures are infrequent and of short duration. In such cases, ventilation is one of many controls that may be necessary to prevent excessive physiological strain from heat stress.

The engineer must distinguish between the control needs for hot-dry industrial areas and warm-moist conditions. In **hot-dry** areas, a process gives off only sensible and radiant heat without adding moisture to the air. This increases the heat load on exposed workers, but the rate of cooling by evaporation of sweat is not reduced. Heat balance may be maintained, but it may be at the expense of excessive sweating. Hot-dry work situations occur around furnaces,

forges, metal-extruding and rolling mills, glass-forming machines, and so forth.

In **warm-moist** conditions, a wet process gives off mainly latent heat. The rise in the heat load on workers may be insignificant, but the increased moisture content of the air seriously reduces cooling by the evaporation of sweat. The warm-moist condition is potentially more hazardous than the hot-dry condition. Typical warm-moist operations are found in textile mills, laundries, dye houses, and deep mines where water is used extensively for dust control.

The industrial heat problem is affected by the local climate. Solar heat gain and elevated outdoor temperatures increase the heat load at the workplace, but these contributions may be insignificant compared to the process heat generated locally. The moisture content of the outdoor air is an important factor that can affect hot-dry work situations by seriously restricting an individual's evaporative cooling. For warm-moist conditions, solar heat gain and elevated outdoor temperatures are more important because the moisture contributed by the outdoor air is insignificant compared to that released by the process.

Both ASHRAE and the International Organization for Standardization (ISO) have standards for thermal comfort conditions for humans (ASHRAE *Standard* 55 and ISO *Standard* 7730). The research these standards are based on was performed mainly under environmental conditions similar to those in commercial and residential buildings, with relatively low activity levels (mainly sedentary, metabolic rate of 70 W/m^2), normal indoor clothing (insulation value of 0.08 to 0.155 m$^2 \cdot$K/W), and a limited range of environmental parameters.

Analyses by Zhivov and Olesen (1993) and Olesen and Zhivov (1994) show that existing thermal comfort standards can be extended to workplaces with higher levels of activity.

Methods for evaluating the general thermal state of the body both in comfort conditions and under heat and cold stress are based on an analysis of the heat balance for the human body, which is discussed in Chapter 8 of the 1997 *ASHRAE Handbook—Fundamentals*. A person may find the thermal environment unacceptable or intolerable due to local effects on the body caused by asymmetric radiation, air velocity, vertical air temperature differences, or contact with hot or cold surfaces (floors, machinery, tools, etc.).

Moderate Thermal Environments

ISO *Standard* 7730 defines the **predicted mean vote and predicted percent dissatisfied (PMV and PPD) indices** (Fanger 1982) for evaluating moderate thermal environments. To quantify comfort, the PMV index gives a value on the seven-point ASHRAE thermal sensation scale:

+3	hot
+2	warm
+1	slightly warm
0	neutral
–1	slightly cool
–2	cool
–3	cold

An equation in the standard for calculating the PMV index is based on six factors: clothing, activity, air temperature, mean radiant temperature, air speed, and humidity. Even if the PMV is 0, at least 5% of the occupants will be dissatisfied with the thermal environment. This method is also discussed in Chapter 8 of the 1997 *ASHRAE Handbook—Fundamentals*.

The PMV index is determined assuming that all evaporation from the skin is transported through the clothing to the environment; therefore, the PMV index is applicable only within $-2 < PMV < +2$, that is, for thermal environments where sweating is minimal. The PMV index is not applicable for hot environments.

Another method used to estimate combined effects in moderate environments is the **effective temperature** ET*, which is described in Chapter 8 of the 1997 *ASHRAE Handbook—Fundamentals.* In the comfort range, it gives similar results to the PMV index.

ASHRAE *Standard* 55 specifies ranges for operative temperatures that will be acceptable to at least 90% of the occupants. For example, for a sedentary activity level (70 W/m^2) and typical indoor clothing, the standard recommends the following operative temperature ranges: in winter (heating period, 0.14 to 0.155 m$^2 \cdot$K/W), 20 to 24°C; in summer (cooling period, 0.08 m$^2 \cdot$K/W), 23 to 26°C.

Operative temperatures for activities higher than 70 W/m^2 (but less than 175 W/m^2) can be found from ISO *Standard* 7730 or can be calculated from the operative temperatures at sedentary conditions using the following equation (ASHRAE *Standard* 55):

$$t_o^{act} = t_o^{sed} - 0.33(0.155 + R_{cl})(M - 70) \quad (1)$$

where

t_o^{act} = operative temperature for activity, °C
t_o^{sed} = operative temperature for sedentary conditions, °C
R_{cl} = insulation value for garment ensemble, m$^2 \cdot$K/W
M = metabolic rate, W/m^2

Heat Stress—Thermal Standards

Heat stress is the thermal condition of the environment that, in combination with metabolic heat generation of the body, causes the deep body temperature to exceed 38°C. The recommended heat stress index for evaluating an environment's heat stress potential is the **wet-bulb globe temperature** (WBGT), which is defined as follows:

Outdoors with solar load:

$$WBGT = 0.7t_{nw} + 0.2t_g + 0.1t_{db} \quad (2)$$

Indoors or outdoors with no solar load:

$$WBGT = 0.7t_{nw} + 0.3t_g \quad (3)$$

where

t_{nw} =natural wet-bulb temperature (no defined range of air velocity; different from saturation temperature or psychrometric wet bulb), °C
t_{db} =dry-bulb temperature (shielded thermometer), °C
t_g =globe temperature (Vernon bulb thermometer, 150 mm diameter), °C

The **threshold limit value** (TLV) for heat stress is set for different levels of physical stress, as shown in Figure 1 (NIOSH 1986). This graph depicts the allowable work regime (in terms of rest periods and work periods each hour) for different levels of work over a range of WBGT. For applying Figure 1, it is assumed that the rest area has the same WBGT as the work area. If the rest area is at or below 24°C WBGT, the resting time is reduced by 25%. The curves are valid for workers acclimatized to heat. Refer to criteria of the National Institute for Occupational Safety and Health (NIOSH 1986) for recommended WBGT ceiling values and time-weighted average exposure limits for both acclimatized and unacclimatized workers.

The **WBGT index** is an international standard (ISO *Standard* 7243) for the evaluation of hot environments. The WBGT index and activity levels should be evaluated on 1 h mean values; that is, WBGT and activity are measured and estimated as time-weighted averages on a 1 h basis for continuous work, or on a 2 h basis when the exposure is intermittent. Although recommended by NIOSH, the WBGT has not been accepted as a legal standard by the Occupational Safety and Health Administration (OSHA). It is generally used in conjunction with other methods to determine heat stress.

Although Figure 1 is useful for evaluating heat stress, it is of limited use for control purposes or for the evaluation of comfort. Air velocity and psychrometric wet-bulb measurements are usually needed in order to specify proper controls, and neither is measured in WBGT determinations. However, Harris (1988) used the

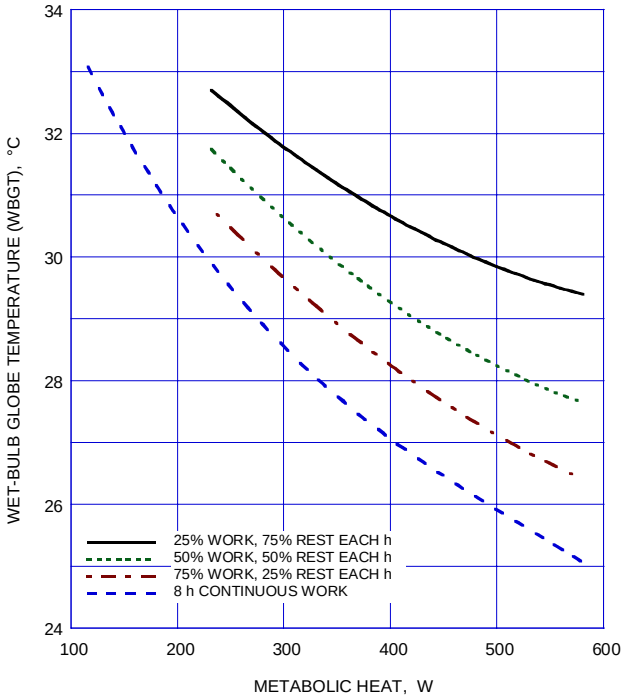

Fig. 1 Recommended Heat Stress Exposure Limits for Heat-Acclimatized Workers
[Adapted from NIOSH (1986)]

adiabatic wet-bulb temperature line on a psychrometric chart to represent natural wet bulb as a conservative substitute in heat stress situations. More useful tools, including the **heat stress index** (HSI), may be found in Chapter 8 of the 1997 *ASHRAE Handbook—Fundamentals* and in ISO *Standards* 7730 and 7933.

The thermal relationship between humans and their environment depends on four independent variables:

- Air temperature
- Radiant temperature
- Moisture content of the air
- Air velocity

Together with the rate of internal heat production (the metabolic rate), these factors may combine in various ways to create different degrees of heat stress. Heat stress index formulas include calculations of the relative contributions to stress resulting from metabolism, radiant heat gain (or loss), convective heat gain (or loss), and evaporative (sweat) heat gain (or loss). For supplemental information on the evaluation and control of heat stress using such methods as reduction of radiation, changes in work-rest pattern, spot cooling, and cooling vests and suits, refer to NIOSH (1986), ACGIH (1998b), Constance (1983), Caplan (1980), and Brief et al. (1983).

Local Discomfort and Individual Parameters

Even if the combined effect of comfort parameters provides a heat balance for the body as a whole, parts of the body may experience discomfort from drafts, radiant asymmetry, and/or vertical temperature differences.

Air Speed. Air at increased speeds is often used in industry to provide cooling in warm environments. Depending on the conditions, an air speed that is too high may cause a **draft**, which is defined as unwanted convective cooling of one or more parts of the body. Drafts are probably the largest source of complaints from occupants at low activity levels (sedentary, standing) in air-conditioned spaces.

The maximum value of the mean air speed in an occupied zone depends on the air temperature t_a and the turbulence intensity Tu. ASHRAE *Standard* 55 provides information on air speed and temperature limits for sedentary (less than 70 W/m^2), light (95 W/m^2), medium 115 W/m^2), and high (greater than 175 W/m^2) levels of human activity; however, this standard does not provide precise relationships. Air speeds as high as 1.5 m/s are acceptable, unless they cause problems unrelated to thermal comfort (e.g., blowing of papers or blowing of shield gas in semiautomatic welding).

Combinations of air temperature and speed related to comfort conditions in winter and summer periods for different levels of human activity (assuming typical indoor clothing) are presented in Figure 2, which is based on the data presented in ISO *Standard* 7730. Other research and normative data on acceptable and optimal thermal comfort environments are discussed by Olesen and Zhivov (1994).

The effect of turbulence intensity on the sensation of draft has been investigated by Fanger et al. (1988) for different methods of air distribution. **Turbulence intensity** is the ratio of the magnitude of the velocity fluctuation to the mean velocity:

$$\mathrm{Tu} = 100\frac{V'}{\bar{V}} \tag{4}$$

where

Tu = turbulence intensity, %
V' = standard deviation of air velocity fluctuation
V = mean air velocity

Based on studies of different air distribution methods, Fanger et al. (1988) found that turbulence intensity in ventilated spaces depends on the type of ventilation system and varies from 10 to 70%. For air velocities ranging from 0.05 to 0.4 m/s and air temperatures ranging from 20 to 26°C, tests were conducted at three levels of turbulence intensity: low (Tu less than 12%), medium (Tu between 20% and 35%), and high (Tu greater than 55%). For displacement systems having the same mean air velocity and temperature, Fanger et al. found that periodically fluctuating airflow is less comfortable than steady airflow. Very little data on turbulence intensity of different air distribution methods are available, and the effect of turbulence on draft sensation at higher activity levels has not been studied.

Radiant Temperature Asymmetry. Limits of 10 K and 5 K for the radiant asymmetry from cold walls and warm ceilings, respectively, are recommended in both ASHRAE *Standard* 55 and ISO *Standard* 7730. These data are based on testing with sedentary persons in 0.09 m^2·K/W clothing (Fanger et al. 1985). Similar data are available for warm walls and cold ceilings. In industrial workplaces, radiant asymmetry from overhead radiant heaters or a hot roof is the main cause of problems. The values established for sedentary persons are too conservative for the higher activity levels and higher ceilings encountered in industry.

Langkilde et al. (1985) showed that significantly higher radiant asymmetry is acceptable. Based on criteria similar to those just described, and requiring that no more than 5% of the occupants are dissatisfied, they recommend an asymmetry limit of 10 to 14 K.

Vertical and Horizontal Air Temperature Differences. Another comfort parameter described in ASHRAE *Standard* 55 and ISO *Standard* 7730 is the temperature difference between the head and feet. The recommended limit of 3 K is based on studies with sedentary persons (Olesen et al. 1979) and cannot be used directly with higher activity levels. It is not the air temperature difference alone, but the combined effect of differences in air temperature, air velocity, and radiant temperature between the head and feet that causes discomfort. Data for industrial environments are available only in GOSSTROY (1992), in which the vertical temperature difference in occupied zones is limited to 4 K, and the horizontal temperature difference cannot exceed 4 K at light activity, 5 K at medium activity, and 6 K at high activity.

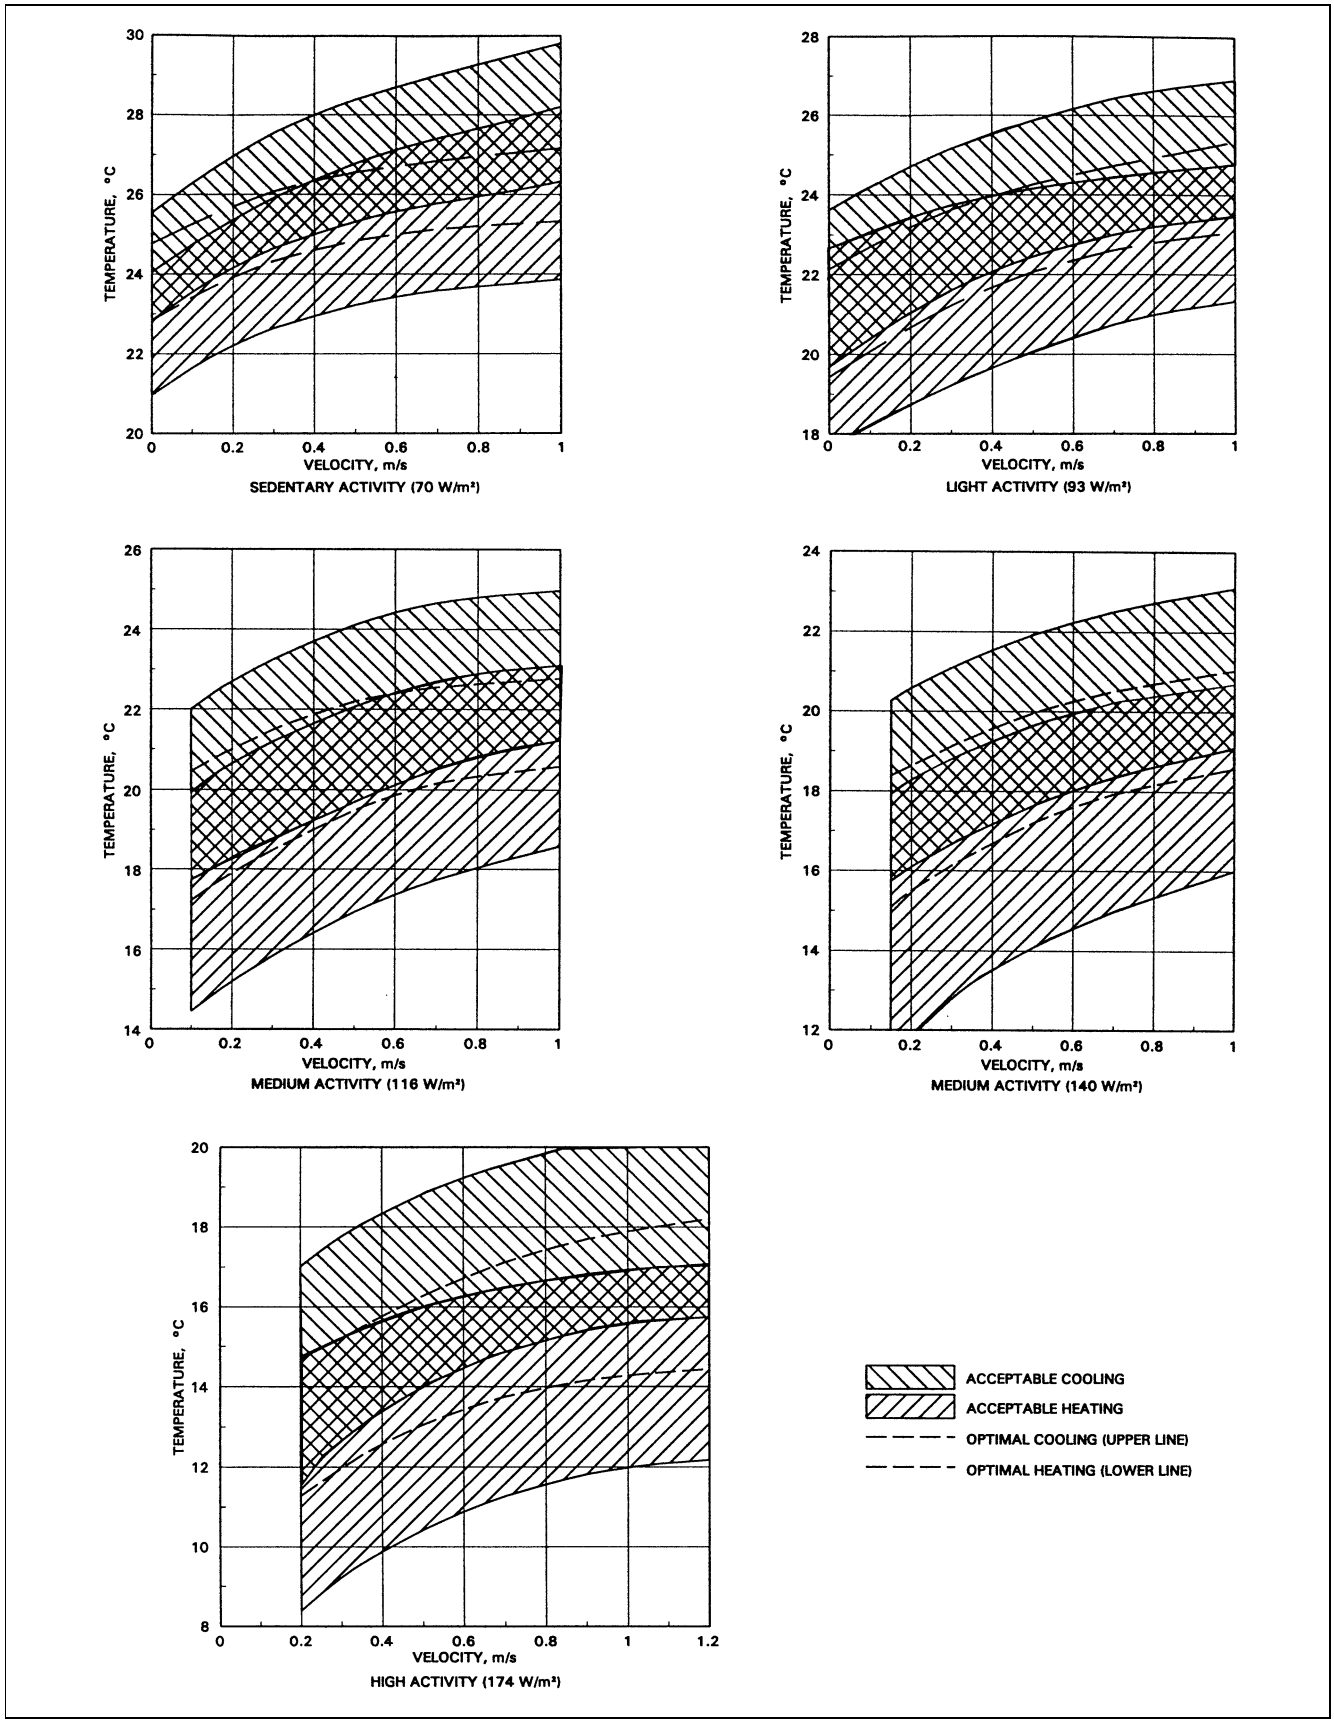

Fig. 2 Optimal and Acceptable Ranges of Air Temperature and Air Speed in Occupied Zone for Different Levels of Human Activity (ISO *Standard* 7730)

Spot Cooling. If the workplace is located near a source of radiant heat that cannot be entirely controlled by radiation shielding, spot cooling is recommended (Olesen and Nielsen 1980, 1981, 1983; Azer 1982a, 1982b, 1984). The air temperature of the workplace is limited to 20 to 30°C, depending on the heat load and the air speed shown in Table 1.

Table 2 gives information about combinations of air temperature and speed in jets used for spot cooling. More detailed information is provided in GOSSTROY (1992). If the air temperature in the occupied zone is less than or greater than the temperatures listed in Table 2, the air temperature in the jet should be increased or decreased, respectively, by 0.4 K for each degree of temperature difference. The average temperature in the jet may not be lower than 16°C.

The temperature of the radiating surface should be averaged over the period of radiation. If the radiation lasts less than 15 min or more than 30 min, the jet air temperature can be respectively 2 K greater than or less than the values listed in Table 2.

HEAT EXPOSURE CONTROL

Control at Source

Heat exposure can be reduced by insulating hot equipment, locating such equipment in zones with good general ventilation or outdoors, covering steaming water tanks, providing covered drains for direct removal of hot water, and maintaining tight joints and valves where steam may escape.

Local Exhaust Ventilation

Local exhaust ventilation removes heated air generated by a hot process and/or nonbuoyant gases emitted by process equipment, while removing a minimum of air from the surrounding space.

The following criterion can be used to evaluate the economics of local exhaust versus general (dilution) ventilation:

$$\frac{C_{le} - C_o}{K_G(C_{oz} - C_o)} > (1.2 \text{ to } 1.5) \tag{5}$$

where

C_{le} = concentration of gas, vapor, or particles evacuated by local exhausts, kg/kg
C_o = concentration of gas, vapor, or particles in air supplied, kg/kg
C_{oz} = concentration of gas, vapor, or particles in occupied zone, kg/kg
K_G = coefficient of air exchange efficiency for removing gas contaminants from occupied zone

If the value calculated is greater than 1.2 to 1.5, it is more economical to use local exhaust. Chapter 29 covers the design of exhaust hoods and duct systems for local exhaust.

Radiation Shielding

In some industries, the major environmental heat load is radiant heat from hot objects and surfaces, such as furnaces, ovens, furnace flues and stacks, boilers, molten metal, hot ingots, castings, and forgings. Because air temperature has no significant effect on radiant heat flow, ventilation is of little help in controlling such exposure. The only effective control is to reduce the amount of radiant heat impinging on the workers. Radiant heat exposure can be reduced by insulating or placing radiation shields around the source (Chapter 3 of the 1997 *ASHRAE Handbook—Fundamentals*).

Radiation shields are effective in the following forms:

- **Reflective shielding.** Sheets of reflective material or insulating board are semipermanently attached to the hot equipment or arranged in a semiportable floor stand.
- **Absorptive shielding (water-cooled).** These shields absorb and remove heat from hot equipment.
- **Transparent shields.** Heat-reflective tempered plate glass, reflective metal chain curtains, and close mesh wire screens moderate radiation without obstructing view of the hot equipment.
- **Flexible shielding.** Aluminum-treated fabrics give a high degree of radiation shielding.
- **Protective clothing.** Reflective garments such as aprons, gauntlet gloves, and face shields provide moderate radiation shielding. For extreme radiation exposures, complete suits with vortex tube cooling may be required.

If the shield is a good reflector, it will remain relatively cool in severe radiant heat. Bright or highly polished tinplate, stainless steel, and ordinary flat or corrugated aluminum sheets are efficient and durable. Foil-faced plasterboard, although less durable, gives reflects well on one side. To be efficient, however, the reflective shield must remain bright.

The best radiation shields are infrared reflectors, which should reflect the radiant heat back to the primary source, where it can be removed by local exhaust. However, unless the shield completely surrounds the primary source, some of the infrared energy will be reflected into the cooler surroundings and possibly into an occupied area. The direction of the reflected heat should be studied to ensure proper installation of the shielding.

VENTILATION DESIGN PRINCIPLES

General Ventilation

General ventilation supplies and/or exhausts air to provide heat relief, dilute contaminants to an acceptable level, and replace (make up) exhaust air. Ventilation can be provided by natural or mechanical supply and/or exhaust systems. Outdoor air is unacceptable for ventilation if it is known to contain any contaminant at a concentration above that given in ASHRAE *Standard* 62. If air is thought to contain any contaminant not listed in the standard, guidance on acceptable exposure levels should be obtained from OSHA standards (ACGIH 1998a). General ventilation rates must be high enough to dilute the carbon dioxide produced by the occupants.

Ventilation design for the industrial environment can be established using the following techniques (Goodfellow 1985, 1986, 1987):

- Field testing
- Fluid dynamic modeling
- Computer modeling

For complex industrial ventilation problems, fluid dynamic modeling or computer modeling are often used in addition to field testing.

Field Testing

A field testing program must be organized and developed in detail prior to its trial in the field. Ventilation flow in large process buildings is usually complex, so an inexperienced sampling team could collect irrelevant or insufficient data for the subsequent analysis. Therefore, the field testing program should be reviewed and approved by plant operating personnel before the actual field testing begins. A good approach is to (1) perform preliminary calculations for all sources, (2) identify information gaps, and (3) determine what data must be collected.

Although each processing or manufacturing operation has unique ventilation flows, design parameters, and field testing protocol, many elements of a field testing program can be applied to all ventilation problems. The major engineering activities in a ventilation field testing program are listed in order in Table 3, which includes brief descriptions of the tasks and scope of the work required for each activity.

Step 1 in Table 3, gathering information, includes obtaining and studying all reports and drawings pertinent to the plant. Specific

Table 1 Acceptable Air Speed in Workplace

Activity Level	Air Speed, m/s
Continuous exposure	
Air-conditioned space	0.25 to 0.4
Fixed workstation, general ventilation or spot cooling	
Sitting	0.4 to 0.6
Standing	0.5 to 1.0
Intermittent exposure, spot cooling, or relief stations	
Light heat loads and activity	5 to 10
Moderate heat loads and activity	10 to 15
High heat loads and activity	15 to 20

Table 2 Recommended Spot Cooling Air Speed and Temperature

Activity Level	Air Speed in Jet, m/s, Averaged on 0.1 m^2 of Workplace	Average Air Temperature in Jet Cross Section, °C				
		Heat Flux Density, W/m^2				
		140-350	700	1400	2100	2800
Light—I	1	28	24	21	16	—
	2	—	28	26	24	20
	3	—	—	28	26	24
	3.5	—	—	—	27	25
Moderate—II	1	27	22	—	—	—
	2	28	24	21	16	—
	3	—	27	24	21	18
	3.5	—	28	25	22	19
Heavy—III	2	25	19	16	—	—
	3	26	22	20	18	17
	3.5	—	23	22	20	19

information about (1) current and future operating practices and (2) the nature of dust, chemical contaminants, and heat or cold stresses is required. A visit to the site should include a walk-through ventilation survey using a questionnaire or data sheet developed by the ventilation engineer and experienced process and operating personnel for the specific industry. The questionnaire is used to identify the operating practices (present and future) to be used as the design basis for the ventilation system. An industrial hygienist should work with the ventilation engineer to establish the scope and extent of the sampling program.

Step 4 in Table 3, developing details of the field testing program, includes preparation of the field data log sheets prior to the actual field testing.

Step 5 in Table 3, carrying out the field testing program, includes the following:

- Measurement of air velocities through all openings. Sufficient time must be allowed to determine representative velocities.
- Measurement of the temperature for each velocity measured. For air entering the building, the ambient temperature should be recorded hourly. The thermometer or temperature probe should not be exposed to sunlight or radiant heat from hot objects. Good temperature readings are important for heat balance calculations, and there must be sufficient temperature data to evaluate the air density distribution.
- Measurement of the mean surface temperatures of hot surfaces to determine the subsequent heat release and air movement.
- Recording weather data. Weather data also should be obtained from the nearest airport or meteorological station. The data, which should be recorded hourly, include ambient temperature, relative humidity, wind speed, and wind direction.
- Recording plant activities during the testing program. This includes the operational status of all major process and environmental equipment, as well as production levels. Plant records and charts from process operations should be obtained. It is helpful if the ventilation field testing team can work with plant personnel.

Table 3 Engineering Activities for Ventilation Field Testing Program

Activity	Specific Tasks
1. Gather information	Obtain drawings, reports, operating procedures Review existing data and studies Visit plant Define problem (summer, winter, heat/cold stress, chemical supply, exhaust)
2. Collect data on ventilation openings	Develop isometric drawings: plans, sections Develop schedule of openings (type, size, location)
3. Develop plant questionnaire	Develop process flow sheet and general layout Identify significant heat sources in building Identify typical operating practice Identify gaps in data to be filled in by field testing
4. Develop details of field testing program	Determine building ventilation flow rates Determine in-plant flows Develop field data log sheets for ventilation measurements, weather conditions, plant operating records, etc.
5. Carry out field testing program	Perform field measurements (velocity, temperature, pressure, etc.)
6. Analyze data and perform calculations	Determine plant ventilation flow balance Determine in-plant flow patterns Perform heat balance calculations (total plant/ventilation) Calculate air set-in-motion volumes
7. Perform computer simulation of ventilation flows (natural ventilation)	Calibrate using field test data Run program for different conditions (summer, winter, etc.)
8. Produce field testing report	Summarize test conditions and test results Make recommendations

Step 8 in Table 3, the preparation of a report on the ventilation field testing program, includes reporting all field data, calculations, and test results. Using this report, an experienced ventilation engineer can recommend cost-effective solutions for any plant ventilation problem.

Fluid Dynamic Modeling

Fluid dynamic modeling (small-scale modeling) is a valuable tool for modeling problems and developing alternative cost-effective solutions. It has been used extensively for a wide variety of industrial ventilation applications (Baturin 1972; Goodfellow 1985, 1987). Applications of scale modeling include the following:

- Finalizing building ventilation flow rates and schemes
- Examining internal flow patterns and contaminant concentrations at any location
- Examining external flow patterns, including quantitative measurements of downwash and transport of contaminants to other buildings
- Establishing the effectiveness of source hoods

Fluid dynamic modeling can be used in solving ventilation problems in existing plants and in the design of ventilation systems for new plants. For an existing plant, fluid dynamic modeling can supplement the field testing program.

For the design of ventilation systems for new process buildings, the following steps are recommended: (1) develop the overall ventilation concepts and architectural constraints using computer models; (2) design the structural steel while the small-scale model is constructed and tested; and (3) use the results of the small-scale

modeling to refine the ventilation design and to finalize all requirements.

Fluid dynamic modeling includes the following activities:

1. Define contaminant source characteristics.
2. Define environment flows, such as airflow rates, loads, and contaminant flows.
3. Develop details of the scope of the work.
4. Design the model system.
5. Construct the model system.
6. Test the program.
7. Produce the report.

In defining the contaminant source characteristics, the size of the industrial building and details about the source flux (e.g., heat and contaminant release rates) must be determined. Information about the major sources of heat is used to calculate heat balances and air volumes.

In defining environment flows, data are required on the external and internal flow conditions for the prototype. Information may be needed about site conditions such as wind speed and direction.

Design of the model system requires an examination of the scaling parameters and possible fluid media to select the best model for the specific ventilation problem. Although the most common media used in models are air and water, a variety of working or buoyancy-driven fluids are available. Fluid systems used include air and heated air, water and saltwater, water and carbon tetrachloride, and mercury and carbon tetrachloride. Usually, air models are the simplest and least expensive models to build and test, but they must be large to ensure fully turbulent flow. Because water has a smaller kinematic viscosity than air, a small model is required to ensure a high Reynolds number and turbulent flow. Flow visualization is easier with water-based models because velocities are lower than with air. Data measured in the model flow can be related quantitatively to the full-scale prototype flow by establishing dynamic similarity (geometric and kinematic) between the model and the prototype. If the model and prototype are to have similar ventilation, their Archimedes numbers must be equal (Baturin 1972):

$$\mathrm{Ar}_m = \mathrm{Ar}_p$$

$$\left(\frac{gL_o(t_o - t_s)}{V_o{}^2 T_s}\right)_m = \left(\frac{gL_o(t_o - t_s)}{V_o{}^2 T_s}\right)_p \tag{6}$$

where

g = gravitational acceleration rate, m/s^2
L_o = length scale, m
t_o = initial temperature of jet, °C
t_s = temperature of surrounding air, °C
V_o = initial air velocity of jet, m/s
T_s = room air temperature (absolute), K
p = subscript identifying prototype
m = subscript identifying model

An adequate simulation of the convective flows requires that the value of the Grashof-Prandtl number exceed 2×10^7:

$$\mathrm{Gr} \times \mathrm{Pr} = \frac{gL^3 \Delta t}{\nu^2 T_s} \times \frac{c_p \nu \rho}{k} = \frac{gL^3 \Delta t\, c_p \rho}{\nu T_s k} \geq 2 \times 10^7 \tag{7}$$

where

ν = kinematic viscosity, m^2/s
Δt = temperature difference between two points, K
c_p = specific heat at constant pressure, J/(kg·K)
k = thermal conductivity, W/(m·K)
ρ = density, kg/m^3

The technique used to measure a contaminant must be evaluated for its impact on the cost of the testing program and on the degree of accuracy of the measurements.

For any model testing program, the use of photography and video cameras to record results is suggested. The photographs and videos are invaluable for analyzing test results and for presenting the proposed solutions to management.

Computer Modeling

Figure 3 shows the flowchart for a computer ventilation model based on design equations for flow and heat balances.

Once the observed ventilation flow rates are correctly modeled, the computer program can be used to study the effects of different weather conditions (e.g., summer/winter, wind direction and speed) on the ventilation. The computer program is useful also for evaluating and comparing proposed schemes to find the most cost-effective method of improving the ventilation.

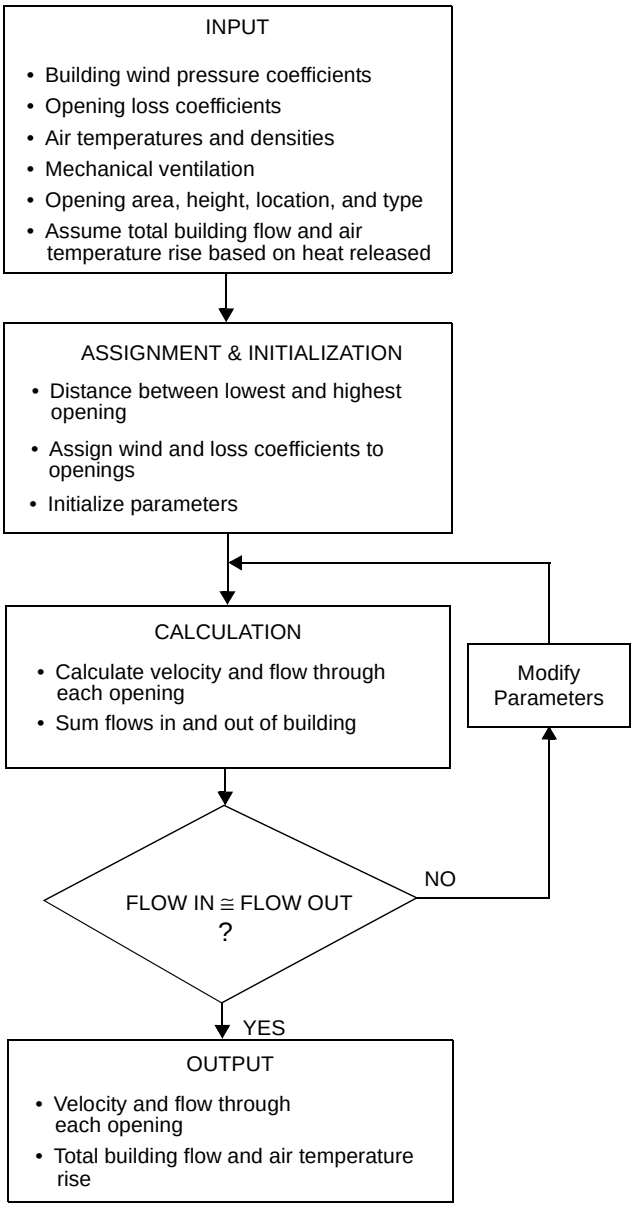

Fig. 3 Computer Ventilation Model Flow Diagram
(Goodfellow 1985)

Computer ventilation models can reliably predict the gross ventilation rates for complex process buildings. Computers enable the designer to examine the effect of architectural changes, wind conditions, or process changes on the performance of the proposed ventilation scheme. Problems such as contamination resulting from cross drafts or high temperatures in the work environment can be identified quickly and corrected. Other ventilation questions, such as internal flow patterns, intermittent flows, two- or three-dimensional flow, the location of fresh air, and contaminant concentrations in the breathing zone, can be answered using computer models.

Computer programs available for microcomputers can solve complex three-dimensional ventilation problems (Cawkwell and Goodfellow 1990). Proceedings for conferences such as Ventilation '85, '88, '91, '94, and '97 and RoomVent '90, '92, '94, and '96 include many technical papers on new computer programs for calculating contaminant levels as a function of the location and time spent in a workplace environment. These computer programs are used in the routine engineering design of ventilation systems.

Need for Makeup Air

For safe, effective operation, most industrial plants require makeup air to replace the large volumes of air exhausted to provide comfort and safety for personnel and good conditions for process operations. Makeup air consistently provided by good air distribution allows more effective cooling in the summer and more efficient and effective heating in the winter. The use of windows or other inlets that cannot function in stormy weather is discouraged. The most important functions of makeup air can be summarized as follows:

1. To replace air being exhausted through combustion processes and local and general exhaust systems (see Chapter 29).
2. To eliminate uncomfortable cross drafts by proper arrangement of supply air and to prevent infiltration (through doors, windows, and similar openings) that may make hoods unsafe or ineffective, defeat environmental control, bring in or stir up dust, or adversely affect processes by cooling or disturbances.
3. To obtain air from the cleanest source. Supply air can be filtered; infiltration air cannot.
4. To control building pressure and airflow from space to space for three reasons:
   (a) To avoid positive or negative pressures that make it difficult or unsafe to open doors, to replace air (Item 1), and to eliminate drafts and prevent infiltration (Item 2). See Table 4.
   (b) To confine contaminants and reduce their concentration and to control temperature, humidity, and air movement.
   (c) To recover heat and conserve energy.

GENERAL COMFORT AND DILUTION VENTILATION

Effective air diffusion in ventilated rooms and the proper quantity of conditioned air are essential for creating a comfortable working environment, for removing contaminants, and for reducing the initial and operating costs of a ventilation system.

To provide a comfortable and safe environment in the workplace, general ventilation systems must supply air that has the proper speed and temperature, as well as contaminant concentrations that are within permissible limits. In most cases, the objective is to provide tolerable (acceptable) working conditions rather than total comfort (optimal) conditions.

The design of a general ventilation system is based on the assumption that local exhaust ventilation, radiation shielding, and equipment insulation and encapsulation have been selected to minimize both the heat load and the contamination level in the workplace. In cold climates, infiltration and heat loss through the building shell must also be minimized.

Table 4 Negative Pressures That May Cause Unsatisfactory Conditions Within Buildings

Negative Pressure, Pa	Adverse Conditions That May Result
2.5 to 5.0	Worker draft complaints—High-velocity drafts through doors and windows.
2.5 to 12	Natural draft stacks ineffective—Ventilation through roof exhaust ventilators and flow through stacks with natural draft greatly reduced.
5 to 12	Carbon monoxide hazard—Backdrafting will take place in hot water heaters, unit heaters, and other combustion equipment not provided with induced draft.
7 to 25	General mechanical ventilation reduced—Airflows reduced in propeller fans and low-pressure supply and exhaust systems.
12 to 25	Doors difficult to open—Serious injury may result from unchecked, slamming doors.
25 to 60	Local exhaust ventilation impaired—Centrifugal fan fume exhaust flow reduced.

Source: ACGIH (1998b).

Quantity of Supplied Air

Sufficient air must be supplied to replace air exhausted by process ventilation and local exhausts, to provide dilution of contaminants (gases, vapors, or airborne particles) not captured by local exhausts, and to provide the required thermal environment. The amount of supplied air should be the largest of the amounts needed for temperature control, dilution, and replacement.

The airflow rate Q_o to be supplied through diffusers for temperature control can be estimated from the following equation:

$$Q_o = Q_{exh} + \frac{q - \rho c_p Q_{exh}(t_{oz} - t_o)}{\rho c_p K_t (t_{oz} - t_o)} \quad (8)$$

where

Q_o = required supply airflow rate, m^3/s
Q_{exh} = flow rate of air evacuated from occupied zone by general and/or local exhaust and process equipment, m^3/s
q = surplus heat gain or heat supplied to warm the air, kW
c_p = specific heat of air at constant pressure, kJ/(kg·K)
ρ = density of air, kg/m^3
t_{oz} = air temperature in occupied zone, °C
t_o = temperature of supplied air, °C
t_{exh} = temperature of exhausted air, °C
K_t = coefficient of efficiency for removing heat from occupied zone (see Table 5)
$= \frac{t_{exh} - t_o}{t_{oz} - t_o}$

The airflow rate Q_o required to remove water vapor released into the space at a rate M_w is given by the following equation:

$$Q_o = Q_{exh} + \frac{M_w - \rho Q_{exh}(W_{oz} - W_o)}{\rho K_w (W_{oz} - W_o)} \quad (9)$$

where

M_w = rate of water vapor release, kg/s
W_o = humidity ratio, kg water per kg dry air supplied
W_{oz} = humidity ratio, kg water per kg dry air in occupied zone
W_{exh} = humidity ratio, kg water per kg exhausted air
K_w = coefficient of efficiency for removing water vapor from occupied zone (see Table 5)
$= \frac{W_{exh} - W_o}{W_{oz} - W_o}$

The airflow rate Q_o required for dilution ventilation can be calculated as follows:

Table 5 Heat and Moisture Removal Efficiency Coefficients for Mechanically Ventilated Spaces with Insignificant Heat Load

	Heat/Moisture Removal Efficiency Coefficients K_t/K_w			
	Air Change Rate, ACH			
Air Supply Method	**3**	**5**	**10**	**>15**
Concentrated air jets	0.95/1.1	1.0/1.05	1.0/1.0	1.0/1.0
Concentrated air jets with vertical and/or horizontal directing jets	1.0/1.0	1.0/1.0	1.0/1.0	1.0/1.0
Inclined air jets from a height of				
Greater than 4 m	1.15/1.4	1.1/1.2	1.0/1.1	1.0/1.0
Less than 4 m	1.0/1.2	1.0/1.1	1.0/1.05	1.0/1.0
Trough ceiling-mounted air diffusers with				
Radial (linear) attached jets	0.95/1.1	1.0/1.05	1.0/1.0	1.0/1.0
Conical (compact) jets	1.05/1.1	1.0/1.05	1.0/1.0	1.0/1.0

Note: Insignificant heat load is defined as below 23 W/m^3.

$$Q_o = Q_{exh} + \frac{G - \rho Q_{exh}(C_{oz} - C_o)}{\rho K_G} \quad (10)$$

where

G = rate of contaminant release into space, kg/s
C_o = concentration of gas, vapor, or particles in air supplied, kg/kg
C_{oz} = concentration of gas, vapor, or particles in occupied zone, kg/kg
C_{exh} = concentration of gas, vapor, or particles in exhaust, kg/kg
K_G = coefficient of efficiency for removing gaseous contaminants from occupied zone

$$= \frac{C_{exh} - C_o}{C_{oz} - C_o}$$

The values of the coefficients K_t, K_w, and K_G depend on the method of air distribution, characteristics of the ventilated space, and activities within the space. They can be determined by laboratory and field tests.

In some cases, the value of K_t can also be obtained analytically (Shilkrot 1993; Pozin 1993). For mixing-type air distribution, the values of K_t, K_w, and K_G are 1 ± 0.1. Displacement ventilation and air supply with inclined jets lower than 4 m take advantage of thermal stratification. When the sources of heat and gaseous emissions are close to each other, both K_t and K_G can be greater than 1.2 and, in some cases, can reach 2.5 or more. Values of K_t and K_w for typical mixing-type air distribution are listed in Table 5. Values of K_t and K_w for displacement ventilation are close to those for natural ventilation and are listed in Table 10. When the sources of heat and gaseous emission are separated or are distributed uniformly in the occupied zone, the value of K_G for displacement ventilation does not differ much from 1, although it may be greater than 1.2 (Shilkrot and Zhivov 1992).

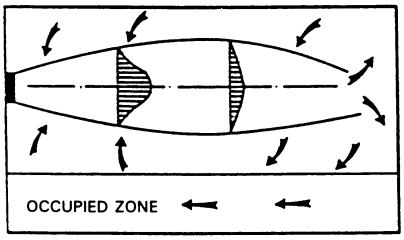
Local air supply does not provide the desired air quality for the entire occupied zone, but only for certain areas that are permanently occupied. This dramatically reduces the amount of supplied air.

The design value of the concentration C_{oz} of a contaminant in the occupied zone should not exceed an acceptable level of exposure such as a **permissible exposure limit** (PEL), a **threshold limit value** (TLV), or an in-house TLV. It is desirable to set design objectives below statutory PELs and TLVs because of variations in sensitivity to contaminants and because acceptable limits can be lowered. Determination of the generation rate G of the contaminant [in Equation (10)] can be based on production records, material balance, similar operations, and experience. However they are obtained, the acceptable exposure level and the contaminant generation rate are required for designing a dilution ventilation system properly. Designs based on the number of air changes per hour or other estimates are inadequate and could lead to unacceptably high exposure levels or to unnecessarily high installation costs and/or energy consumption.

Air Supply Methods

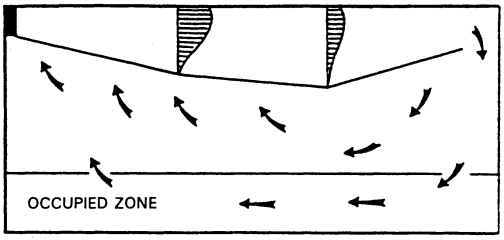
Air supply to industrial spaces can be by natural or mechanical ventilation systems. Although natural ventilation systems driven by gravity forces and/or wind effect are still widely used in industrial spaces (especially in hot premises in cold and moderate climates), they are inefficient in large buildings, may cause drafts, and cannot solve air pollution problems. Thus, most ventilation systems in industrial spaces are either mechanical or a combination of mechanical supply with natural exhaust. The most commonly used methods of air supply to industrial spaces are

- Mixing
- Displacement
- Unidirectional airflow (piston flow)
- Spiral vortex
- Localized



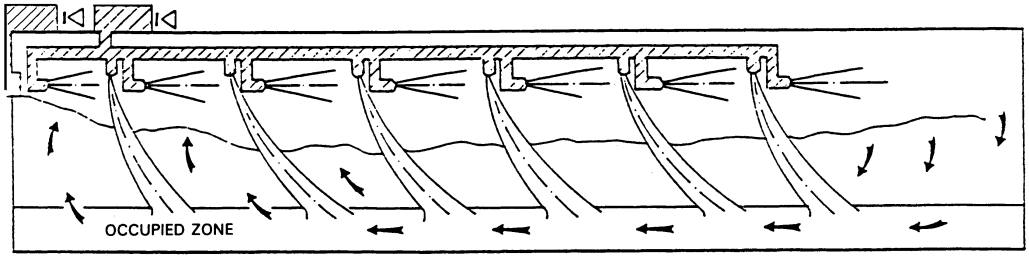
Mixing-Type Air Distribution. In mixing systems, air is normally supplied into the space at velocities much greater than those acceptable in the occupied zone. Supply air temperature can be above, below, or equal to the air temperature in the occupied zone, depending on the heating/cooling load. The supply air diffuser jet mixes with room air by entrainment, which reduces air velocities and equalizes the air temperature. The occupied zone is ventilated either directly by the air jet or by the reverse flow created by the jet. Properly selected and designed mixing air distribution creates relatively uniform air velocity, temperature, humidity, and air quality conditions in the occupied zone and over the room height.

In industrial spaces with mixing-type air distribution, air can be supplied with



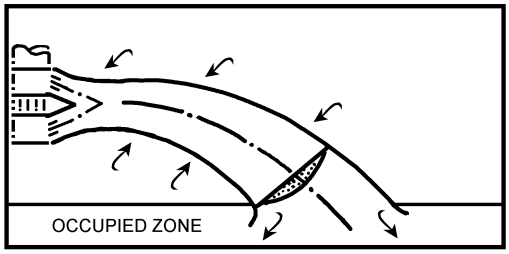
- Horizontal air jets, attached or not attached to the ceiling, with the occupied zone ventilated by reverse airflow (Figure 4A and 4B)
- Horizontal concentrated air jets assisted by additional vertical and/or horizontal directing jets (Figure 4C)
- Inclined air jets through the grilles and nozzles installed on walls and/or columns at a height of 3 to 6 m (Figure 5)
- Radial, conical, or compact air jets through ceiling-type air diffusers installed in or close to the ceiling (Figure 6A,B,C) or on the vertical duct drops (Figure 7)
- Horizontal compact or linear jets, attached to the ceiling, supplied through wall-mounted grilles (Figure 6D,E)
- Radial or linear jets through perforated surfaces of horizontal round or rectangular ducts (Figure 8)

Principles of mixing-type air distribution in industrial rooms are discussed by AIR-IX (1987), Cole (1995), Stroiizdat (1992b), Grimitlyn and Pozin (1993), Shepelev (1978), Tarnopolsky (1992), Zhivov (1992, 1993, 1994), and Zhivov et al. (1996).

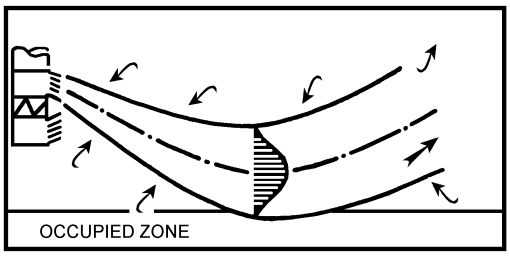


Displacement Ventilation Systems. Conditioned air slightly cooler than the desired room air temperature in the occupied zone is supplied from air outlets at low air velocities—0.5 m/s or less (Jack-

A. Air is supplied by nonattached horizontally projected jet, and occupied zone is ventilated by reverse flow.



B. Air is supplied by horizontally projected jet attached to the ceiling, and occupied zone is ventilated by reverse flow.



C. Air is supplied by horizontally projected concentrated air jets and vertical and/or horizontal directing jets, and occupied zone is ventilated by reverse flow and vertical directing jets.

B. SCHEMATIC OF HEATED AIR SUPPLY

C. INCLINED AIR SUPPLY IN MECHANICAL SHOP

Fig. 6 Air Supply with Inclined Jets
(Zhivov 1992; AIR-IX 1987)

man 1991; Skåret 1985; Skistad 1994; Shilkrot and Zhivov 1996). Under the influence of buoyancy, cold air spreads along the floor and floods the lower zone of the room. The air close to the heat source is heated and rises upward as a convective airstream; in the upper zone, this stream spreads along the ceiling. The lower part of the convective airstream induces the cold air of the lower zone of the room, and the upper part of the convective airstream induces the heated air of the upper zone of the room. The height of the lower zone depends on the air volume discharged through the panels into the occupied zone (Figure 9A) and on the amount of convective heat discharged by the sources (Figure 9B).

Typically, the outlets are located at or near the floor, and the supply air is introduced directly into the occupied zone. In some applications of displacement ventilation (e.g., in computer rooms or hot industrial buildings), air may be supplied to the occupied zone through a false floor. In other applications, supply air outlets may be located above the occupied zone. Returns are located at or close to the ceiling/roof through which air is exhausted from the room.

Displacement ventilation has been common in Scandinavia in the past 20 years and is becoming popular in other European countries. Displacement ventilation is preferable when contaminants are released in combination with surplus heat, and contaminated air is warmer and/or lighter than the surrounding air. Displacement ventilation design guidelines and limitations are described by Skistad (1994), Laurikainen (1995) and Zhivov et al. (1997).

Unidirectional Airflow Ventilation. Airflow can be vertical [air supplied from the ceiling and exhausted through the floor or vice versa (Figure 10A)] or horizontal [air supplied through one wall and exhausted through returns located on the opposite wall (Figure 10B)]. The outlets are uniformly distributed over the ceiling and floor or walls to provide a low-turbulence plug-type flow across the entire room. This type of system is mainly used for ventilating clean rooms, in which the main objective is to remove contaminant particles within the room (see Chapter 15), or in halls with high heat and/or contaminant loads with double flooring or floor pedestals.

Spiral Vortex Flow. This method of air distribution can be used to localize air contaminants in certain room areas and evacuate the polluted air from those areas. Air is supplied through vertical supply ducts located along a closed contour (preferably the walls), thus generating a vertical spiral vortex (Figure 11). An exhaust outlet can

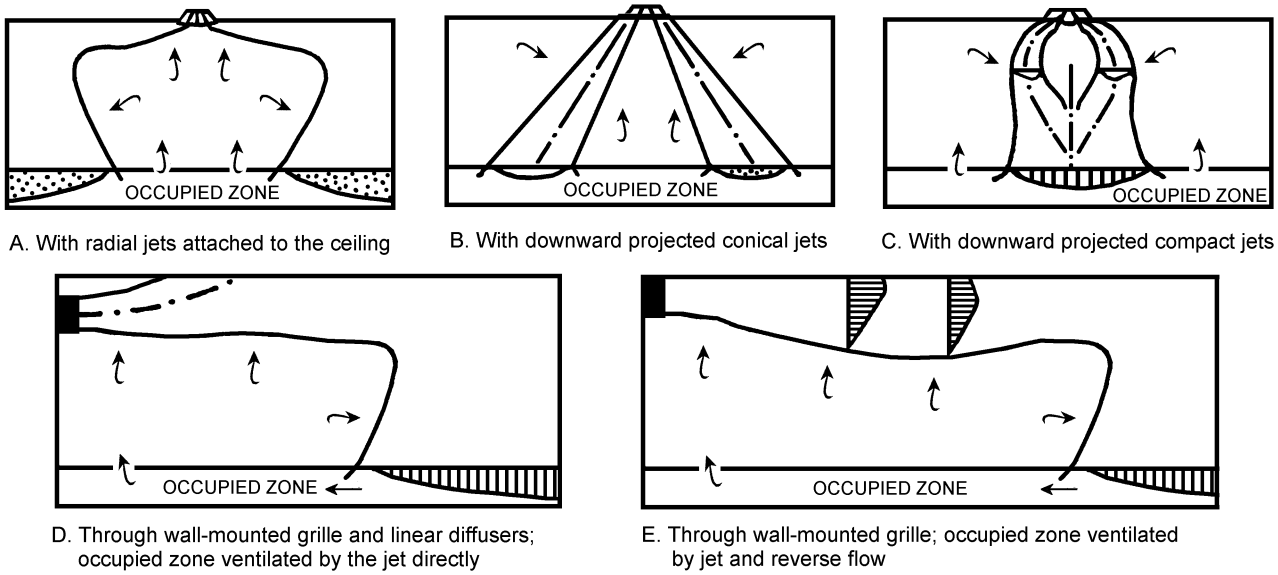

Fig. 6 Nonconcentrated Air Supply Methods

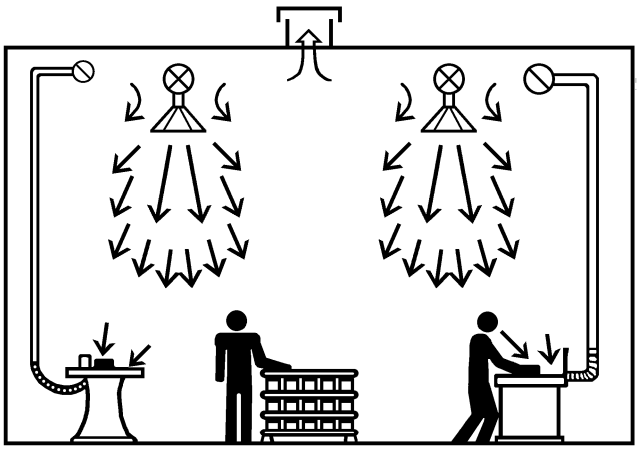

Fig. 7 Air Supply by Conical Air Jets Through Air Diffusers Installed on Vertical Duct Drops
(AIR-IX 1987)

be located in the ceiling near the center of the rotational flow. Low pressure in the vortex core concentrates contaminants in the core and prevents their diffusion to the clean space; contaminants are transported to the exhaust outlet along the core axis (Kuz'mina et al. 1986; Nagasawa et al. 1990)

Localized Ventilation. Air is supplied locally for occupied regions or a few permanent work areas (Figure 12). Conditioned air is supplied toward the breathing zone of the occupants to create comfortable conditions and/or to reduce the concentration of pollutants. These zones may have air 5 to 10 times cleaner than the surrounding air. In localized ventilation systems, air is supplied through one of the following devices:

- Nozzles or grilles (e.g., for spot cooling); specially designed low-velocity/low-turbulence devices (Kristensson and Lindqvist 1993)
- Perforated panels suspended on the vertical duct drops and positioned close to the work station
- Combination of vertical perforated supply air panels that creates an oasis around the work station and screens the work station from the surrounding environment (Kristensson and Lindqvist 1993; AIR-IX 1987)

installed lower than 4 m to supply conditioned air closer to the occupants and to take advantage of thermal stratification.

Guidelines for Selecting an Air Distribution Method

The economical and hygienic efficiencies of general ventilation systems depend mainly on the proper choice of air distribution method. Zhivov (1992) recommends the following steps for selecting a method of air distribution:

1. Select several possible methods of air distribution that are suitable for the given room, the comfort conditions required in the occupied zone, the size of the equipment, and the internal loads and operating modes of the HVAC or air-conditioning systems in a year-round cycle (variable/constant air volume system).
2. Determine the air volume requirements.
3. Determine the dimensions (length L and width B) of the area ventilated through one air diffuser, the type and size of air diffuser, the height of its installation, and the position of the controls for the design mode of system operation (e.g., highest heat loads in summer).
4. Check airflow pattern and air parameters in the occupied zone for other characteristic modes of system operation (e.g., heating regime). This is extremely important for VAV systems.
5. Compare the possible methods, and choose the most economical one.

Guidelines for the selection of an air distribution method for typical situations are presented in Table 6. Among the most important criteria used for selection are

- Room floor area and height
- Technological process and size of process equipment used; space obstruction of this equipment
- Number, location, and type (permanent or temporary) of work areas
- Type and amount of contaminants released into space, heating/cooling loads, air change rates
- Type of HVAC system used (variable air volume or constant air volume)
- Data on ventilation effectiveness for different air supply methods

If there are significant surplus heat gains in a room, the methods shown in Figure 5A, 6C, or 9 should be used with air diffusers

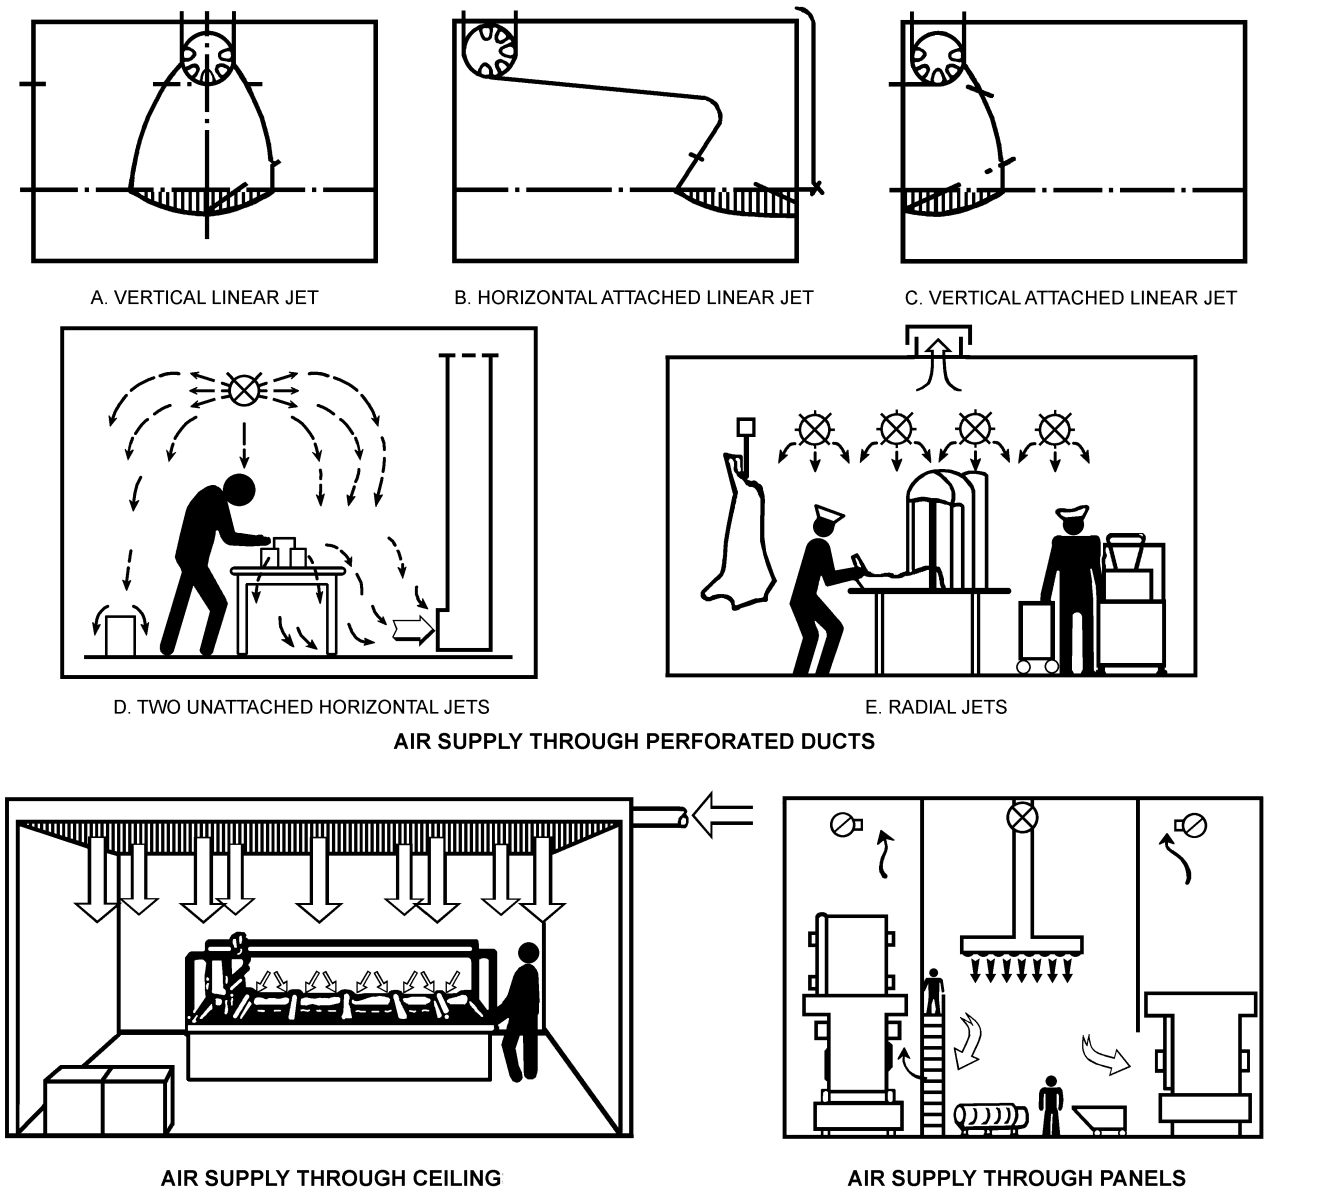

Fig. 8 Air Supply Through Perforated Ducts, Ceilings, and Panels
(AIR-IX 1987)

In variable air volume (VAV) systems, variations in the air volume supplied through diffusers and in the initial temperature difference over an annual cycle change the ratio between gravitational and inertial forces in the air jets. This affects the trajectory and throw of a jet, as well as the distance to the point where the jet separates from the ceiling. Undesirable airflow patterns or larger zones that are poorly ventilated may result, particularly in spaces with many obstructions. Zhivov (1990) discusses operation modes and air distribution design with VAV systems.

If the initial temperature differential ($t_o - t_{oz}$) of the supplied air is increased, the airflow supplied for temperature control can be reduced. Mixing-type air distribution methods provide high entrainment of the ambient air into the diffuser air jet, making it possible to increase the supply air temperature in the heating mode or decrease it in the cooling mode.

Displacement ventilation cannot be used to supply heated air and can be used to supply chilled air only if the temperature differential is less than 5 to 6 K.

When local exhaust ventilation is required for contaminant control, the exhaust rates are frequently greater than the required general ventilation for comfort. Under these conditions, the exhaust rate determines makeup air rates. A supply system must have air distribution arranged so that the makeup air is provided without disturbance at the hoods and process.

Caplan and Knutson (1978) and Peterson et al. (1983) established that the manner of air supply to a room with a hood has a major impact on the hood performance. The **hood performance factor** (or **hood index**) is defined as the logarithm (base 10) of the ratio of contaminant concentration within the hood to that just outside the hood. Adequate hood performance factors range from 4 to 6, with the higher number indicating a more effective hood installation (Fuller and Etchells 1979).

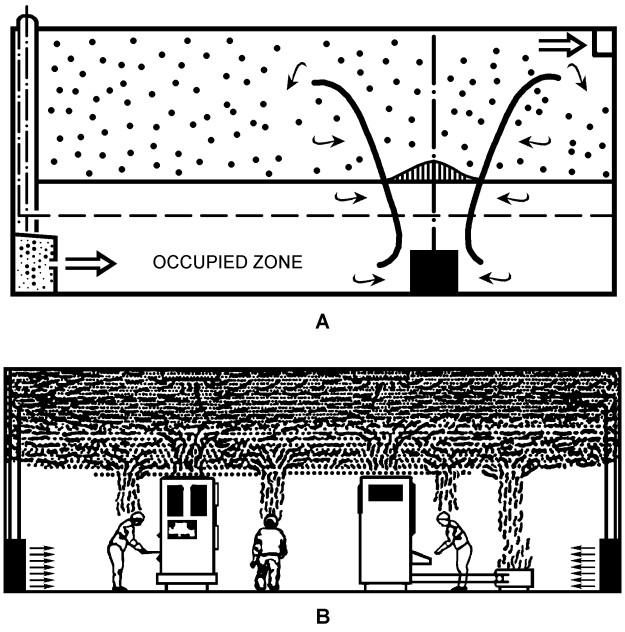

Fig. 9 Displacement Ventilation
(Kristensson and Lindqvist 1993)

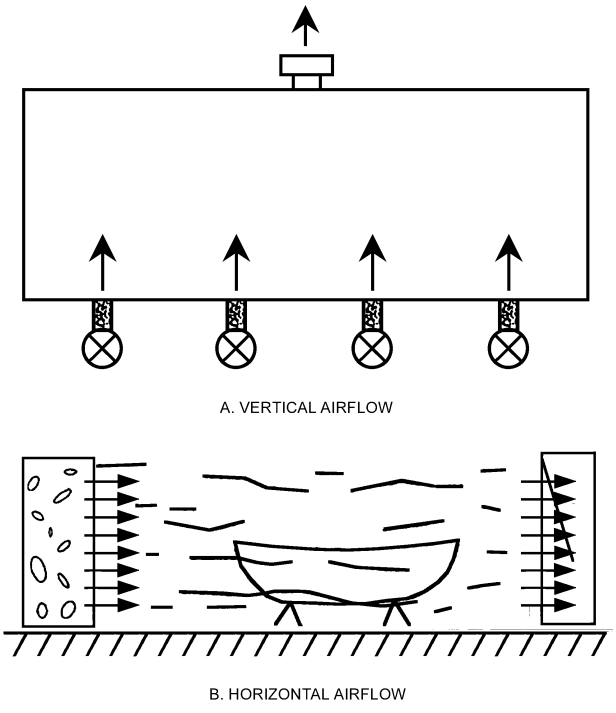

Fig. 10 Unidirectional Flow Systems
(AIR-IX 1987; LVIS 1996)

Local Area or Spot Cooling

In hot workplaces that have only a few work areas, it is impractical and wasteful to maintain a comfortable environment in the entire building. However, working conditions in areas occupied by workers can be improved by air-conditioned cabins, individual cooling, and spot cooling.

Air-conditioned cabins provide thermal comfort effectively, but they are expensive. Control rooms for monitoring production and manufacturing processes can use this technology.

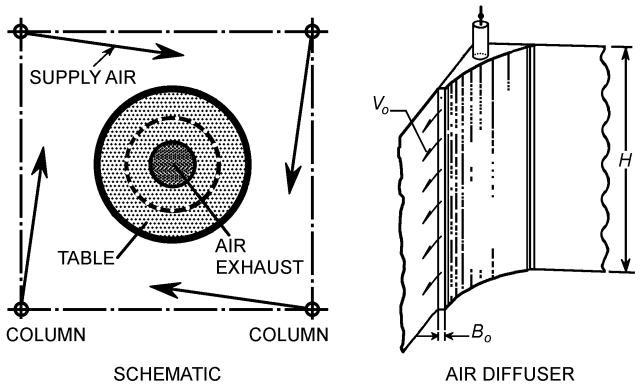

Fig. 11 Spiral Vortex Ventilation System
(Nagasawa et al. 1990; Kuz'mina et al. 1986)

Individual cooling can be provided by air- or water-cooled suits, vests, or helmets. **Air-cooled suits** are appropriate for moderately high temperatures and activity levels. The supply air can be cooled by a conventional heat exchanger or by a vortex tube. The suits are simple and self-regulating, provided that there is sufficient airflow. When the supply air is at skin temperature, heat is removed by increasing the evaporation of sweat. Lowering the supply air temperature improves the convection heat loss, thereby increasing the cooling capacity. **Water-cooled suits** have almost unlimited cooling capacity and lower pumping requirements, making them superior to air-cooled suits. A water-cooled garment needs a control system to protect the wearer from undercooling or overcooling. Various physiological measurements, including oxygen consumption and skin temperature measured at selected sites, have been used in the control of water-cooled garments.

Individual cooling with vests or helmets is appropriate if the thermal conditions are not extreme. Vests and helmets remove less heat than suits, but they cost less, are easier to use, and allow increased mobility.

Spot cooling is probably the most popular method of improving the thermal environment. Spot cooling can be provided by radiation (decreasing the mean radiant temperature), by convection (increasing the air velocity), or by a combination of the two methods. Spot cooling equipment is fixed at the workstation, whereas individual cooling has the worker wearing the cooling equipment.

Radiant spot cooling is provided by cooling panels installed near each workstation. Cooling panels decrease the mean radiant temperature, which allows greater radiant heat loss from the workers. The cooling power of radiant spot cooling can be changed either by altering the surface temperature of the cooling panels or by altering the angle factor between the cooling panels and the workers. (The angle factor is determined by the distance from the cooling panel to the worker and by the position of the cooling panel relative to the worker.) Radiant spot cooling is not very efficient. It may improve the thermal comfort of the workers, but it may also create local discomfort due to radiant asymmetry. In the design of radiant spot cooling, water condensation on the cooling panels should be considered. Condensation occurs when the surface temperature of the panel is equal to or less than the dew point temperature of the room air. If the surface temperature is below 0°C, the panel will be covered with ice. In practice, the poor efficiency, water condensation, and positioning of the panels may limit the application of radiant spot cooling.

Convective spot cooling by air jets is an efficient way of providing acceptable thermal comfort conditions. Convective spot cooling exposes workers to air with an increased velocity; the jet air may be the same temperature as the air in the workplace or cooler. Different combinations of jet outlet velocity and temperature can produce the same cooling effect. The optimal combination of jet velocity and temperature depends on the type of work performed, the clothing

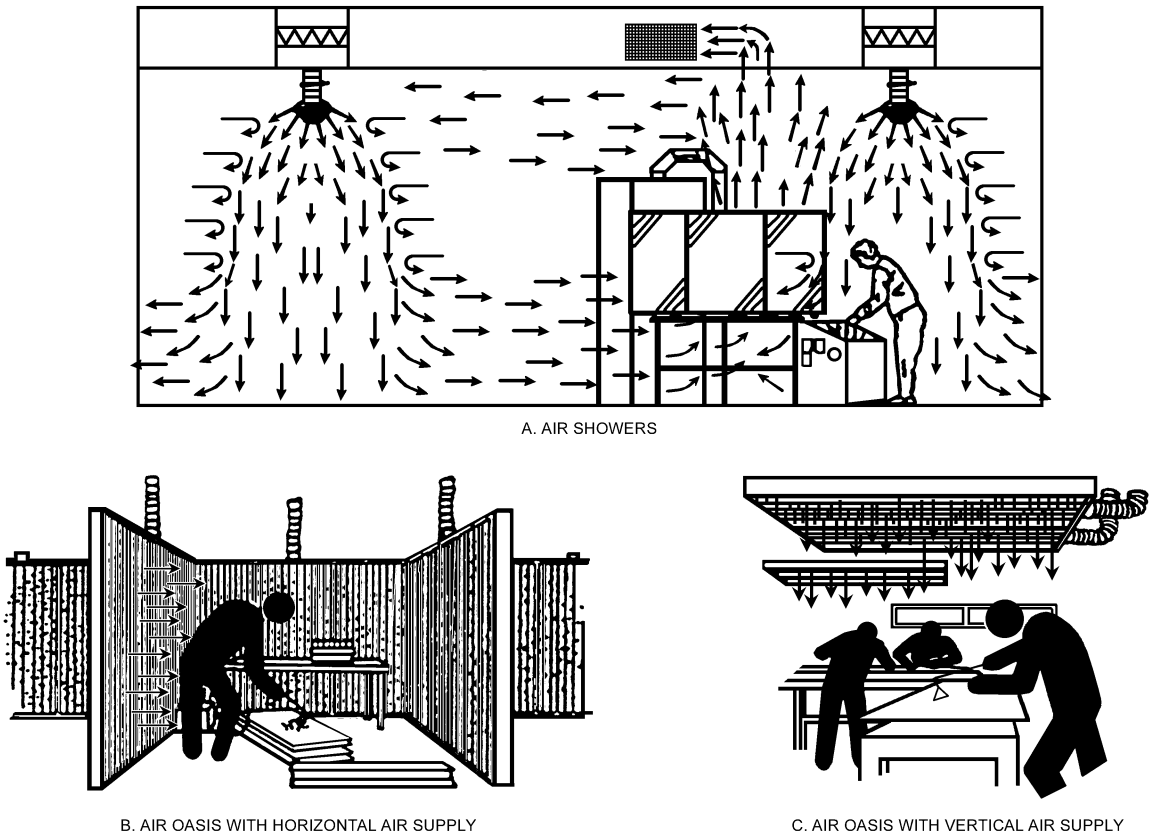

Fig. 12 Localized Ventilation Systems

worn, the surface area of exposed body parts, the size of the target area, and the direction of the jet.

A design procedure for spot cooling by air jets has been developed and optimized (Azer 1984, Hwang et al. 1984). The procedure is based on a semi-empirical model of the fully developed region of a cold jet projected downward in a hot environment. **Skin wettedness**, which is defined as the fraction of the subject's body surface area covered by evaporative moisture, is used as a physiological index. The cooling air jet is supposed to provide a skin wettedness of 0.5 as an acceptable physiological strain. For maximum cooling, studies (Robertson and Downie 1978; Melikov et al. 1994) show that the initial (potential core) region and the transition region of the jet should be used for spot cooling workers. The fully developed region of the jet does not cool as well because intensive mixing of cold jet air with warm room air increases the jet target temperature.

Subjective studies (Olesen and Nielsen 1983; Melikov et al. 1991) found significant differences in the target velocities preferred by individuals; therefore, individual control of the jet velocity and jet temperature are recommended. Spot cooling systems that also allow workers to adjust the distance to the jet outlet and the direction of the jet are preferable. Convective spot cooling, especially at high temperatures, reduces heat stress but may cause local discomfort due to draft. In hot environments, such as those in foundries and steel mills, velocities as high as 15 to 20 m/s are common (Table 1). When high-velocity air is used, it is important to avoid hot air convection, dust entrainment (which can be hazardous to eyes), and disturbance of local exhaust systems.

Air Distribution Design in Industrial Spaces

Chapter 31 of the 1997 *ASHRAE Handbook—Fundamentals* should be reviewed for basic principles of air distribution design and air diffuser selection. Design methods for air distribution in large industrial spaces (Figures 4 through 12) are discussed by Zhivov (1990, 1993).

Air Distribution for Local Relief. The following factors should be considered in the design of air distribution for local relief:

Outlet Location. For general low-level ventilation, outlets should be at about 3 m, although 2.5 to 3.5 m is acceptable. For spot cooling, the outlets should be kept close to the worker to minimize mixing with warmer air in the space. In most spot cooling installations, the outlets should be brought down to the 2 m level.

Discharge Velocity, Temperature, and Air Volume. Discharge velocity, temperature, and air volume should be designed to provide thermal comfort for workers as recommended in Tables 1 and 2. Guidelines are discussed in Chapter 31 of the 1997 *ASHRAE Handbook—Fundamentals*.

Air Diffusers and Their Performance. A wide variety of air diffusion devices can be used with different air distribution methods. Typical applications for air supply diffusers are summarized in Table 7.

Grilles are one of the most universal types of air diffusers. They can have one or two rows of vertical or horizontal vanes and different aspect and vane ratios. Vanes affect grille performance if their depth is at least equal to the distance between the vanes. A grille discharging air uniformly forward (with the vanes in a straight position) has a spread of 14 to 24°, depending on the duct approach, the discharge velocity, and the type of diffuser. Turning the vanes affects the direction and throw of the discharged airstream. Parallel, horizontal vanes direct the airstream vertically within 45°. If the **vane ratio** (vane depth divided by distance between vanes) is less than 2, the jet inclination will be smaller than the angle of the vanes.

Vertical vanes spread the air horizontally, and horizontal vanes spread the air vertically. A grille with diverging vanes (i.e., vertical

Note: Approximate ranges are given for air diffuser performance constants:
K_1 = coefficient of velocity decay along the jet
K_2 = coefficient of temperature decay along the jet
For actual values of these constants, consult manufacturers' guides.

vanes with uniformly increasing angular deflection from the centerline to a maximum at each end of 45°) has a spread of about 60° and reduces the throw considerably. With increasing divergence, the quantity of air discharged by the grille decreases for a given total upstream pressure.

A grille with converging vanes (i.e., vertical vanes with uniformly decreasing angular deflection from the centerline) has a slightly higher throw than a grille with straight vanes, but the spread is approximately the same for both. Compared to the airstream discharged from a grille with straight vanes, the airstream from a grille with converging vanes converges slightly for a short distance in front of the outlet and then spreads more rapidly.

Ceiling-mounted air diffusers can be round, rectangular, or linear and have outlets covered with grilles, perforations, flat plaques, or vanes forming a slot. They can be regulated or nonregulated. Depending on their design, they can form attached radial, concentrated, or linear jets as well as nonattached conical or concentrated jets. Rectangular air diffusers with triangular or four-sided grilles form nonuniform circular flow and can be considered as three or four separate jets.

For applications in industrial and commercial facilities with high ceilings, these diffusers can be mounted on duct drops (installation height 3 to 5 m) supplying compact conical or nonattached radial jets. Nonattached radial and conical jets typically collapse into conical or compact jets under the influence of buoyant forces.

For VAV applications with a considerable air volume and initial temperature differential, air diffusers with a regulated outlet area and/or a regulated direction of air supply, as well as those with induction of room air, perform better within the year-round cycle of system operation.

Round, square, and rectangular nozzles with outlet sizes of 10 mm to 2 m are commonly used for applications ranging from small rooms to large spaces in industrial buildings. They are also used to form directing jets for a mixing-type system.

Converging nozzles form air jets with considerably higher throw and lower noise levels than other air diffusers. Diverging nozzles supply compact jets with increased angle of divergence and reduced throw. Typically, the latter type of jet can be achieved either by placing two or more concentric cones at the supply side of the air diffuser or by placing a swirl insert inside the straight nozzle.

Round, half/quarter round, or flat perforated panels supply air directly into the occupied zone. They discharge air with low velocity (0.2 to 0.5 m/s) and low turbulence. These diffusers can be installed either near walls and columns or inside walls or other interior structures. Flat perforated plenums can be integrated into the ceiling construction to supply air with jets projected downward.

New features of perforated panels include

- Induction chambers, which allow supply air to mix with room air inside the air diffuser housing. This design allows supply air to have a greater air temperature differential without causing discomfort in the occupied zone.
- Internal deflectors to adjust the flow direction. These panels are capable of decreasing the restricted zone (zone with abnormal velocities) in front of the air diffuser.

Round or rectangular perforated ducts with partially or completely perforated or slotted walls are used primarily to supply air in spaces where a high air change rate is required and air velocity in the occupied zone is limited due to process restrictions (e.g., to prevent contaminant spillage from local exhausts). The supply surface may be created either (1) by perforating the duct wall, (2) by cutting incomplete holes in the wall and bending metal peaks inside/outside the duct (to deflect air jets in the correct direction from the duct surface), or (3) by stamping converging nozzles in the desired areas of the sheet metal bend that is used to form the spiral duct.

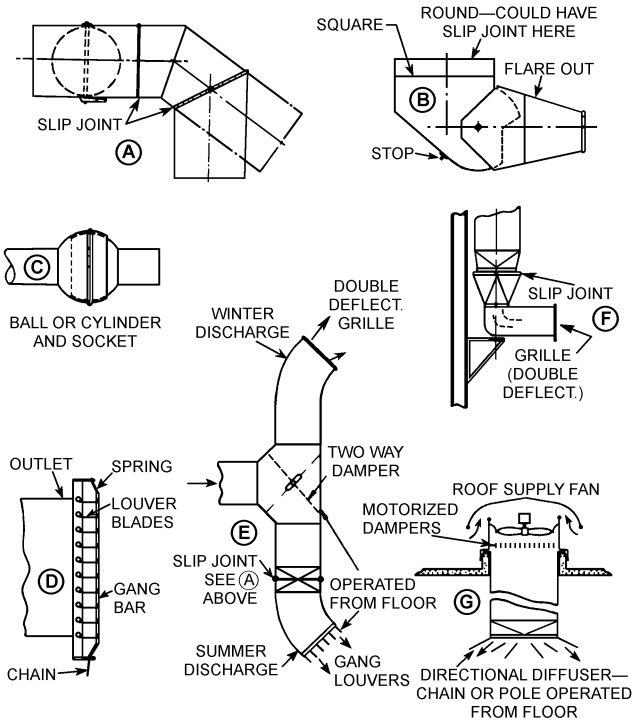

Fig. 13 Directional Outlets for Spot Cooling

Outlet dampers should always be provided for volume and directional control. Figure 13 shows some of the directional outlets used for low-level general ventilation and spot cooling. Outlet A (Navy Type E) has been used in various forms for many years in ship machinery spaces. Outlets B and C are excellent for local area or spot cooling. The adjustable louvers of D applied to directional outlets such as E or F provide excellent control; commercial directional grilles serve the same purpose. The two-way damper arrangement in E is used in local area or aisle ventilation; it directs the supply air upward in winter to mix discharge air with warm or hot air rising from internal sources. Outlet G is a commercial directional diffuser that can be adjusted to provide a variable downward airflow pattern that ranges from flat to vertical. The outlet is shown on a roof supply fan, which is a common application, but the outlet drop must extend through the layer of hot ceiling air to provide effective relief ventilation.

Locker Room, Toilet, and Shower Space Ventilation

The ventilation of locker rooms, toilets, and shower spaces is important in industrial facilities to remove odor and reduce humidity. In some industries, adequate control of workroom contamination requires prevention of ingestion, as well as inhalation, so adequate hygienic facilities, including appropriate ventilation, may be required in locker rooms, change rooms, showers, lunchrooms, and break rooms. State and local regulations should be consulted at early stages of design.

Supply air may be introduced through door or wall grilles. In some cases, plant air may be so contaminated that filtration or, preferably, mechanical ventilation, may be required. When control of workroom contaminants is inadequate or not feasible, total employee exposure can be reduced by minimizing the level of contamination in the locker rooms, lunchrooms, and break rooms by pressurizing these areas with excess supply air.

When mechanical ventilation is used, the supply system should have supply fixtures such as wall grilles, ceiling diffusers, or supply plenums to distribute the air adequately throughout the area.

Table 8 Ventilation for Locker Rooms, Toilets, and Shower Spaces

Description of Space	Ventilation
Locker Rooms	
Coat hanging or clean change room for nonlaboring shift employees with clean work clothes	5 L/(s·m^2)
Change room for laboring employees with wet or sweaty clothes	10 L/(s·m^2); 3 L/s exhausted from each locker
Change room for laborers or worker assigned to heavy work; clothes will be wet or pick up odors	15 L/(s·m^2); 5 L/s exhausted from each locker
Toilet Spaces	10 L/(s·m^2); at least 12 L/s per toilet facility; 95 L/s minimum
Shower Spaces	10 L/(s·m^2); at least 24 L/s per shower head; 95 L/s minimum

Note: The source of this table is unknown. Nevertheless, the information has been used with apparent success for many years (*ASHRAE Guide and Data Book* 1970). Also refer to Article 16 of the BOCA *National Building Code* and ASHRAE *Standard* 62.

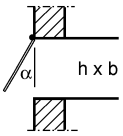
In the locker rooms, the exhaust should be taken primarily from the toilet and shower spaces, as needed, and the remainder from the lockers and the room ceiling. In the absence of specific codes, Table 8 provides a guide for ventilation of these spaces.

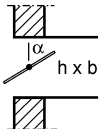
NATURAL VENTILATION

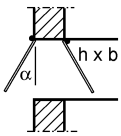
Natural ventilation is a controlled flow of air caused by thermal and wind pressures. It is commonly used in Canada and in European countries. Numerous studies of natural ventilation have been conducted, and methods of design have been developed (Baturin 1972; Shepelev 1978; Goodfellow 1985; Shilkrot 1993). Shilkrot in Stroiizdat (1992a) summarizes these design methods.

Natural ventilation can be used in spaces with significant heat release as long as contamination of the incoming air by gases and particles does not exceed 30% of the design exposure limits. Natural ventilation is not recommended when air filtration and treatment are required by the process or when the incoming outdoor air causes mist or condensation.

In the summer, air inlets for natural ventilation are located in exterior walls; the lower level of the openings is 0.3 to 1.8 m above the floor. Air inlets can be arranged in one, two, or more rows in the longer exterior walls. Windows, doorways, other openings in the exterior walls, or apertures in floors over basements (with air transportation along special channels) also can be used as air inlets.







During seasons other than summer, air inlets must be located higher than 3 m above floor level in rooms with ceilings lower than 6 m. If the room height exceeds 6 m, low-level inlets must be located higher than 4 m. These inlets must be supplied with baffles to direct air upward. Schematics of and pressure loss coefficients for inlets are given in Table 9.

Interior ventilated halls can obtain outside air through ridge vents in adjacent "cold" halls. Cold halls must be separated from "hot" ones by screens dropped from the roof to create an airway above the floor that is 2 to 4 m deep. Air supply via ridge vents on the roof is not recommended but can be used if necessary.

Air is evacuated from naturally ventilated spaces through wind-protected continuous ridge vents, skylights, or round roof ventilators. Many types of ridge vents and roof ventilators have been designed; their sizes and pressure loss coefficients are available from the manufacturers. All inlets and outlets for natural ventilation must be supplied with controls for easy opening and closing.

The air exchange rate G_o required for temperature control in the occupied zone can be calculated from the following room heat balance equation [similar to Equations (8) through (10)]:

Table 9 Pressure Loss Coefficients for Inlet Apertures

Schematic	Baffle Type	Aspect Ratio, *h/b*	Pressure Loss Coefficient ξ at Different Baffle Angles α

Table 10 Coefficients K_t and K_w of Natural Ventilation Effectiveness for Industrial Spaces with Significant Heat Load

Room Category	K_t/K_w
Blacksmith and press shops, oven bays at foundries, rail rolling mills, bloomings, cooling bays, etc.	2.0/2.7
Heat treatment shops	1.9/2.6
Drying shops	1.8/2.5
Casting shops	1.7/2.3
Blast furnace shops	1.6/2.2
Rolling mills	1.5/2.1
Electrolysis shops, machine and compressor rooms	1.4/1.9
Shops for vulcanization and plastic production	1.3/1.8

Note: Significant heat load is defined as higher than 23 W/m^3.

$$G_o = \frac{q}{c_p K_t (t_{uz} - t_{oz})} \tag{11}$$

where

G_o = air exchange rate, kg/s
q = surplus heat released in the space, kW
c_p = specific heat of air, kJ/(kg·K)
t_{uz} = air temperature in upper zone, °C
K_t = coefficient of natural ventilation efficiency calculated from the air temperatures of the occupied zone t_{oz}, the air removed from the upper zone t_{exh}, and the outdoor air t_o

$$= \frac{t_{exh} - t_o}{t_{oz} - t_o}$$

The method of zone-by-zone heat balances (Shilkrot 1993) can be used to define K_t values. Computed values of K_t for different industrial applications are given in Table 10.

Both natural ventilation design and displacement ventilation design assume temperature stratification throughout the room height. Air close to the heat source is heated and rises as a convective stream. Part of this heated air is evacuated through outlets in the upper zone, and part of it remains in the upper zone, in the **heat cushion**. Separation level Z (Figure 14), which is the lower level of the upper zone, is defined in terms of the equality of G_{conv} and G_o, which are the airflow rate in the convective flows above the heat source and the airflow supplied to the occupied zone, respectively. It is assumed that

the air temperature in the lower zone is equal to that in the occupied zone t_{oz} and that the air temperature t_{uz} in the upper zone is equal to that of the evacuated air t_{exh}.

The incoming air jet can destroy the air temperature stratification when the rarefaction Δp_{jet} created by this jet on the level of separation Z is strong enough to move the heated air from the upper zone to the lower zone:

$$\Delta p_{jet} \geq g(\rho_{oz} - \rho_{uz})(Z - h_o) \quad (12)$$

where

Δp_{jet} = rarefaction created by incoming air jet, Pa
g = gravitational acceleration, m/s^2
ρ_{oz} = density of air in occupied zone, kg/m^3
ρ_{uz} = density of air in upper zone, kg/m^3
Z = separation level, m
h_o = height of air supply opening, m

Calculations by Shilkrot (1993) show that when the supply air velocity V_o in the inlet is 2 to 3 m/s and the separation level Z is more than 1 m higher than the air supply opening h_o (i.e., $Z - h_o > 1$ m), a temperature difference of 2 to 3 K between the air in the upper and lower zones ensures the stability of the stratification. Shilkrot has also shown that when the Richardson number R_N is greater than 5, the turbulent exchange between the upper and the lower zones can be neglected.

For single-bay shops, the following steps are recommended for natural ventilation design:

1. Determine the surplus heat load (i.e., heat gains minus heat losses) q (kW) in the space.
2. Select K_t from Table 10.
3. Compute air exchange rate G_o (kg/s) for temperature control in the occupied zone:

$$G_o = \frac{q}{c_p K_t (t_{oz} - t_o)} \quad (13)$$

4. Compute the outgoing air temperature, °C:

$$t_{exh} = t_o + \frac{q}{c_p \rho_o Q} \quad (14)$$

5. Select the separation level Z:

$$Z = 0.4H \text{ to } 0.7H \quad (15)$$

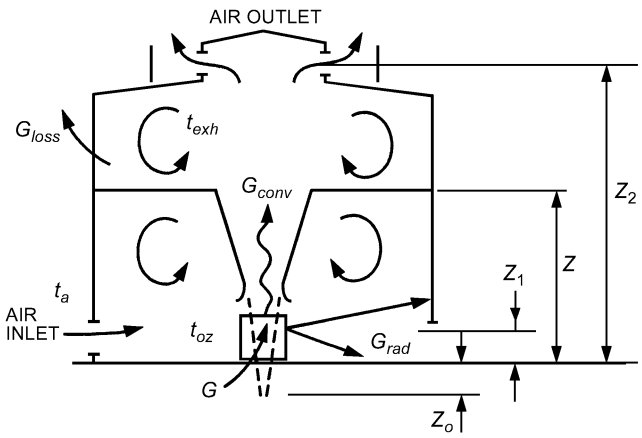

Fig. 14 Natural Ventilation of Single-Bay Building

where

H = ventilated space height, m ($6 \leq H \leq 24$)
Z = $0.7H$ when $H = 6$ m; $Z = 0.4H$ when $H = 24$ m

6. Determine the pressure difference available to transport air through the inlet and outlet apertures:

$$\Delta p = g(Z - Z_1)(\rho_o - \rho_{oz}) + g(Z_2 - Z)(\rho_o - \rho_{exh}) \quad (16)$$

where $\rho = \rho_{20°C} \times T_{20°C}/T = 1.20 \times 293/T = 352/T$, kg/m^3.

7. Calculate the pressure loss in the air inlets, Pa:

$$\Delta p_1 = \beta \Delta p \quad (17)$$

β is part of the pressure available for air transportation through inlets. To reduce the velocity of the incoming air, the inlet area can be increased to keep β in the range 0.1 to 0.4.

8. Calculate the area F_1 (m^2) of the inlet apertures:

$$F_1 = \frac{G_o}{\sqrt{2\rho_{out}\Delta p_1/\xi_1}} \quad (18)$$

Values of the pressure loss coefficient ξ are listed in Table 9.

If the area of the inlets is given, the pressure drop Δp_1 can be calculated from the following equation:

$$\Delta p_1 = \frac{\xi_1}{2\rho_{out}}\left(\frac{G_o}{F_1}\right)^2 \quad (19)$$

9. Calculate the pressure drop available for the air outlets:

$$\Delta p_2 = \Delta p - \Delta p_1 \quad (20)$$

10. Determine the area F_2 of the air outlets (vent in roof ridge, roof ventilators, etc.):

$$F_2 = \frac{G_o}{\sqrt{2\rho_{exh}\Delta p_2/\xi_2}} \quad (21)$$

Stroiizdat (1992a) discusses a method for natural ventilation design applicable to multibay shops, multistory buildings, and combined natural and mechanical ventilation systems.

AIR CURTAINS

Air curtains are local ventilation devices that supply a high-velocity stream of air to reduce airflow through apertures in building shells (Asker 1970; Strongin 1993; Powlesland 1971, 1973; Stroiizdat 1992a) and in process equipment (Bintzer and Malehom 1976; Goodfellow 1985; Ivanitskaya et al. 1986; Strongin and Nikulin 1991). They are also used to localize gaseous and particulate emissions near their sources and to convey them toward local exhausts (Stoler and Savelyev 1977; Posokhin and Broida 1980; Posokhin 1985). Different applications of air curtains for jet assisted hoods are discussed in Chapter 29.

Air curtains provide better thermal environments for workstations located near doorways. They can also reduce the energy consumption of HVAC systems.

Shutter-type air curtains create a resistance to airflow through a door, thus reducing the incoming airflow (Figure 15). They direct air toward the incoming outside air at an angle ranging from 30 to 40°. Shutter-type air curtains may be single-sided or double-sided and projected upward or downward. Double-sided air curtains deter the incoming airflow better. Upward-projected air curtains are recommended when the gate width is greater than its height. They also provide better coverage of the lower area of the door opening.

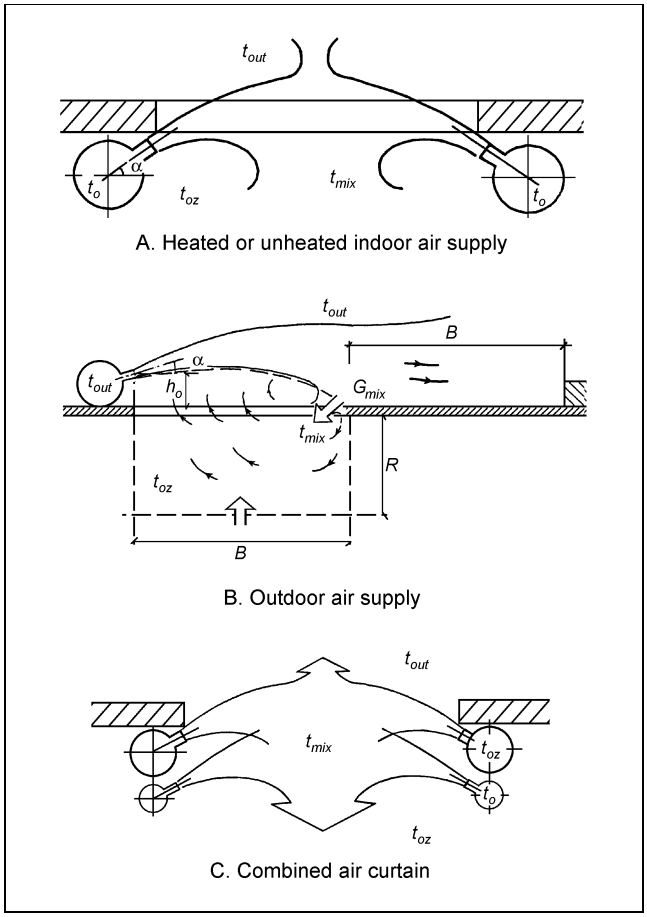

Fig. 15 Shutter-Type Curtains

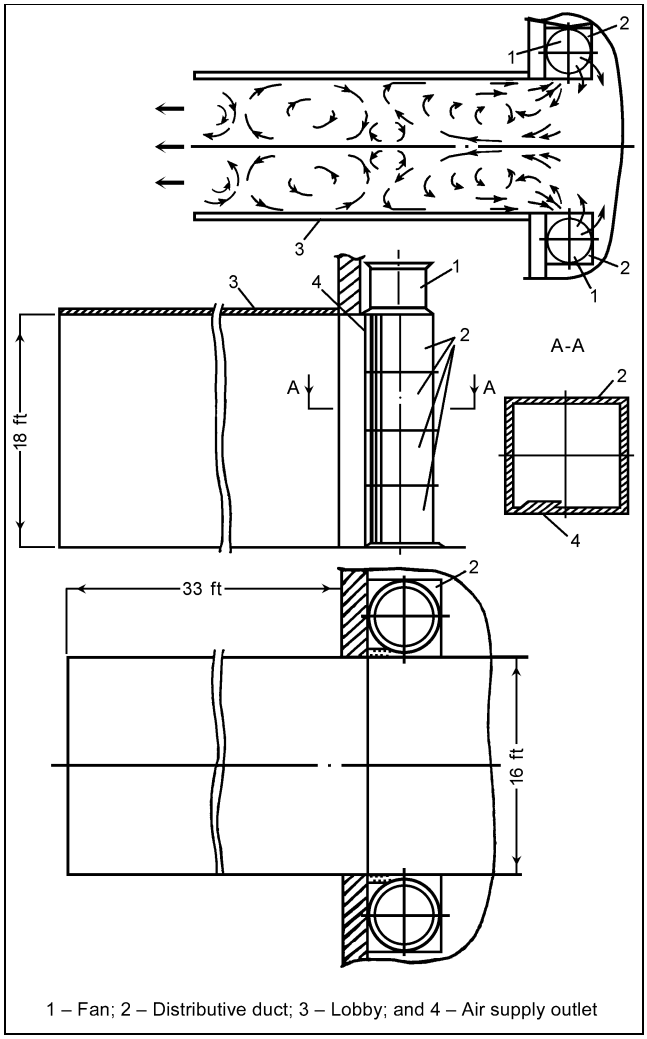

Fig. 16 Air Curtain for Medium-Sized Gate with Lobby

Air curtains can supply heated air, air at room temperature, or air at the outdoor temperature. Air curtains with heated air are recommended for doors smaller than 3.6 m by 3.6 m and for process apertures that are opened frequently (e.g., more than five times or for longer than 40 min during an 8 h shift) and that are located in regions with design outdoor winter temperatures of –15°C or lower. Air curtains provide desired air temperatures for workstations near apertures; however, the heat consumption is relatively high. Air curtains that supply unheated indoor air have application in spaces (1) with a heat surplus, (2) with temperature stratification over the room height, (3) with low air temperatures (less than 8°C) near the aperture area, and (4) in regions with a mild climate. Shutter-type air curtains also are recommended for use in cooled spaces.

Air curtains with a lobby are shown in Figure 16. Performance is based on transition of the supply air jet impulse into counterpressure, which prevents outdoor airflow into the room. Air is supplied counter to the outdoor airflow or at a small angle to it. A curtain jet propagates along the channel walls, slows down, and makes a U-turn, reversing along its axis. The length of the lobby is chosen to exceed 2.5 times its width (for double-sided air curtains) and so that air is not forced outside. To shorten the lobby, air is usually supplied by a jet with a coerced angle of divergence. Air curtains with a lobby for supplying outdoor air are shown in Figure 17.

Combined air curtains are used in very cold climates (winter temperatures as low as –65°C), for doors larger than 3.6 m by 3.6 m, and for spaces with several doors. A combined air curtain with a specially designed lobby is shown in Figure 18. The lobby has corrugated iron walls that reduce the wind pressure on the gate aperture. Air curtains in the lobby supply untreated outdoor air, while air curtains inside the building supply heated air. Combined air curtains without a lobby are shown in Figure 15C.

Air curtain controls should be designed to turn curtains on when the door is opened and turn them off when the door is closed or when the air temperature near the door reaches the target value.

Principles of Air Curtain Design

The velocity of the supplied air can be calculated from the following equation:

$$V_o = \sqrt{\frac{2\Delta p f}{\beta_o \rho E}} \tag{22}$$

where

V_o = velocity of supply air, m/s
Δp = average pressure difference between inside and outside air near the aperture with the air curtain turned on, Pa
f = ratio of area A_{ap} of air supply slots to door area A_o. For air curtains with heated air or unheated indoor air and for combined air curtains, f = 10 to 20. For air curtains supplying outdoor air or protecting air-conditioned spaces, f = 20 to 40.
β_o = Boussinesq coefficient (describes uniformity of air velocity in opening cross section); for air curtain supply nozzle, β_o ranges from 1.05 to 1.1

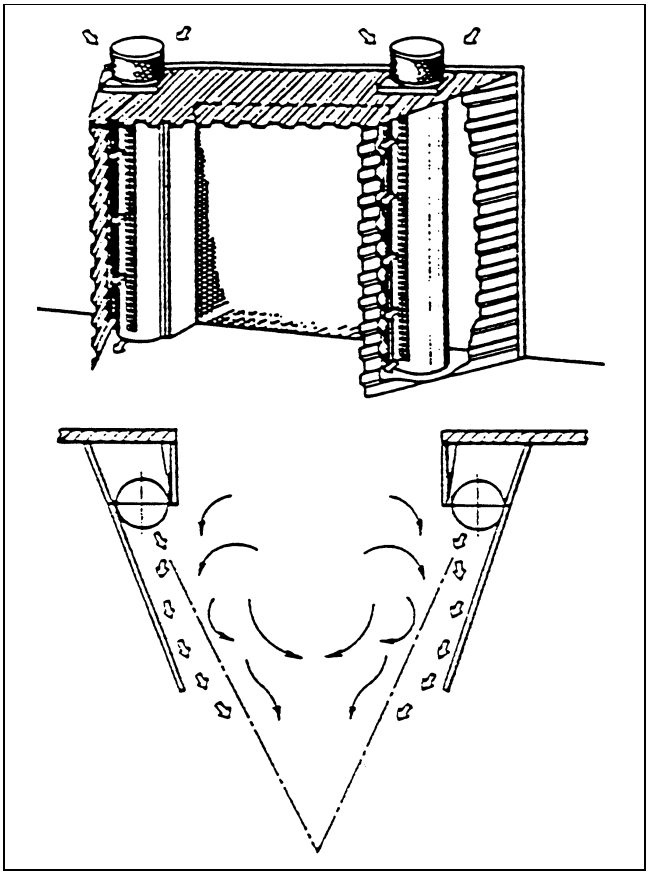

Fig. 17 Air Curtain with Lobby and Outside Air Supply

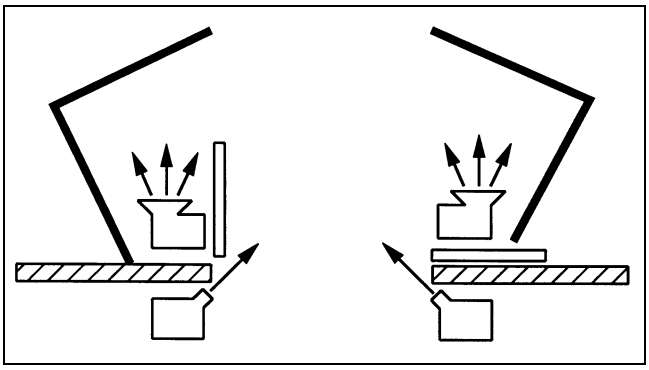

Fig. 18 Combined Air Curtain with Lobby
(Strongin and Nikulin 1987)

ρ = density of air supplied by air curtain, kg/m^3
E = coefficient of air curtain dynamic efficiency (given in Table 11)

Airflow supplied by the air curtains as shown in Figure 15 can be calculated from the following equation:

$$G_o = \rho V_o A_o \quad (23)$$

The temperature t_o of the supplied air can be estimated from the heat balance equation for the aperture under consideration:

$$t_o = t_{out} + m_1(t_{mix} - t_{out}) + m_2(t_{oz} - t_{out}) \quad (24)$$

Table 11 Air Curtain Dynamic Efficiency Coefficient *E*

sin α	Air Curtains Supplying Heated Air, Unheated Air, and Combinations	Air Curtains Supplying Outdoor Air or Protecting Air-Conditioned Spaces
0.1	0.10	0.15
0.2	0.15	0.20
0.3	0.20	0.25
0.4	0.25	0.30
0.5	0.30	0.40
0.6	0.35	—

f	m_1	m_2
10	2.0	−0.6
15	2.3	−1.0
20	2.5	−1.3

where

t_{mix} = normative air mixture temperature
m_1 and m_2=coefficients for the air curtain in Figure 15A; values are given in Table 12

ROOF VENTILATORS

Roof ventilators are heat escape ports located high in a building and properly enclosed for weathertightness (Goodfellow 1985). Stack effect plus some wind induction are the motive forces for gravity operation of continuous and round ventilators. Round ventilators can be equipped with a fan barrel and motor, permitting gravity or motorized operation.

Many ventilator designs are available, including the **low ventilator**, which consists of a stack fan with a rain hood, and a **ventilator with a split butterfly closure** that floats open to discharge air and closes by itself. Both use minimum enclosures and have little or no gravity capacity. Split butterfly dampers tend to make the fans noisy and are subject to damage from slamming during strong wind conditions. Because noise is frequently a problem in powered roof ventilators, the manufacturer's sound rating should be reviewed.

Roof ventilators can be listed in order of their heat removal capacity. The **continuous ventilation monitor** removes substantial, concentrated heat loads most effectively. One type, the streamlined continuous ventilator, is efficient, weathertight, and designed to prevent backdraft, and it usually has dampers that may be readily closed in winter to conserve building heat. Its capacity is limited only by the available roof area and the proper location and sizing of low-level air inlets. **Gravity ventilators** have low operating costs, do not generate noise, and are self-regulating (i.e., higher heat release results in higher airflow through the ventilators). Care must be taken to ensure that positive pressure exists at the ventilators; otherwise, outside air will enter the ventilators. This is of particular importance during the heating season.

Next according to their heat removal capacity are (1) the round gravity or windband ventilator, (2) the round gravity ventilator with fan and motor added, (3) the low-hood powered ventilator, and (4) the vertical upblast powered ventilator. The shroud for the vertical upblast design has a peripheral baffle to deflect the air upward instead of downward. Vertical discharge is highly desirable to reduce roof damage caused by the hot air if it contains condensable oil or solvent vapor. Ventilators with direct-connected motors are desirable because of the locations of the units and the belt maintenance required for units having short shaft centerline distances. Round gravity ventilators are applicable to warehouses with light heat loads and to manufacturing areas having high roofs and light loads.

Streamlined continuous ventilators must operate effectively without mechanical power. Efficient ventilator operation is gener-

ally obtained when the difference in elevation between the average air inlet level and the roof ventilation is at least 10 m and the exit temperature is 14 K above the prevailing outdoor temperature. Chapter 25 of the 1997 *ASHRAE Handbook—Fundamentals* has further details. Under these conditions and with a wind velocity of 8 km/h, the ventilator throat velocity will be about 1.9 m/s, and it will remove 1.0 kJ/(kg·K) × 1.2 kg/m^3 × 14 K × 1.9 m/s = 32 kW/m^2.

To ensure this level of performance, sufficient low-level openings must be provided for the incoming air. Manufacturers recommend an inlet velocity of 1.3 to 2.5 m/s. Insufficient inlet area and significant air currents are the most common reasons gravity roof ventilators malfunction. A positive supply of air around the hot equipment may be necessary in large buildings where the external wall inlets are remote from the equipment.

The cost of electrical power for mechanical ventilation is offset by the advantage of constant airflow. Mechanical ventilation can also create the pressure differential necessary for good airflow, even with small inlets. Inlets should be sized correctly to avoid infiltration and other problems caused by high negative pressure in the building. Often, a mechanical system is justified to supply enough makeup air to maintain the work area under positive pressure.

Careful study of airflow around buildings is necessary to avoid reintroducing contaminants from the exhaust into the ventilation system. Discharging the exhaust at the roof level or from an area opposite the outside intake may not prevent the exhaust from reentering the building. Chapter 43 covers building exhaust and air intake design.

Fusible link dampers, which close in case of fire, may be required by building codes.

HEAT CONSERVATION AND RECOVERY

Because of the large air volumes required for ventilating industrial plants, heat conservation and recovery should be practiced and will provide substantial savings. Heat conservation and recovery should be incorporated into preliminary planning for an industrial plant.

In some cases, it is possible to provide unheated or partially heated makeup air to the building. Rotary, regenerative heat exchangers recover up to 80% of the heat available from the differential between the exhaust and the outdoor air temperatures. Reductions of 5 to 10 K in the heating requirement should be routine for most industrial systems. Although most of the heat conservation and recovery methods in this section apply to heating, the savings possible with air-conditioning systems are equally impressive. The following are some methods of heat conservation and recovery:

1. In the original design of the building, process, and equipment, provide insulation and heat shields to minimize heat loads. Vaporproofing and reduction of glass area may be required. Changes in process design may be necessary to keep the building heat loads within reasonable bounds. Review the exhaust needs for hoods and process and keep those to a practical, safe minimum.
2. Design the supply and exhaust general ventilation systems for optimal operation throughout the year. Use VAV systems and efficient air distribution methods that provide minimal restrictions on the system operation. The air should be supplied as close to the occupied zone as possible (Zhivov 1990). Recirculated air should be used in the winter makeup, and unheated or partially heated air should be brought to the hoods or process (ACGIH 1998b; Holcomb and Radia 1986).
3. Design the system to achieve the highest efficiency and lowest residence time for contaminants. It is good practice to permit workers to adjust the air patterns to which they are exposed; people want direct personal control over their working environment.
4. When possible, recycle exhaust air. For example, office exhaust can be directed first to work areas, then to locker rooms or process areas, and finally to the outside. Air heated from cooling equipment in motor or generator rooms can be recycled. The cooling systems for many large motors and generators can be arranged to discharge into the building in the winter to provide heat and to the outside in the summer to avoid heat loads.
5. Supply air can be passed through air-to-air, liquid-to-air, or hot-gas-to-air heat exchangers to recover building or process heat. Rotary, regenerative, and air-to-air heat exchangers are discussed in Chapter 44 of the 2000 *ASHRAE Handbook—Systems and Equipment*.
6. Operate the system for economy. Shut the systems down at night or on weekends whenever possible, and operate the makeup air in balance with the needs of operating the process equipment and hoods. Keep heating supply air temperatures at the minimum, and cooling supply temperatures at the maximum, consistent with the needs of process and employee comfort. Keep the building in balance so that uncomfortable drafts do not necessitate excessive heating.

CHAPTER 29

INDUSTRIAL LOCAL EXHAUST SYSTEMS

Local Exhaust Fundamentals 29.1
Air Movement in Vicinity of Local Exhaust 29.4
Local Exhaust from Buoyant Sources 29.10
Jet-Assisted Hoods 29.14
Other Local Exhaust System Components 29.16
Operation 29.19

INDUSTRIAL exhaust ventilation systems collect and remove airborne contaminants consisting of particulates (dust, fumes, smokes, fibers), vapors, and gases that can create an unsafe, unhealthy, or undesirable atmosphere. Exhaust systems can also salvage usable material, improve plant housekeeping, or capture and remove excessive heat or moisture.

Local Exhaust Versus General Ventilation

Local exhaust ventilation systems are normally the most cost-effective method of controlling air pollutants and excessive heat. For many manual operations, capturing pollutants at or near their source is the only way to ensure compliance with threshold limit values (TLVs) in the worker's breathing zone. Especially where recirculation is not used, local exhaust ventilation optimizes ventilation airflow, thus optimizing system costs.

In some industrial ventilation designs, the main emphasis is on filtering the air captured by local exhausts prior to evacuating it to the outdoors or returning it to the production space (Chambers 1993). As a result, these systems are evaluated by the efficiency of their filters. However, if only a small percentage of the emission is captured, the degree of separation efficiency becomes almost irrelevant.

The pollutant capturing efficiency of local ventilation systems depends on the hood design, the hood's positioning near the source of contamination, and the exhaust airflow. The selection and layout of the hood has a significant influence on the initial and operating costs of both local and general ventilation systems. In addition, poorly designed and maintained local ventilation systems can cause deterioration of building structures and equipment, negative health effects, and lower working capacity.

No local exhaust ventilation system is 100% effective in capturing pollutants and/or surplus heat. In addition, the installation of local exhaust ventilation system may not be possible under some circumstances, due to the size or mobility of the process. In such situations, **general ventilation** is needed to dilute the pollutants and/or surplus heat. Air supplied by the general ventilation system is usually conditioned. Supply air replaces air extracted by the local and general exhaust systems and improves comfort conditions in the occupied zone.

Chapter 12, Air Contaminants, of the 1997 *ASHRAE Handbook—Fundamentals* covers definitions, particle sizes, allowable concentrations, and upper and lower explosive limits of various air contaminants. Chapter 28, Ventilation of the Industrial Environment, of this volume and Chapter 1 of *Industrial Ventilation: A Manual of Recommended Practice* (ACGIH 1998) detail steps to determine the air volumes necessary to dilute the contaminant concentration using general ventilation. Refer to Chapter 28 for further information on replacement and makeup air.

If insufficient replacement air is provided, the pressure of the building will be negative relative to local atmospheric pressure. Negative pressure allows air to infiltrate through open doors, window cracks, and combustion equipment vents. As little as 12 Pa of negative pressure can cause drafts and might cause backdrafts in combustion vents, thereby creating a potential health hazard. Negative plant pressure can also cause excessive energy use. If workers near the plant perimeter complain about cold drafts, unit heaters are often installed. Heat from these units is usually drawn into the plant interior because of the velocity of the infiltration air, leading to overheating. Too often, the solution is to exhaust more air from the interior, causing increased negative pressure and more infiltration. Negative plant pressure reduces the exhaust volumetric flow rate because of increased system resistance, which could decrease local exhaust efficiency. Wind effects on building balance are discussed in Chapter 15, Airflow Around Buildings, of the 1997 *ASHRAE Handbook—Fundamentals*.

Positive-pressure plants and balanced plants (those having equal exhaust and replacement air rates) use less energy. However, if there are clean and contaminated zones in the same building, surplus pressure in the contaminated zones could cause contaminants to move into the clean zones.

The preparation of this chapter is assigned to TC 5.8, Industrial Exhaust.

LOCAL EXHAUST FUNDAMENTALS

System Components

Local exhaust ventilation systems typically consist of the following basic elements:

- Hood or entry point of the system to capture pollutants and/or excessive heat
- Duct system to transport polluted air
- Air cleaning device to remove captured pollutants from the airstream for recycling or disposal
- Air-moving device (e.g., fan or high pressure air ejector), which provides the motive power to overcome system resistance
- Exhaust stack, which discharges system air to the atmosphere
- Return duct system to return cleaned air back to the plant

System Classification

By Contaminant Source Type. Knowledge of the process or operation is essential before a hood can be designed. The type and size of the hood depends on the type and geometry of the pollution source. There are three types of pollution sources, each of which creates different contaminant movement (Posokhin 1984). **Buoyant (heat) sources** cause contaminants to move in buoyant plumes over the heated surfaces. **Nonbuoyant (diffusion) sources** create contaminant diffusion in all directions due to the concentration gradient (e.g., in the case of emission from painted surface). The emission rate is significantly affected by the intensity of the ambient air turbulence and air velocity. **Dynamic sources** create contaminant movement with an air jet (e.g., linear jet over a tank with push-pull ventilation) or due to particle flow (e.g., from a grinding wheel). In some cases, the above factors influencing contaminant distribution in the room are combined.

The geometry of the contaminant source can be **compact** or **linear**. Hoods are round, rectangular, or slotted to accommodate the geometry of the source.

By Hood Type. Hoods are either enclosing or nonenclosing (Figure 1). **Enclosing hoods** provide better and more economical contaminant control because their exhaust rates and the effects of room air currents are minimal compared to those for nonenclosing hoods. Hood access openings for inspection and maintenance should be as small as possible and out of the natural path of the contaminant. Hood performance (i.e., how well it controls the contaminant) should be checked by an industrial hygienist.

A **nonenclosing hood** can be used if access requirements make it necessary to leave all or part of the process open. Careful attention must be paid to airflow patterns around the process and hood and to the characteristics of the process in order to make nonenclosing hoods functional. Nonenclosing hoods can be classified according to their location relative to the contaminant source (Posokhin 1984) as either **updraft coaxial**, **sidedraft (lateral)**, or **downdraft** (Figure 2).

By System Mobility. Local exhaust systems with nonenclosing hoods can be **stationary** (i.e., having a fixed hood position), **moveable**, **portable**, or **built-in** (into the process equipment). Moveable (turnable) hoods are used when the process equipment must be accessed for repair, loading, and unloading (e.g., in electric ovens for melting steel). Hoods attached to flexible extraction arms (Figure 3) are used when the source of contamination is not fixed, as in arc welding (Zhivov 1993; Zhivov and Ashe 1997). Flexible extraction arms usually have a hood connected to a duct 140 to 160 mm in diameter and have higher efficiencies for lower airflow rates compared to stationary hoods. When the source of contamination is confined to a small, poorly ventilated space such as a tank, an additional flexible hose extension with a hood and a magnetic foot can be hooked on the fume extraction arm.

The portable extractor shown in Figure 4 is commonly used for the temporary extraction of fumes and solvents in confined spaces or during maintenance. It has a built-in fan and filter and a linear or round nozzle attached to a flexible hose about 45 mm in diameter. Built-in local exhausts, such as gun-mounted exhaust hoods and fume extractors built into stationary or turnover welding tables, are

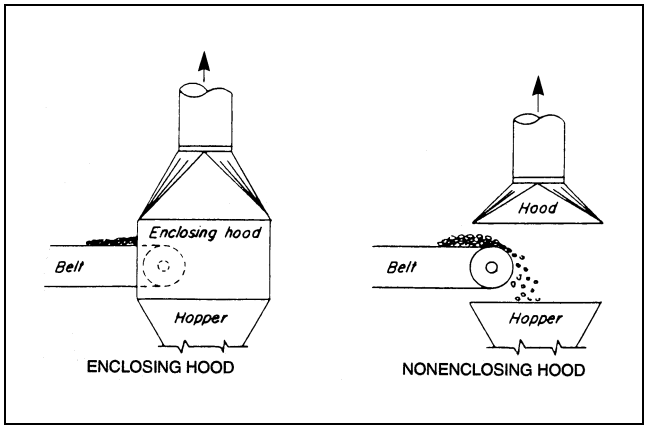

Fig. 1 Enclosing and Nonenclosing Hoods

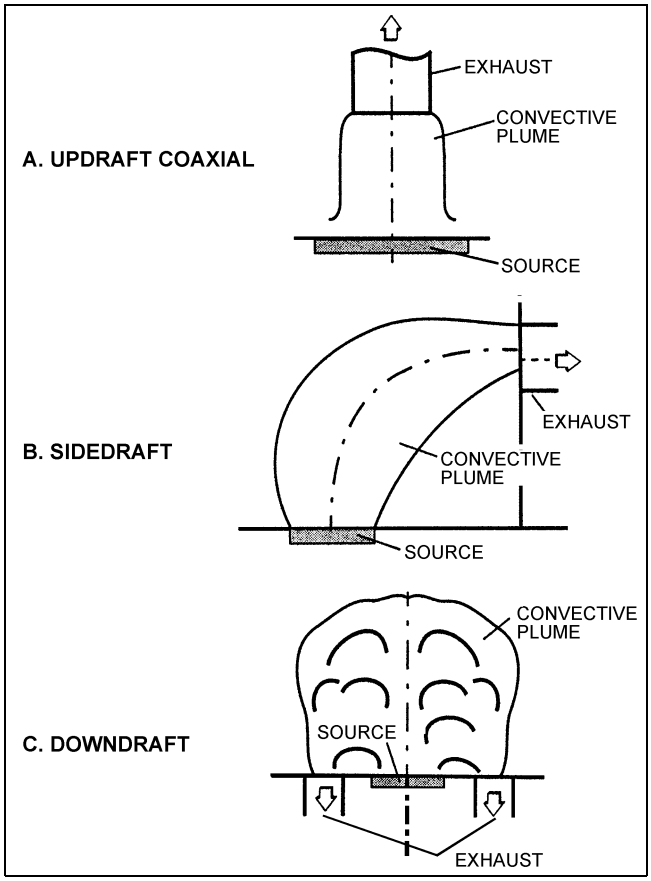

Fig. 2 Nonenclosing Hoods

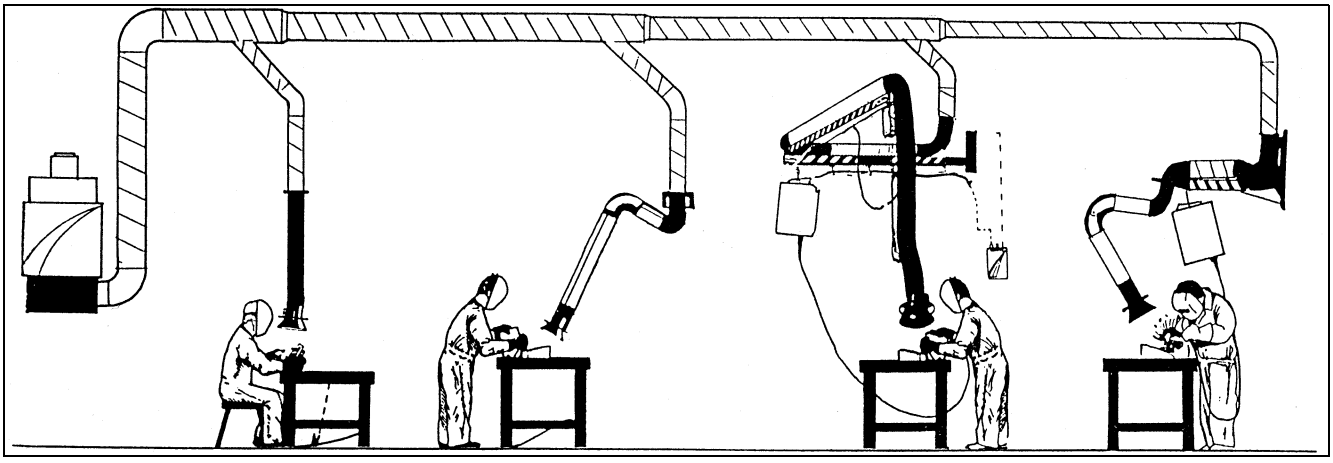

Fig. 3 Hoods Attached to Flexible Fume Extraction Arms

commonly used to evacuate welding fumes. Lateral exhaust hoods, which exhaust air through slots on the periphery of open vessels such as those used for galvanizing metals, are another example of built-in local exhausts.

Nonenclosing hoods should be located so that the contaminant is drawn away from the operator's breathing zone. **Canopy hoods** should not be used where the operator must bend over a tank or process (ACGIH 1998).

Effectiveness of Local Exhaust

The most effective hood uses the minimum exhaust airflow rate to provide maximum contaminant control. The **capturing effectiveness** should be high, but it would be difficult and costly to develop a hood that is 100% efficient. Makeup air supplied by general ventilation to replace exhausted air can dilute contaminants that are not captured by the hood (Posokhin 1984).

Capture Velocity. Capture velocity is the air velocity at the point of contaminant generation upstream of a hood. The contaminant enters the moving airstream at the point of generation and is conducted along with the air into the hood. Designers use capture velocity to select a volumetric flow rate Q to withdraw air through a hood. Table 1 shows ranges of capture velocities for several industrial operations. These figures are based on successful experience under ideal conditions. If velocities anywhere upstream of a hood are known [$V = f(Q_{x,y,z})$], the capture velocity is set equal to V_c at point (x, y, z) where contaminants are to be captured, and Q is found. The transport equations between the source and the hood must be solved to ensure that contaminants enter an inlet.

Hood Volumetric Flow Rate. After the hood configuration and capture velocity are determined, the exhaust volumetric flow rate can be calculated. For **enclosing hoods**, the **target exhaust volumetric flow rate** (the airflow rate that allows contaminant capture) is

$$Q_o^* = V_o A_o \quad (1)$$

where

Q_o^* = target exhaust volumetric flow rate, m^3/s
V_o = average air velocity in hood opening that ensures capture velocity at the point of contaminant release, m/s
A_o = hood opening area, m^2

The inflow velocity V_o is typically 0.5 m/s. However, research with laboratory hoods indicates that lower velocities can reduce the vortex downstream of the human body, thus lessening the reentrainment of contaminant into the operator's breathing zone (Caplan and Knutson 1977; Fuller and Etchells 1979). These lower face velocities require that the replacement air supply be distributed to minimize the effects of room air currents. This is one reason replacement air systems must be designed with exhaust systems in mind. Because air must enter the hood uniformly, interior baffles are sometimes necessary (Figure 5).

For **nonenclosing hoods**, the target airflow rate is proportional to some characteristic flow rate Q_o that depends on the type of contaminant source (Posokhin and Zhivov 1997):

$$Q_o^* = KQ_o \quad (2)$$

where

K = dimensionless coefficient depending on hood design
Q_o = characteristic airflow rate depending on contaminant source, m^3/s (for example, for a buoyant source, Q_o can be equal to airflow in the convective plume; for a dynamic source, Q_o can be equal to airflow rate in the jet)

For a nonenclosing hood with a nonbuoyant contaminant source, the characteristic airflow can be calculated using the following equation:

$$Q_o = V_o A_o \quad (3)$$

Table 1 Range of Capture (Control) Velocities

Condition of Contaminant Dispersion	Examples	Capture Velocity, m/s
Released with essentially no velocity into still air	Evaporation from tanks, degreasing, plating	0.25 to 0.5
Released at low velocity into moderately still air	Container filling, low-speed conveyor transfers, welding	0.5 to 1.0
Active generation into zone of rapid air motion	Barrel filling, chute loading of conveyors, crushing, cool shakeout	1.0 to 2.5
Released at high velocity into zone of very rapid air motion	Grinding, abrasive blasting, tumbling, hot shakeout	2.5 to 10

Note: In each category above, a range of capture velocities is shown. The proper choice of values depends on several factors (Alden and Kane 1982):

Lower End of Range	Upper End of Range
1. Room air currents favorable to capture	1. Distributing room air currents
2. Contaminants of low toxicity or of nuisance value only	2. Contaminants of high toxicity
3. Intermittent, low production	3. High production, heavy use
4. Large hood; large air mass in motion	4. Small hood; local control only

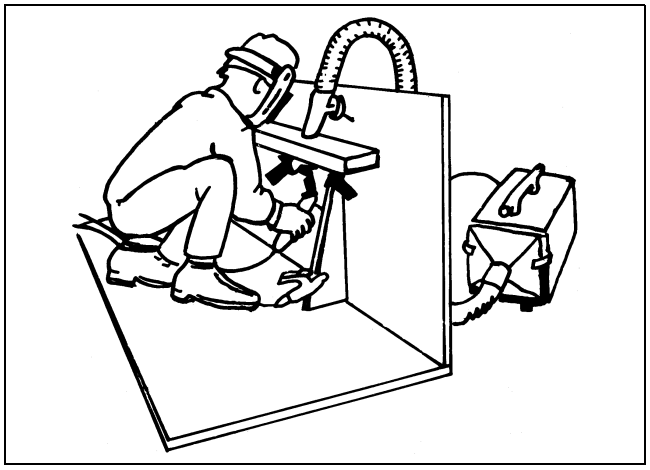

Fig. 4 Portable Fume Extractor with Built-in Fan and Filter

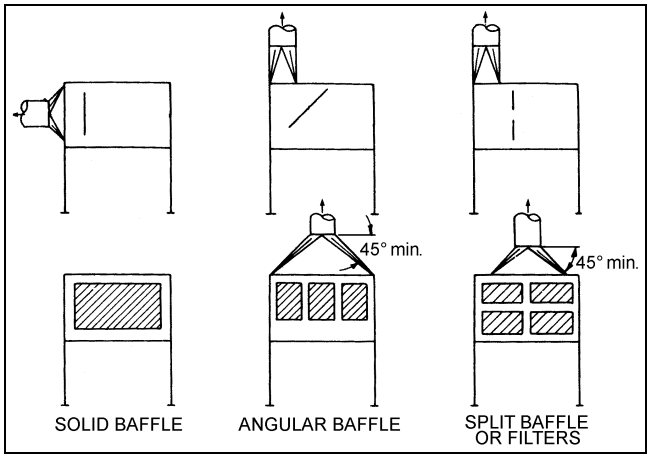

Fig. 5 Use of Interior Baffles to Ensure Good Air Distribution

An exhaust airflow rate lower than Q_o* results in reduced contaminant capturing effectiveness. An exhaust airflow rate greater than Q_o* results in excessive capturing effectiveness (Figure 6).

Airflow near the hood can be influenced by drafts from the supply air jets (spot cooling jets) or by turbulence of the ambient air caused by the jets, upward/downward convective flows, moving people, and drafts from doors and windows. Process equipment may be another source of air movement. For example, high-speed rotating machines such as pulverizers, high-speed belt material transfer systems, falling granular materials, and escaping compressed air from pneumatic tools all produce air currents.

These factors can significantly reduce the capturing effectiveness of local exhausts and should be accounted for in Equations (2) and (3) by the correction coefficient on room air movement. For example, Equation (2) will be replaced with the following:

$$Q_o^* = K_r K Q_o \tag{4}$$

where K_r = coefficient on room air movement; $K_r > 1$.

The exhausted air may contain combustible pollutant-air mixtures. In this case, the exhaust airflow rate should be increased to dilute combustible mixture to less than 25% of the lower explosive limit of the pollutant (NFPA *Standard* 86). Thus,

$$Q_o > \frac{G}{0.25 C_{exp(min)}} \tag{5}$$

where

G = amount of pollutant released by the source, mg/s
$C_{exp(min)}$ = lower explosive limit of pollutant, mg/m^3

Principles of Hood Design Optimization

Numerous studies of local exhaust and common practices have led to the development of the following list of hood design principles (Posokhin 1984):

- The hood should be located as close as possible to the source of contamination.
- The hood opening should be positioned so that it causes the contaminant to deviate the least from its natural path.
- The hood should be located so that the contaminant is drawn away from the operator's breathing zone.
- The hood must be the same size as or larger than the cross section of the flow entering the hood. If the hood is smaller than the flow, a higher volumetric flow rate will be required.
- The velocity distribution in the hood opening cross section should be nonuniform, following the velocity profile of the incoming flow. This can be achieved by incorporating vanes in the hood opening (Figure 7). In the case of a stationary hood and a contaminant source that is not fixed (e.g., welding or soldering), the air velocity along the hood must be uniform; this can be achieved using vanes or perforations.

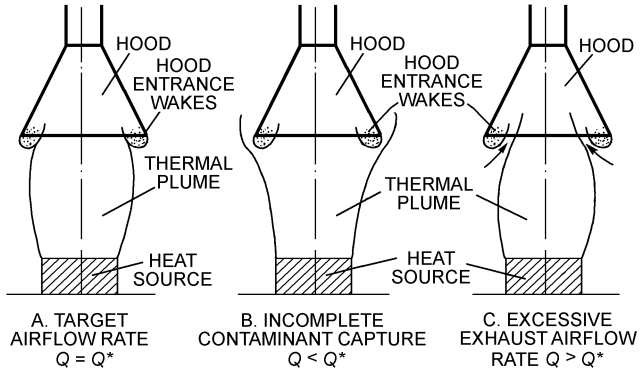

Fig. 6 Hood Performance at Different Exhaust Airflow Rates

AIR MOVEMENT IN VICINITY OF LOCAL EXHAUST

Theoretical Considerations

Airflow near the hood can be described using the incompressible, irrotational flow (i.e., potential flow) model. The total pressure p_{tot} in the area upstream of the hood remains constant and can be described with the following equation:

$$p_{tot} = p_{st} + p_d = \text{Constant} \tag{6}$$

where

p_{st} = static pressure at any point of the flow, Pa
p_d = $\rho V^2/2$ = dynamic pressure at any point of the flow, Pa
ρ = air density, kg/m^3
V = air velocity, m/s

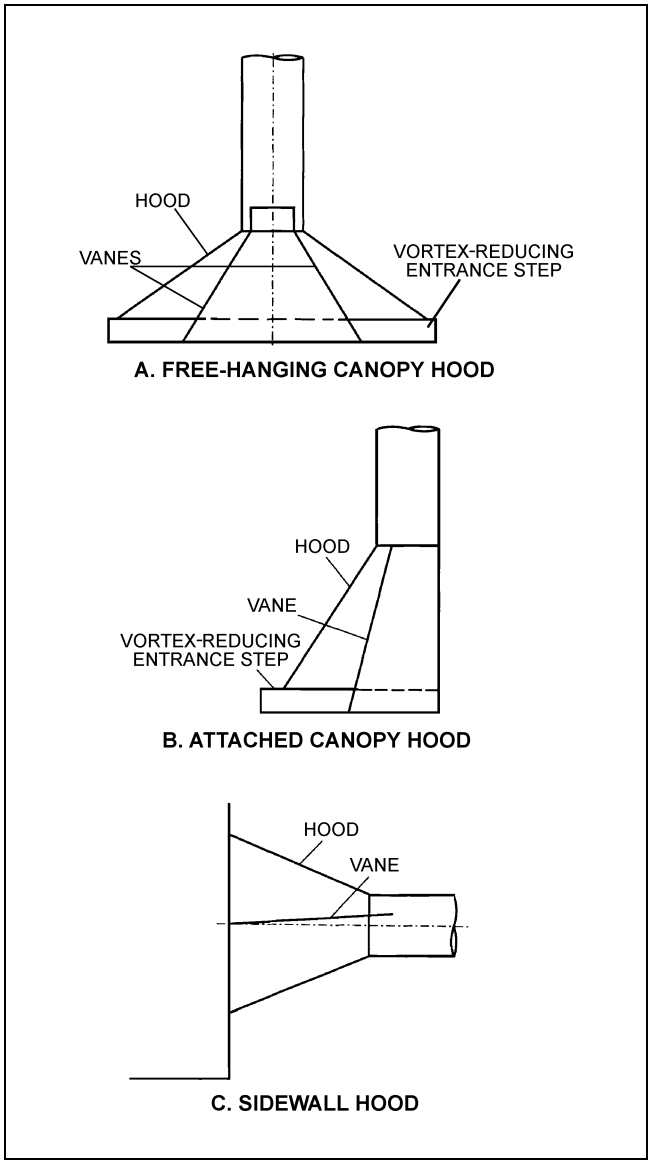

Fig. 7 Hoods with Nonuniform Velocities in Opening Cross Sections

At some distance from the hood, the total pressure p_{tot} in the airflow is equal to the ambient air pressure (i.e., $p_{tot} = 0$). Thus,

$$p_d = -p_{st} \tag{7}$$

The above discussion does not apply to wakes with vortex air movement (Figure 8).

Numerical simulation of hood performance is complex, and results depend on hood design, flow restriction by surrounding surfaces, source strength, and other boundary conditions. Thus, most currently used methods of hood design are based on analytical models and experimental studies.

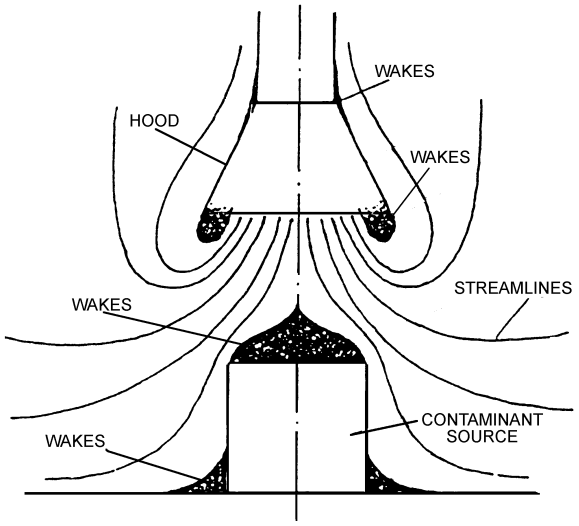

Fig. 8 Airflow in the Hood Vicinity

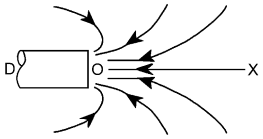
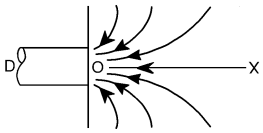
According to these models, the exhaust airflow rate is calculated based on a desired capture velocity at a particular location in front of the hood. It is easier to understand the design process for a sink with vanishingly small dimensions—a point or a linear source of suction. The point source can approximate airflow near a round or square/rectangular hood, and the linear source approximates the airflow near a slot hood.

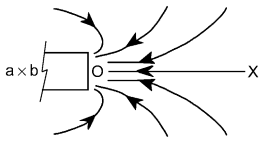
A point source will draw air equally from all directions. Given the exhaust airflow, the velocity at any distance can be calculated by the following equation:

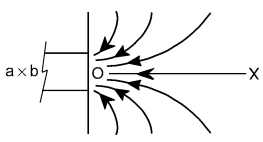
$$V_x = Q/4\pi x^2 \tag{8}$$

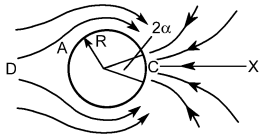
where





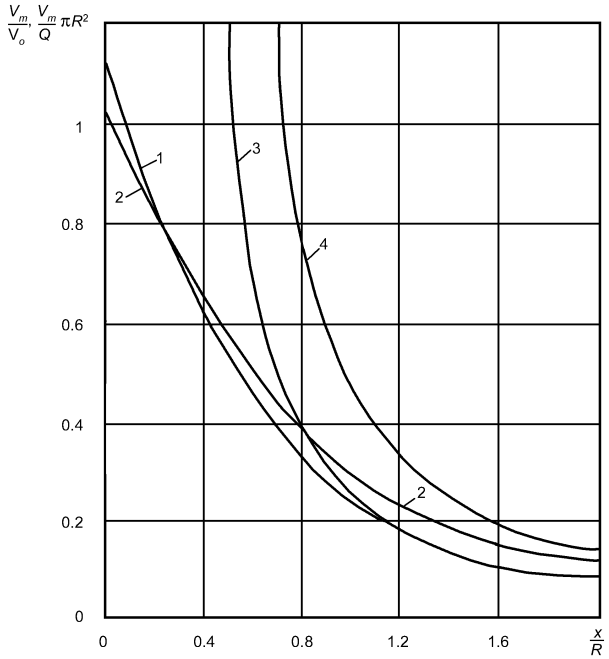






V_x = air velocity at distance x, m/s
x = distance from hood, m

A linear source will create a two-dimensional flow with the velocity V_x calculated as follows:



$$V_x = Q/2\pi x \tag{9}$$

Centerline velocities for different realistic hoods are presented in Table 2 (Posokhin and Zhivov 1997). Figure 9 compares relative velocity change for realistic hoods and a point source. At a distance greater than $x/R = 1$, velocities induced by realistic hoods are practically equal to those induced by a point source. This means that in

Table 2 Centerline Air Velocities Induced by Nonenclosing Hoods

Hoot Type	Schematic	Equation	Applicable Range	Reference
Round freestanding hood, unflanged		$\frac{V_x}{V_o} = (1 + 10x^2/A)^{-1}$	$x \le 1.7\sqrt{A}$; $\alpha \le 30°$	DallaValle (1952)
Round freestanding hood, flanged		$\frac{V_x}{V_o} = 1.1(0.07)^{x/D}$ $\frac{V_x}{V_o} = 0.1(x/D)^{-1.6}$	$0 \le \frac{x}{D} \le 0.5$; $C \ge D$ $0.5 \le \frac{x}{D} \le 1.5$; $C \ge D$	Garrison (1977)
Rectangular freestanding hood, unflanged		$\frac{V_x}{V_o} = (0.93 + 8.58\alpha_F^2)^{-1}$ $\alpha_F = (x/\sqrt{A})(a/b)^{\beta_F}$ $\beta_F = 0.2(x/\sqrt{A})^{-1.3}$	$1 \le \frac{a}{b} \le 16$; $0.05 \le \frac{x}{\sqrt{A}} \le 3$; $\alpha \le 30°$	Fletcher (1977)
Rectangular freestanding hood, flanged		$\left[\frac{V_x}{V_o} = 1 - \frac{2}{\pi}\text{atan}\left(\frac{2x\sqrt{x^2 + a^2 + b^2}}{ab}\right)\right]$	$1 \le \frac{a}{b} \le 16$; $0 \le \frac{x}{\sqrt{A}} \le 1.6$; $\frac{C}{\sqrt{A}} \ge 1$	Tyaglo and Shepelev (1970)
Slot in the pipe wall		$\frac{V_{cx}}{V_o} = \frac{V_{AD}}{V_o} = \frac{2R}{\pi x}\text{atan}\left[\frac{x + R}{x - R}\tan\left(\frac{\alpha}{2}\right)\right]$	$\lvert x \rvert \ge R$	Posokhin (1984)

C = flange width.

Fig. 9 Relative Velocity Decay in Vicinity of a Point Source of Suction and of a Realistic Hood

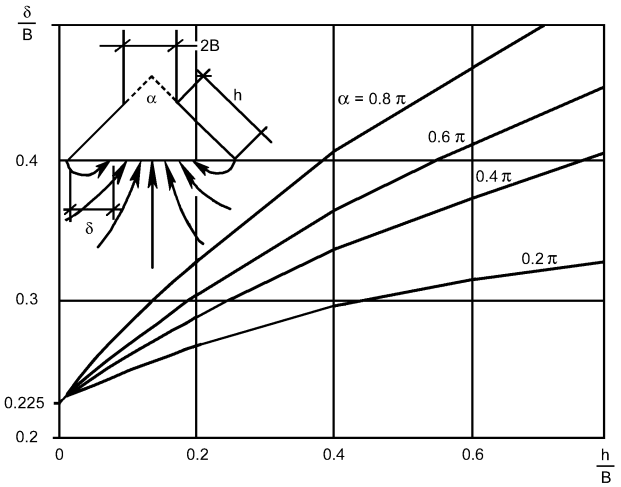

Fig. 10 Influence of Hood Configuration on Hood Entrance Wake Size δ

some cases, airflow in front of realistic hoods can be described using the simplified point source model.

Typically, velocity distribution in the hood face area is not uniform. Wakes formed close to the hood sides, or vena contracta, reduce the effective suction area of the hood. The size of these wakes and the level of velocity uniformity depend on hood design. Figure 10 shows the approximate relationship between wake size δ and the cone angle α of the hood (Posokhin 1984). Vanes, baffles, perforations, and other inserts can be used to control the size of the vena contracta and the velocity uniformity at the hood face area.

Air velocities in front of the hood suction opening depend on the exhaust airflow rate, the geometry of the hood, and the surfaces

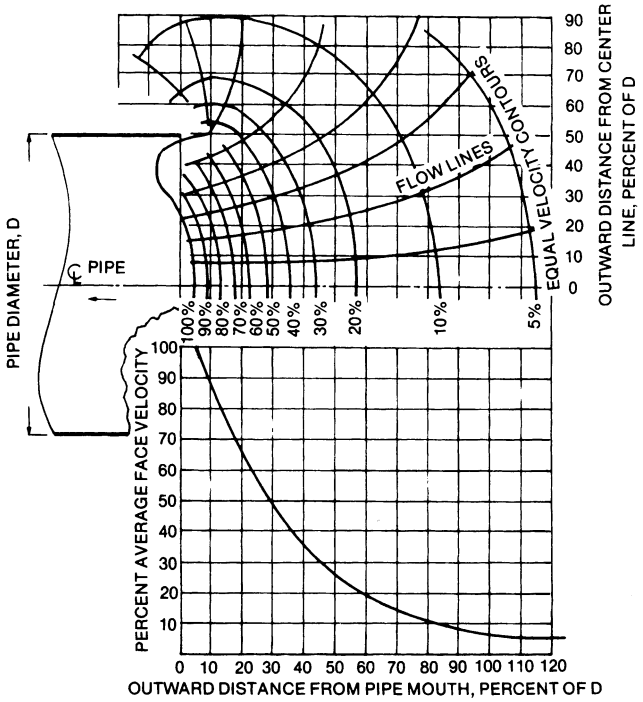

Fig. 11 Velocity Contours for Plain Round Opening

comprising the suction zone. Figure 11 shows lines of equal velocity (**velocity contours**) for a plain round opening. Studies have established the principle of similarity of velocity contours (expressed as a percentage of the hood face velocity) for zones with similar geometry (DallaValle 1952). Figure 12 (Alden and Kane 1972) shows velocity contours for a rectangular hood with an **aspect ratio** (width divided by length) of 0.333. The profiles are similar to those for the round hood but are more elongated. If the aspect ratio is lower than about 0.2 (0.15 for flanged openings), the shape of the flow pattern in front of the hood changes from approximately spherical to approximately cylindrical.

In the suction zone, the velocity decreases rapidly with distance from the hood. Velocity contours plotted in Figures 11 and 12 show that the velocity reaches 10% of the hood face velocity within the distance equal to the square root of the hood suction opening.

Air and Contaminant Distribution with Nonbuoyant Sources

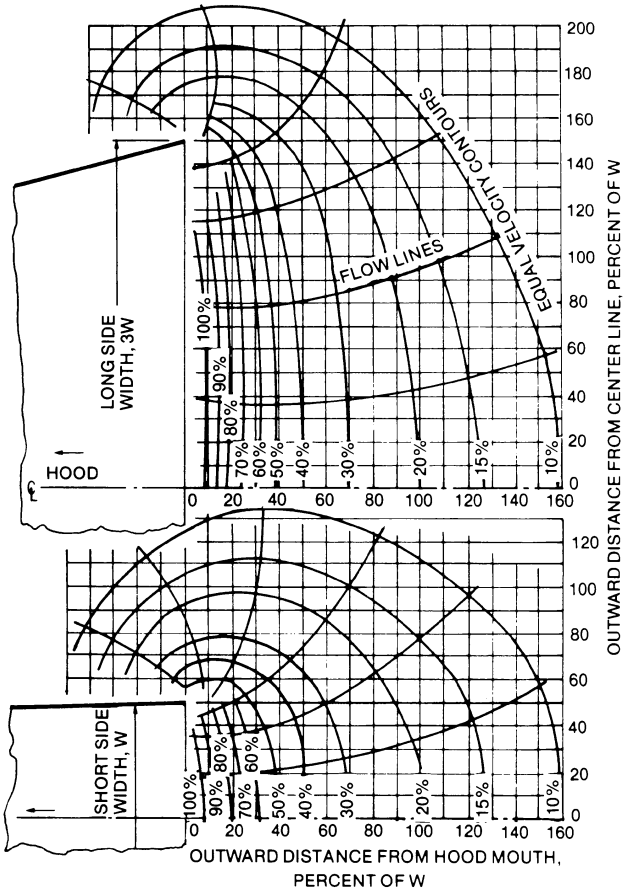
Theories of hood performance with nonbuoyant pollution sources are based on the turbulent diffusion equation. The following equation allows the engineer to determine contaminant concentration decay in the uniform airflow upstream from the contaminant source:

$$C_x = C_o e^{-\frac{V}{D}x} \quad (10)$$

where

x = distance from source,m
C_o = contaminant concentration at source, mg/m^3
C_x = contaminant concentration at distance x from source, mg/m^3
V = air velocity in flow, m/s
D = coefficient of turbulent diffusion, m^2/s
e = 2.7182818 = base for natural logarithm

The value of D depends on the air change rate in the ventilated space and the method of air supply. Studies by Posokhin (1984) show that D for locations outside supply air jets is approximately



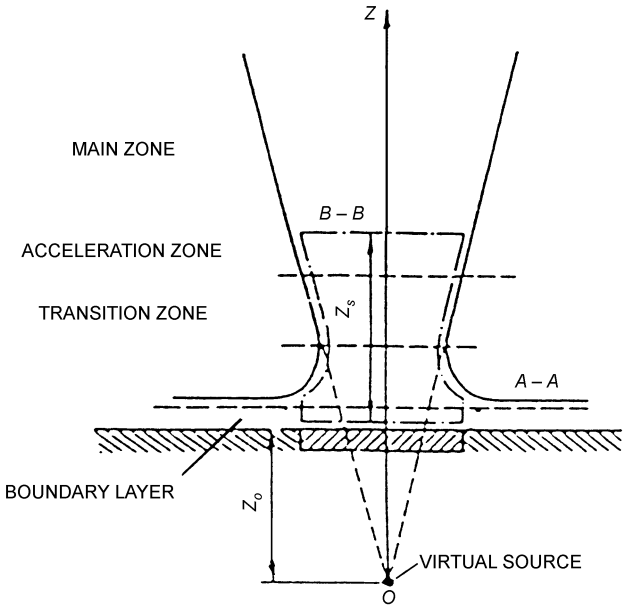


Fig. 12 Velocity Contours for Plain Rectangular Opening with Sides in a 1:3 Ratio

0.025 m^2/s. Air disturbance caused by the operator or robot results in an increase of D by at least a factor of 2. Studies by Zhivov et al. (1997) showed that the value of D is affected by the velocity of cross drafts, their direction against the hood face, and the presence of an operator. For example, with a cross draft directed along the hood face with velocity V = 0.5 m/s, D = 0.15 m^2/s (with the presence of operator); an increase in cross draft velocity to V = 1.0 m/s results in D = 0.3 m^2/s.

Air and Contaminant Distribution with Buoyant Sources

The exhaust from hot processes requires special consideration because of the buoyant effect of heated air near the hot process. Determining the hood size and exhaust rate for a hot process requires an understanding of the convectional heat transfer rate (see the Chapter 3 of the 1997 *ASHRAE Handbook—Fundamentals*) and the physical size of the process. Convected heat and pollutants from the hot process are presumed to be contained in the thermal plume above the source, so the capture of the air transported with this plume will ensure the efficient capture of the contaminant (Burgess et al. 1989).

Analytical equations to calculate velocities, temperatures, airflow rates, and other parameters in thermal plumes over spot and linear heat sources with given heat loads were derived by Zeldovitch (1937), Schmidt (1941), Morton et al. (1956), and Shepelev (1961) based on the momentum and energy conservation equations and assuming Gaussian velocity and temperature difference (between plume and room air temperatures) distribution in thermal plume cross sections. These equations correspond to those received experimentally by other researchers (Popiolec 1981; Skäret 1986);

Z_o – distance from source surface to virtual source
Z_s – distance from source surface to thermal plume cross-section of interest

Fig. 13 Thermal Plume above Heat Source

for example, the equation for the airflow rate in the thermal plume is as follows:

$$Q = Cq_{conv}^{1/3} z^{5/3} \quad (11)$$

where

Q = airflow rate, m^3/s
q_{conv} = convective component of the heat source, W
z = height above the source level, m
C = experimental coefficient

Equation (11) was derived with the assumption that the heat source is very small; it does not account for the actual source dimensions.

Adjusting the point source model to realistic sources using the **virtual source method** (Figure 13) gives a reasonable estimate of the airflow rate in thermal plumes (Ivanitskaya et al. 1974; Elterman 1980; Holman 1989; Mundt 1992). The weak part of this method according to Skistad (1994) is estimating the location of the virtual point. The method of a "maximum case" and a "minimum case" (Skistad 1994) provides a tool for such estimation (Figure 14). According to the maximum case, the real source is replaced by the point source such that the border of the plume above the point source passes through the top edge of the real source (e.g., cylinder). The minimum case is when the diameter of the vena contracta of the plume is about 80% of the upper surface diameter and is located approximately 1/3 diameter above the source. For low-temperature sources, Skistad (1994) recommends the maximum case, whereas the minimum case best fits the measurements for larger, high-temperature sources.

Kofoed (1991) and Kofoed and Nielsen (1991) studied the interaction of the thermal plume with a wall and with another plume. In the case of the wall plume, the airflow rate should be decreased by a factor of 0.63; for interaction with another equal plume, it should be increased by a factor of 1.26.

Another approach to evaluating the thermal plume parameters (Nielsen 1993; Schaelin and Kofoed 1992; Davidson 1989; Aksenov and Gudzovskii 1994) is based on **computational fluid**

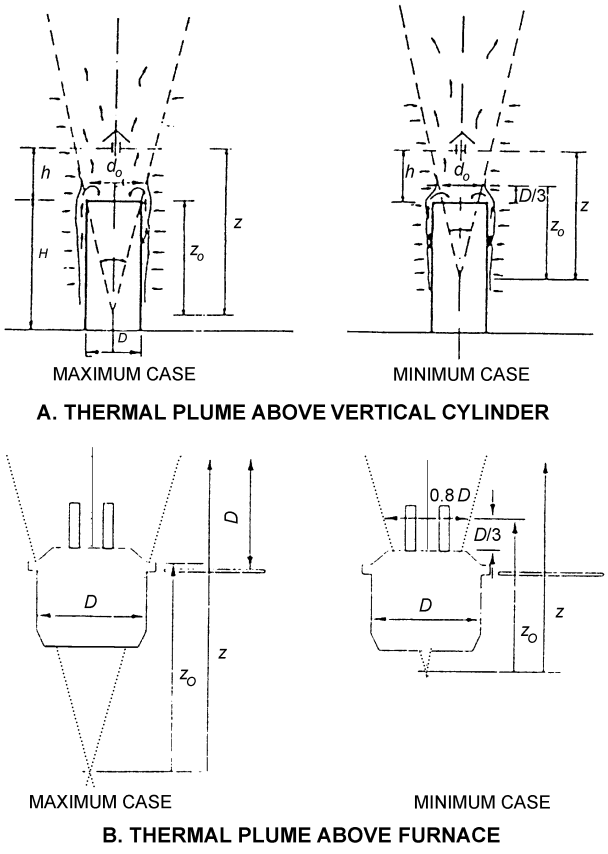

Fig. 14 "Minimum Case" and "Maximum Case" Approaches to Locating Virtual Source
[Reproduced from Skistad (1994)]

dynamics (CFD). With this approach, the airflow in the thermal plume is described by the Navier-Stokes equations and equations for energy and mass balances. Data from numerical and physical experiments on thermal plumes can be used to size overhead hoods above unusual sources or those with complex shapes.

Air Movement Created by Dynamic Sources

Push-pull systems (see the section on Jet-Assisted Hoods) supply air jets in the contaminated zone; they inject contaminated air and direct it toward the hood. Air jets in push-pull systems can be compact or linear. Table 3 presents velocity decay and airflow rates in free and attached compact and linear jets along the zone of practical interest.

To reduce the effect of room air movement on hood performance, the push air jet centerline velocity at the critical cross section (where the push air jet becomes weak, and the influence of the hood is not strong enough) should be from 1 to 2 m/s. According to Stroiizdat (1992), the centerline velocity V_x^{min} in the push jet attached to the heat source should be

$$V_x^{min} > 5.72\sqrt{\frac{l(T_s - T_r)}{T_r}} \tag{12}$$

where

l = distance between the supply nozzle and the exhaust hood, m
T_s = temperature of the heat source surface, K
T_r = room air temperature, K

Table 3 Centerline Velocity and Airflow Rate along Main (3rd) Zone of Supply Air Jet

	Air Supply	
Design Parameter	**Free Jet**	**Wall Jet**
Compact jet (supplied from round or rectangular nozzle)		
Centerline velocity, m/s	$V_x = K_1 V_o \frac{\sqrt{A_o}}{x}$	$V_x = \sqrt{2} K_1 V_o \frac{\sqrt{A_o}}{x}$
Airflow rate, m^3/s	$Q_x = Q_o \frac{2}{K_1} \frac{x}{\sqrt{A_o}}$	$Q_x = Q_o \frac{\sqrt{2}}{K_1} \frac{x}{\sqrt{A_o}}$
Linear jet (supplied from slot)		
Centerline velocity, m/s	$V_x = K_1 V_o \sqrt{\frac{b_o}{x}}$	$V_x = K_1 V_o \sqrt{\frac{2b_o}{x}}$
Airflow rate, m^3/s	$Q_x = Q_o \frac{1}{K_1} \sqrt{\frac{2x}{b_o}}$	$Q_x = Q_o \frac{1}{K_1} \sqrt{\frac{x}{b_o}}$

Note: K_1 = velocity decay coefficient; V_o = supply air velocity, m/s; Q_o = supply airflow rate, m^3/s; A_o = effective area of air discharge, m^2; x = distance along air jet from supply nozzle, m; b = slot width, m.

For the nonattached jet, the centerline velocity should be

$$V_x^{min} = 0.42(T_s - T_r)^{4/9} H^{1/3} \tag{13}$$

where H = maximum distance from the source surface to the nozzle-hood axis, m.

In the case of a push-pull hood over the tank, supply air velocity should not exceed 10 m/s to avoid waves on the liquid surface.

Grinding, polishing, and other finishing operations are another type of dynamic contaminant source. These processes produce particles and impart them with some momentum. The receiving hood used for grinding operations is positioned and sized to catch the particles, which are thrown toward the hood (Burgess et al. 1989). The airflow required for the receiving hood can be calculated based on the capture velocity. It might seem that the distance x used in Equations (8) and (9) can be reduced to $x^* = x - S$, where S is the particle stopping distance (i.e., the distance a particle ejected into still air at the initial velocity will travel while decelerating to rest due to drag forces). However, the data from Hinds (1982) show the difficulty in throwing even fairly large particles an appreciable distance in still air. Any particles in the inhalable range (i.e., $d < 10$ µm) should be considered immovable, so it should be always assumed that $x^* = x$ (Burgess et al. 1989). The hood used for grinding processes acts as a receiver for large particles ($d > 30$ µm), but not for small and intermediate particles ($3 < d < 30$ µm). Bastress et al. (1974) found that respirable particles were not captured efficiently by typical grinding wheel exhaust systems and escaped to the vicinity of the worker's breathing zone. Nonetheless, the standard hood designs recommended in ACGIH (1998), while not 100% efficient at capturing respirable particles, were sufficient to provide worker protection at or below the TLVs for total and respirable inert dust.

Pressure Losses in Local Exhausts

When air enters a hood, dynamic losses cause a loss of total pressure. This is called the **hood entry loss** and may have several components, each given by

$$\Delta p_e = C_o p_v \tag{14}$$

where

Δp_e = hood entry loss, Pa
C_o = loss factor depending on component geometry, dimensionless
p_v = appropriate velocity pressure, Pa

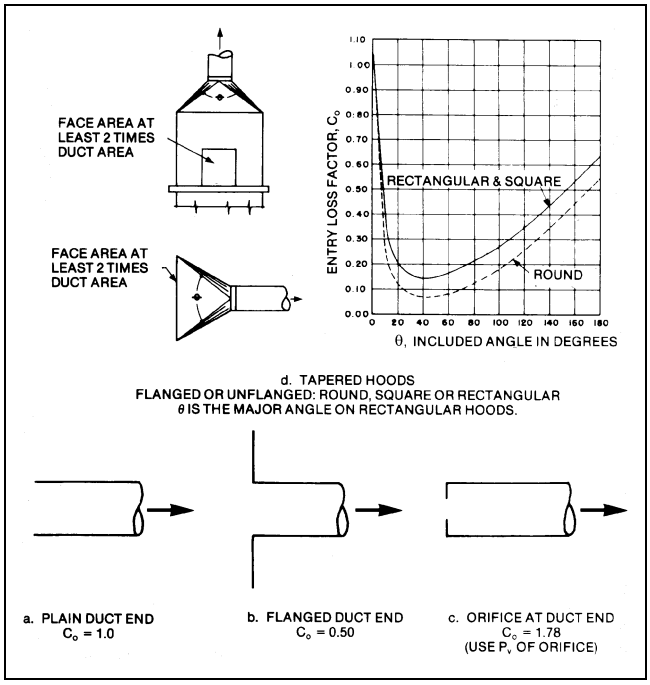

Fig. 15 Entry Losses for Typical Hoods

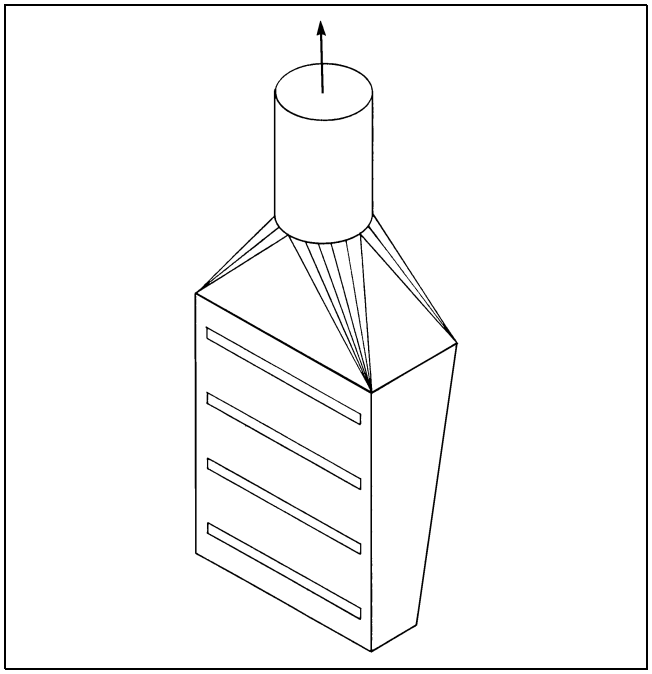

Fig. 16 Multislot Nonenclosing Hood

The following equation relates velocity to velocity pressure:

$$V = \sqrt{\frac{2p_v}{\rho}} \tag{15}$$

If the air temperature is 20°C ± 15°C, the ambient pressure is the standard 101 kPa, the duct pressure is no more than 5 kPa different from the ambient pressure, the dust loading is low (< 2 g/m^3), and moisture is not a consideration, then the density in Equation (15) is 1.2 kg/m^3, and Equation (13) simplifies to

$$V = 1.29\sqrt{p_v} \tag{16}$$

Loss factors C_o for various hood shapes are given in Figure 15. More information on loss factors can be found in Chapter 32, Duct Design, of the 1997 *ASHRAE Handbook—Fundamentals*, Idelchik et al. (1986), and ACGIH (1998). Figure 15 shows an optimum hood entry angle to minimize entry loss. However, this total included angle of 45° is impractical in many situations because of the required transition length. A 90° angle, with a corresponding loss factor of 0.25 (for rectangular openings), is standard for most tapered hoods.

The combination of several consecutive hood components may affect the values of their individual loss factors. Thus, a hood with multiple components should be treated as a single component with a pressure loss obtained in a laboratory or field test.

Total pressure is difficult to measure in a duct system because it varies from point to point across a duct, depending on the local velocity. On the other hand, static pressure remains constant across a straight duct. Therefore, measurement of static pressure in a straight duct at a single point downstream of the hood can monitor the volumetric flow rate. The absolute value of this static pressure, the **hood suction**, is given by

$$p_{st} = p_v + \Delta p_e \tag{17}$$

where p_{st} = hood suction, Pa.

Hood suction is the negative static pressure measured about three duct diameters downstream of the hood. A larger distance is required for included angles of 180° or larger.

Simple Hoods. A simple hood has only one dynamic loss. The hood suction becomes

$$p_{st} = (1 + C_o)p_v \tag{18}$$

where p_v = duct velocity pressure, Pa.

Example 1. A nonenclosing sidedraft flanged hood (Figure 20) with face dimensions of 0.45 m by 1.2 m rests on the bench. The required volumetric flow rate is 700 L/s. The duct diameter is 225 mm; this gives a duct velocity of 17.6 m/s. The hood is designed such that the largest angle of transition between the hood face and the duct is 90°. What is the suction for this hood? Assume standard air density.

Solution: The two transition angles cannot be equal. Whenever this is true, the larger angle is used to determine the loss factor from Figure 15. Because the transition piece originates from a rectangular opening, the curve marked "rectangular" must be used. This corresponds to a loss factor of 0.25. Equation (16), which assumes standard air density, can be used to determine the duct velocity pressure:

$$p_v = (17.6/1.29)^2 = 186 \text{ Pa}$$

From Equation (18),

$$p_{st} = (1 + 0.25)(186) = 232 \text{ Pa}$$

Compound Hoods. The losses for multislot hoods (see Figure 16) or single-slot hoods with a plenum (called compound hoods) must be analyzed somewhat differently. The slots distribute air over the hood face and do not influence capture efficiency. The slot velocity should be approximately 10 m/s to provide the required distribution at the minimum energy cost. Higher velocities dissipate more energy.

Losses occur when air passes through the slot and when air enters the duct. Because the velocities, and therefore the velocity pressures, can be different at the slot and at the duct entry locations, the hood suction must reflect both losses and is given by

$$p_{st} = p_v + (C_o p_v)_s + (C_o p_v)_d \quad (19)$$

where the first p_v is generally the higher of the two velocity pressures, *s* refers to the slot, and *d* refers to the duct entry location.

Example 2. A multislot hood has 3 slots, each 25 mm by 1 m. At the top of the plenum is a 90° transition into the 250 mm duct. The volumetric flow rate required for this hood is 0.78 m^3/s. Determine the hood suction. Assume standard air.

Solution: The slot velocity V_s from Equation (1) is

$$V_s = 0.78/(3 \times 0.025 \times 1) = 10.4 \text{ m/s}$$

Substituting this velocity into Equation (16),

$$p_v = (10.4/1.29)^2 = 65 \text{ Pa}$$

The duct area is 0.0491 m^2. Therefore, the duct velocity determined from Equation (1) is

$$V_d = 0.78/0.0491 = 15.9 \text{ m/s}$$

Substituting this velocity into Equation (16),

$$p_v = (15.9/1.29)^2 = 152 \text{ Pa}$$

For a 90° transition into the duct, the loss factor is 0.25. For the slots, the loss factor is 1.78 (Figure 15). The duct velocity pressure is added to the sum of the two losses because it is larger than the slot velocity pressure. Using Equation (19),

$$p_{st} = 152 + (1.78 \times 65) + (0.25 \times 152) = 306 \text{ Pa}$$

Exhaust volume requirements, minimum duct velocities, and entry loss factors for many specific operations are given in Chapter 10 of ACGIH (1998).

Influence of Air Movement on Local Exhaust Performance

Both air movement caused directly by supply air jets and turbulence of the ambient air resulting from general ventilation system operation, convective plumes, and moving people and process equipment are at least as important as hood face velocity in controlling contaminant spillage. Caplan and Knutson (1978) recommend that air movement caused by the above factors should be less than 1/2 to 2/3 times the hood face velocity.

In studies of hoods with a vertical face area, Zhivov et al. (1997) showed that the preferred orientation of the hood relative to the most likely direction of the cross draft is 135°. This orientation achieves both the lowest contaminant concentration in the operator's breathing zone and the highest capturing effectiveness. A moderate draft from behind the operator significantly increases the contaminant concentration in the operator's breathing zone. A cross draft has minimal effect on operator exposure, but the contaminant removal by the hood is low.

To reduce the influence of cross drafts greater than 0.4 m/s on the performance of a canopy hood above a buoyant source, Stroiizdat (1992) recommends attaching one-, two-, or three-sided removable shields to the hood that drop to a height above the source of 0.8 times the equivalent diameter of the design source.

Schematics in Figure 17 show how air jets can improve hood performance.

LOCAL EXHAUST FROM BUOYANT SOURCES

Overhead Hoods

If the process cannot be completely enclosed, the canopy hood should be placed above the process so that the contaminant moves toward the hood. Canopy hoods should be applied and designed with caution to avoid drawing contaminants across the operator's breathing zone (see Figure 18). The hood's height above the process should be kept to a minimum to reduce the total exhaust airflow rate.

A **low canopy hood** is within 1 m of a process (within the thermal plume transition zone) and requires the lowest volumetric flow rate of all nonenclosing hoods. A **high canopy hood** is more than 3 m above a process and requires a higher volumetric flow rate because room air is entrained in the column of hot, contaminated air rising from the process; this situation should be avoided.

Hemeon (1963) lists Equations (20) through (24) for determining the volumetric flow rate of hot gases for low canopy hoods. Note that canopy hoods located 1 to 3 m above the process cannot be analyzed using these equations.

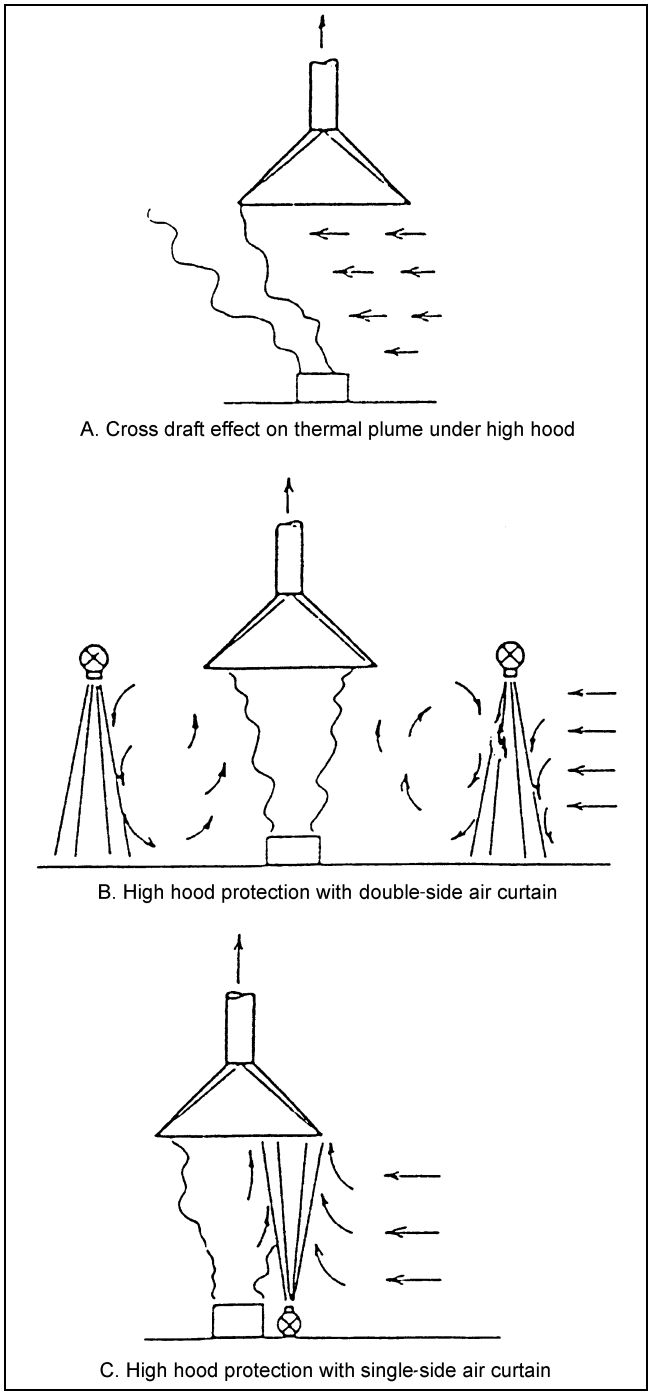

Fig. 17 Hood Performance Improvement with Air Jets

$$Q_o^* = \left(\frac{2gR}{pc_p} \times q_{conv} L A_p^2\right)^{1/3} \quad (20)$$

where

Q_o^* = volumetric flow rate, m^3/s
g = gravitational acceleration, 9.8 m/s^2
R = air gas constant, 287 J/(kg·K)
p = local atmospheric pressure, Pa
c_p = constant pressure specific heat for air, 1004 J/(kg·K)
q_{conv} = convection heat transfer rate, W
L = vertical height of hot object, m
A_p = cross-sectional area of airstream at upper limit of hot body, m^2

For a standard atmospheric pressure of 101.325 kPa, Equation (20) can be written as

$$Q_o^* = 0.038(q_{conv} L A_p^2)^{1/3} \quad (21)$$

For three-dimensional bodies, the area A_p in Equations (20) and (21) is approximated by the plan view area of the hot body (Figure 19A). For horizontal cylinders, A_p is the product of the length and the diameter of the rod.

For vertical surfaces, the area A_p in Equations (20) and (21) is the area of the airstream (viewed from above) as the flow leaves the vertical surface (Figure 19B). As the airstream moves upward on a vertical surface, it appears to expand at an angle of approximately 4 to 5°. Thus, A_p is given by

$$A_p = wL\tan\theta \quad (22)$$

where

w = width of vertical surface, m
L = height of vertical surface, m
θ = angle of air stream expansion, °

For horizontal heated surfaces, A_p is the surface area of the heated surface, and L is the longest length (conservative) of the horizontal surface or its diameter if it is round (Figure 19C).

If the heat transfer is caused by steam from a hot water tank,

$$q_{conv} = h_{fg} G A_p \quad (23)$$

where

q_{conv} = convective heat transfer, kW
h_{fg} = latent heat of vaporization, kJ/kg
G = steam generation rate, kg/(s·m^2)
A_p = surface area of the tank, m^2

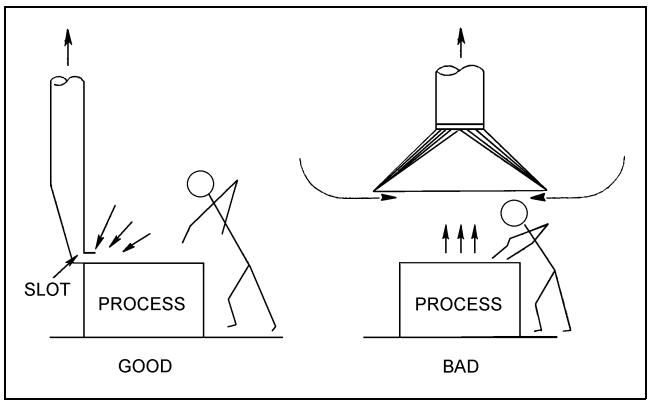

Fig. 18 Influence of Hood Location on Contamination of Air in the Operator's Breathing Zone

At 100°C, the latent heat of vaporization is 2257 kJ/kg. Using this value and Equation (23), Equation (20) simplifies to

$$Q_o^* = 5A_p(GL)^{1/3} \quad (24)$$

The exhaust volumetric flow rate determined by Equation (20) or (24) is the required exhaust flow rate when (1) a low canopy hood of the same dimensions as the hot object or surface is used and (2) side and back baffles are used to prevent room air currents from disturbing the rising air column. If side and back baffles cannot be used, the canopy hood size and the exhaust flow rate should be increased to reduce the possibility of contaminant escape around the hood. A good design provides a low canopy hood overhang equal to 40% of the distance from the hot process to the hood face on all sides (ACGIH 1998). The increased hood flow rate can be calculated using the following equation:

$$Q_t = Q_o^* + V_f(A_f - A_p) \quad (25)$$

where

Q_t = total flow rate entering hood, m^3/s
Q_o^* = flow rate determined by Equation (20) or (24), m^3/s
V_f = desired indraft velocity through the perimeter area, m/s
A_f = hood face area, m^2
A_p = plan view area of Equation (20) or (24)

A minimum indraft velocity of 0.5 m/s should be used for most design conditions. However, if room air currents are appreciable or if the contaminant discharge rate is high and the design exposure limit is low, higher values of V_f may be required.

The volumetric flow rate for a high canopy hood over a round, square, or rectangular (aspect ratio near 1) source can be predicted using Equation (11) with adjustments discussed in the section on Air and Contaminant Distribution with Buoyant Sources.

The diameter D_z of the plume at any elevation z above the virtual source can be determined by

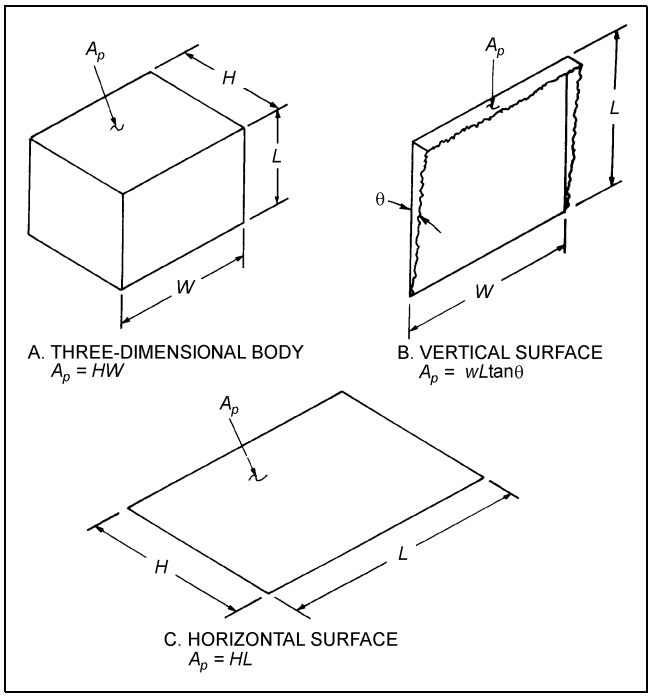

Fig. 19 A_p for Various Situations

$$D_z = 0.5z^{0.88} \quad (26)$$

High canopy hoods are extremely susceptible to room air currents. Therefore, they are typically much larger (often 100% larger) than indicated by Equation (26) and are used only if a low canopy hood cannot be used. The total flow rate exhausted from the hood can be evaluated using Equation (25) if Q_o is replaced by Q_z.

According to Posokhin (1984), the canopy hood is effective when

$$\frac{V_r(z + z_o)}{V_z b} \leq 0.35$$

where

V_r = room air velocity,m/s
z_o = distance from virtual source to upper source level, m
V_z = air velocity on thermal plume axis at hood face level, m/s
b = source width, m

Sidedraft Hoods

Sidedraft hoods are typically used when the contaminant is drawn away from the operator's breathing zone (Figure 2B). With a buoyant source, a sidedraft hood requires a higher exhaust volumetric flow rate than a low canopy hood. If a low canopy hood restricts the operation, a sidedraft hood may be more cost-effective than a high canopy hood. Examples of sidedraft hoods include multislotted "pickling" hoods near welding benches (Figure 16), flanged hoods (Figure 20), and slot hoods on tanks (Figure 21).

Sidedraft hoods should be installed with the low edge of the suction area at the level of the top of the heat source. The distance b between the hood and the source may vary depending on the width of the source (Figure 22); maximum b is equal to the width B of the source. Based on studies by Kuz'mina (1959), the following airflow rate through the sidedraft hood is recommended (Stroiizdat 1992):

$$Q_o^* = cq_{conv}^{1/3}(H + B)^{5/3} \quad (27)$$

where

c = nondimensional coefficient depending on hood design and location relative to contaminant source [see Equations (28) and (29)]
q_{conv} = convective component of the heat source, W
H = vertical distance from source top surface to hood center, m
B = source width, m

For a hood without a screen (Figure 22A),

$$c = 280\left(\frac{I}{H + B}\right)^{2/3} \quad (28)$$

For a hood with a screen (Figure 22B),

$$c = 280m\sqrt{\frac{I}{H + B}} \quad (29)$$

where $m = 1$, when $b/B = 0$; $m = 1.5$, when $b/B = 0.3$; $m = 1.8$ when $b/B = 1$, and $m = 2$ when $b/B > 1$.

For open vessels, the contaminant can be controlled by a lateral exhaust hood, which exhausts air through slots on the periphery of the vessel. The hood capturing effectiveness depends on the exhaust airflow rate and the hood design; however, it is not influenced by air velocity through the slot. Hoods are designed with air exhaust from one side of the vessel or from two sides. Air exhaust from two sides requires a lower exhaust airflow rate. In most applications, a hood with a vertical face (Figure 23A) is used when the distance h_1

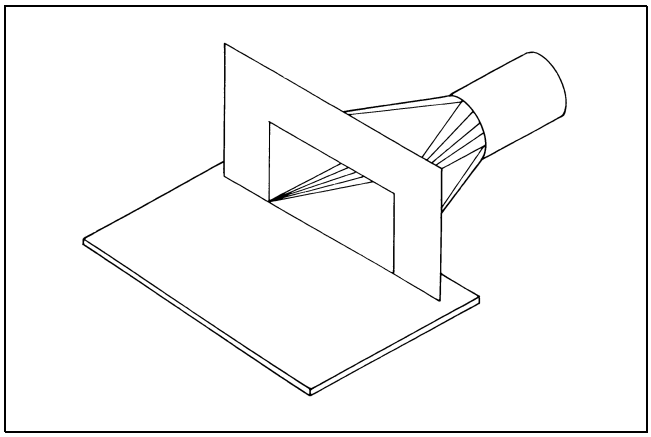

Fig. 20 Hood on Bench

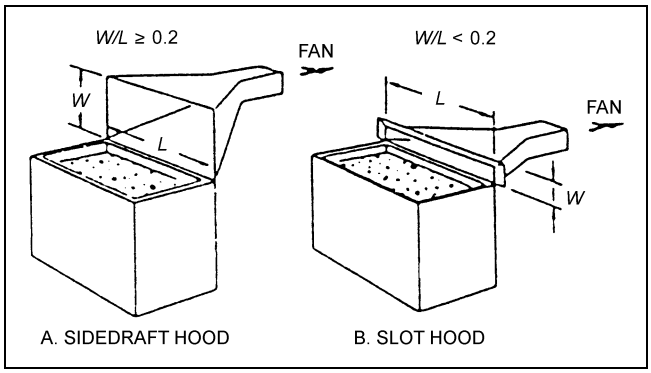

Fig. 21 Sidedraft Hood and Slot Hood on Tank

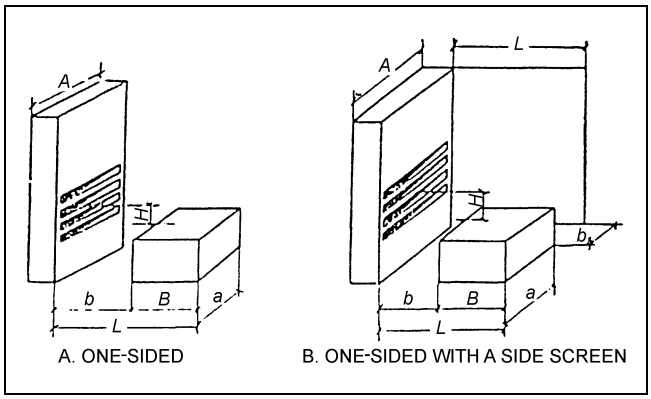

Fig. 22 Schematics of Sidedraft Hood on Work Bench

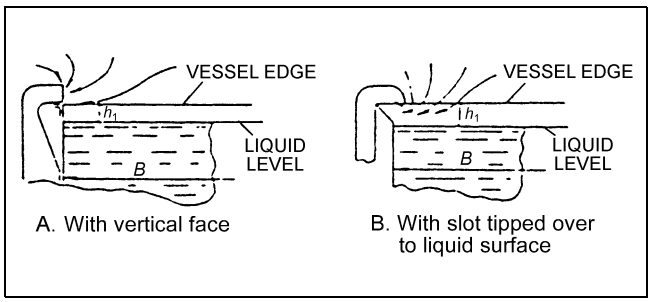

Fig. 23 Schematics of Sidedraft Slot Hood on Tank

Table 4 $K_{\Delta t}$ Coefficient Values

	Liquid-to-Air Temperature Difference, K								
	0	**10**	**20**	**30**	**40**	**50**	**60**	**70**	**80**
$K_{\Delta t}$	1	1.16	1.31	1.47	1.63	1.79	1.94	2.1	2.26

between the vessel edge and the liquid level is smaller than 100 mm (Stroiizdat 1992). When h_l > 100 mm, hoods with the slot tipped over to the liquid surface (Figure 23B) are more effective.

Stroiizdat (1992) recommends the following exhaust airflow rate from one- and two-sided lateral slot hoods:

$$Q_o^* = 1400\left(0.53\frac{Bl}{B+l}+h\right)^{1/3} BlK_1K_{\Delta t}K_t \quad (30)$$

where

B = vessel width, m
l = vessel length, m
h = vertical distance between the liquid level and the hood face center, m
K_1 = hood design coefficient: K_1 = 1 for two-sided hood; K_1 = 1.8 for one-sided hood
$K_{\Delta t}$ = coefficient reflecting liquid temperature (see Table 4)
K_t = coefficient reflecting process toxicity (from 1 to 2; e.g., for electroplating tanks, K_t = 2)

A more cost-effective alternative to a one- or two-sided lateral hood is a **push-pull hood**, described in the section on Jet-Assisted Hoods.

Downdraft Hoods

Downdraft hoods should be considered only when overhead or sidedraft hoods are impractical. Air can be exhausted through a slotted baffle (e.g., downdraft cutting table—see Figure 24) or through a circular slot with a round source (Figure 25A) or two linear slots along the long sides of a rectangular source (Figure 25B). To achieve higher capturing effectiveness, the exhaust should be located as close to the source as possible. Capturing effectiveness decreases with an increase in source height and increases when the top of the source is located below the hood face surface. With a buoyant source, the air velocity induced by the exhaust should be equal to or greater than the air velocity in the plume above the source (Posokhin 1984).

The target airflow rate for a circular downdraft hood is

$$Q_o^* = 0.0314(q_{conv}d^5)^{1/3}\left(1-0.06\frac{q_{conv}^{vert}}{q_{conv}^{horiz}}\right)K_1K_v \quad (31)$$

For a double linear slot downdraft hood,

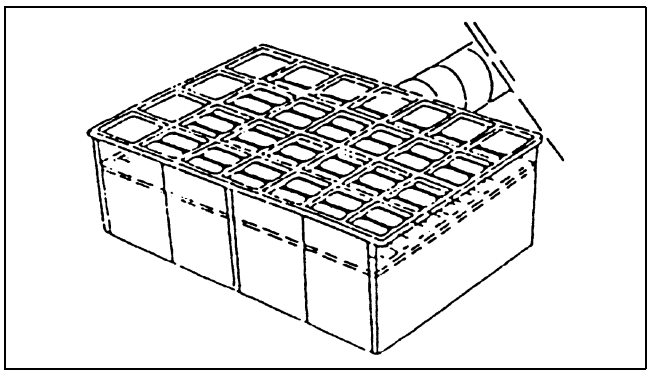

Fig. 24 Downdraft Welding Table

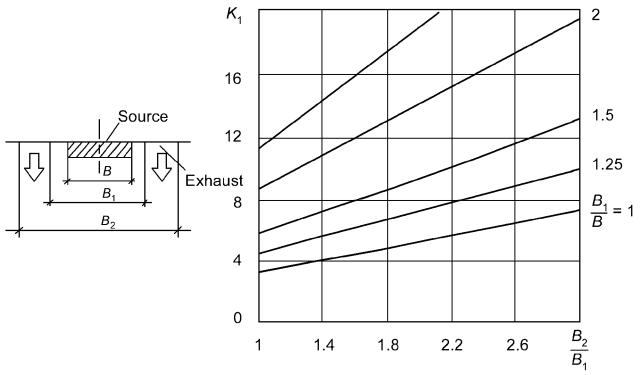
$$Q_o^* = 0.05q_{conv}^{1/3}lbK_1K_v \quad (32)$$

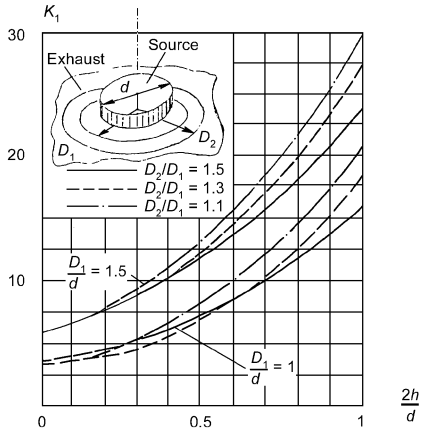
where

d = source diameter, m
l = source length, m
b = source width, m
q_{conv}^{vert} = convective heat component from the source vertical surfaces, W
q_{conv}^{horiz} = convective heat component from the source horizontal surface, W
K_1 = coefficient accounting for hood geometry that can be evaluated using graphs in Figure 25
K_v = coefficient accounting for room air movement V_r



$$= 1 + 44.7\sqrt[3]{V_r^3\frac{d}{q_{conv}}} \text{ for circular downdraft hood} \quad (33)$$

$$= 1 + 44.7\sqrt[3]{V_r^3\frac{b}{q_{conv}}} \text{ for double slot downdraft hood} \quad (34)$$



Example 3. A downdraft hood is to be designed to capture a contaminant from a rectangular source $l \times b \times h$ = 0.6 m × 0.5 m × 0 m. Convective heat component of the source q_{conv} = 1000 W. Room air movement V_r = 0.4 m/s. Two exhaust slots with a width b = 100 mm are located at the distance B_1 = 0.6 m and B_2 = 0.8 m. Determine the exhaust airflow rate.

Solution: Using the graph in Figure 25 for B_2/B_1 = 0.8/0.6 = 1.33, and B_1/b = 0.6/0.5 = 1.2, obtain K_1 = 5. Coefficient K_v accounting for room air movement [Equation (34)] is

$$K_v = 1 + 44.77\sqrt[3]{0.4^3\frac{0.5}{1000}} = 1.25$$

A. Circular slot with round source

B. Linear slots along the long sides of rectangular source

Fig. 25 K_1 Coefficient Evaluation for Downdraft Hoods

The exhaust airflow rate [Equation (32)] is

$$Q_o^* = 0.05 \times 1000^{1/3} \times 0.6 \times 0.5 \times 5 \times 1.25 = 0.937 \text{ m}^3/\text{s}$$

Airflow rate recommended for typical downdraft cutting table (Hagopian and Bastress 1976) can be calculated using Equation (1), where A_o is tabletop area, m^2, and V_f = minimum face velocity, m/s.

JET-ASSISTED HOODS

Major Types and Application Recommendations

Jet-assisted hoods are nonenclosing hoods combined with compact, linear, or radial air jets. They are used to

- Increase capturing effectiveness (Figure 26) by transporting contaminants toward the face of the hood using supply jets (ACGIH 1998; Heinsohn 1991; Elinskii 1989; Stroiizdat 1992; Sciola 1993).
- Separate contaminated zones from relatively clean zones in working spaces (Boshnyakov 1975; Romeyko et al. 1976; Stoler and Savelyev 1977; Posokhin and Broida 1980; Anichkhin and Anichkhina 1984; Cesta 1988; Zhivov 1993). For example, jet-assisted hoods can be used over welding robots (Figure 29).

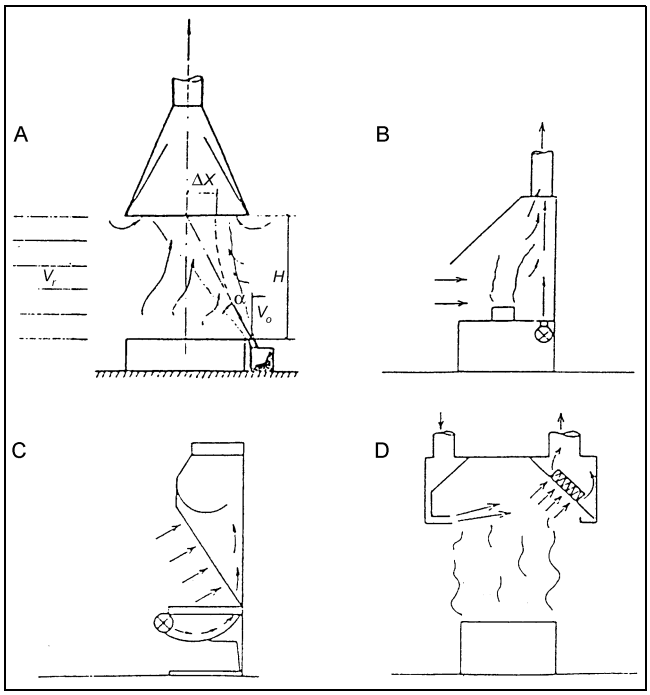


Fig. 26 Examples of Air Jet Usage to Increase Hood Capturing Effectiveness

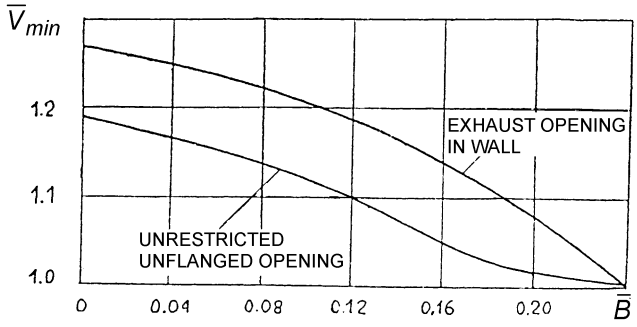

Fig. 27 Graph for Evaluation of $\overline{V}_{min}$

- Prevent contaminated air from moving into clean zones by creating positive static pressure (Strongin and Marder 1988); for example, in drying chambers and cooling tunnels of casting conveyors (Figure 30).
- Protect hoods from room air movement; for example, with some laboratory hoods and industrial ovens, hoods can be used in combination with air curtains (Figure 17).
- Create swirling airflows near the exhaust hood, increasing its capturing effectiveness (Ljungqvist and Waering 1988).

The capturing effectiveness of jet-assisted hoods is 15 to 20% higher than that of conventional hoods for the same operating costs (Strongin and Marder 1988). For the same capturing effectiveness, jet-assisted hoods are 25 to 30% more cost-effective due to lower airflow. When exhausted air must be cleaned, reduced cleaning costs make jet-assisted hoods 100 to 150% more cost-effective. If compensating-type jet-assisted hoods are used, operating costs for heating and cooling in general ventilation systems are also reduced.

Design Procedure

Push-Pull Hoods over Open Surface Tanks. A push-pull exhaust system is a more efficient alternative to lateral exhausts for open-surface vessels such as plating tanks. In a push-pull system, air is blown through one slot on the periphery of a vessel and exhausted from a slot on the opposite side. The inlet to the hood must be large enough to accommodate the jet and the room air entrained by the jet. Push-pull systems can be used on wider vessels than lateral exhaust hoods. Chapter 10 of ACGIH (1998) provides a design procedure for these systems.

Push-Pull Hood for Vertical Apertures. The design principle of a push-pull exhaust hood with a linear jet supplied upward toward the canopy hood above [e.g., the oven aperture (Figure 26A)] is based on maintaining the minimum velocity along the jet such that

$$V_{min} = 9.9\sqrt{\frac{\Delta p}{\rho_g}}\left(\frac{\sqrt{1 + 142q^2} - 1}{89C^2}\right) \quad (35)$$

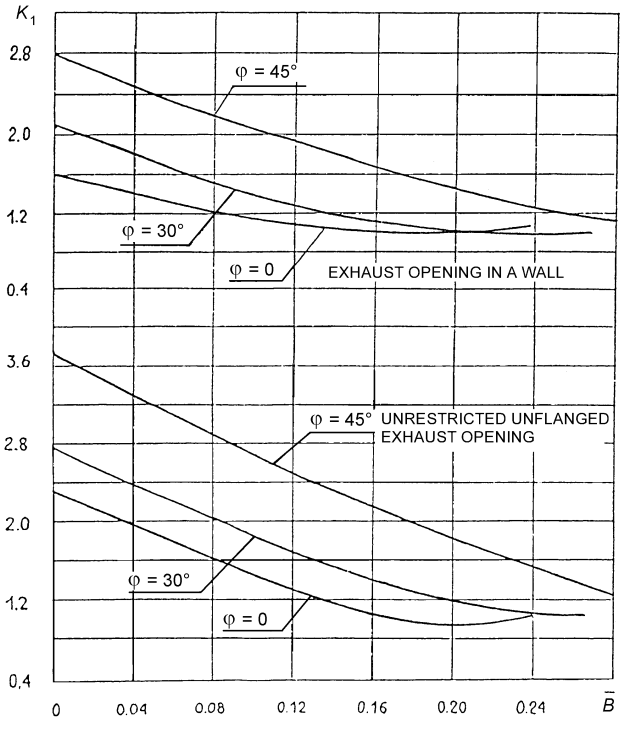

Fig. 28 Coefficient K_1 Evaluation for Pull-Push Hoods with Different Hood Configurations

where

$$C = \frac{1}{1 + 3.74(\rho_g / \rho_{air})} \quad (36)$$

V_{min} = minimum velocity along jet, m/s
Δp = excessive pressure inside the process equipment, Pa
ρ_{air} = density of room air, kg/m^3
ρ_g = density of gas mixture releasing through the aperture in the process equipment, kg/m^3

The supply and exhaust airflow rates Q_{sup} and Q_o, m^3/s, can be determined as follows:

For a nonattached jet,

$$Q_{sup} = 0.435 \frac{V_{min}}{\overline{V_{min}}} a\sqrt{bl} \quad (37)$$

$$Q_{sup} = 0.205 \frac{V_{min}}{\overline{V_{min}}} alK_1K_v \quad (38)$$

For a wall jet,

$$Q_{sup} = 0.31 \frac{V_{min}}{\overline{V_{min}}} a\sqrt{bl} \quad (39)$$

$$Q_{sup} = 0.103 \frac{V_{min}}{\overline{V_{min}}} alK_1K_v \quad (40)$$

where

$\overline{V_{min}}$ = from graph in Figure 27
B = relative width of exhaust hood
= $B/2l$ for a nonattached jet and B/l for a wall jet
B = width of exhaust hood, m
a = length of exhaust hood, m
b = width of supply slot, m
K_1 = coefficient accounting for hood geometry can be evaluated using graphs in Figure 28
K_v = coefficient accounting for room air movement V_r

$$= 1 + \frac{V_r}{V_{min}} \quad (41)$$

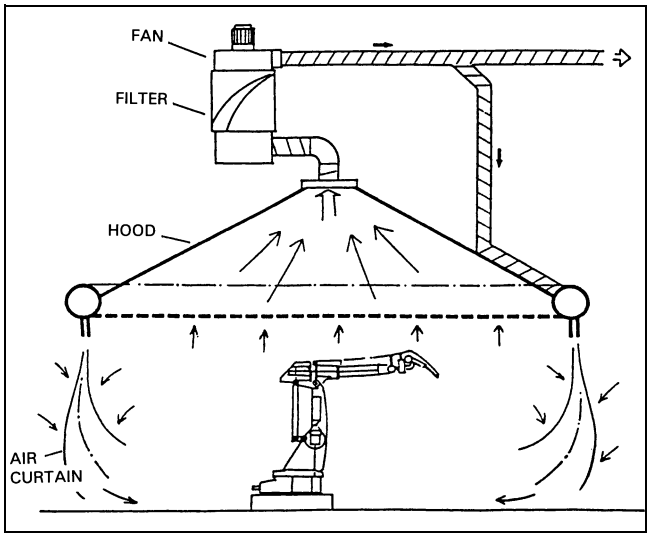

Fig. 29 Push-Pull Hood over Welding Robot

The following are some design considerations:

- Push-pull hoods are economically feasible if $l > 1$ m.
- The jet should be considered a wall jet when the distance H between the supply nozzle and the vertical surface is smaller than $0.15l$. Otherwise, the jet is nonattached.
- When flange width $h > H + B$, the hood is treated as an opening in an infinite surface; when $h \le H + B$, the hood is treated as freestanding.
- The value of the minimum velocity V_{min} along the jet should be greater than 1.5 m/s.
- The width b of the supply air slot is typically chosen to be $0.01l$. However, it should be greater than 5 mm to prevent fouling. The length a of the supply slot should be equal to the length of the aperture.
- The supply air velocity V_o should not exceed 1.5 m/s. This can be achieved by selection of the appropriate slot width b.

Example 4. A push-pull hood is to capture a contaminant from an oven aperture. The surplus pressure in the oven $\Delta p = 2$ Pa, and the temperature inside the oven $t_g = 800$°C ($\rho_g = 0.329$ kg/m^3). Canopy hood is installed at the height of $l = 1.2$ m from the low edge of the oven aperture. The hood projection $B = 0.576$ m, and the hood width is equal to the aperture width $a = 1.8$ m; the aperture height is 1 m. The room air velocity near the hood $V_r = 0.4$ m/s and the room air temperature $t_{air} = 20$°C ($\rho_{air} = 1.2$ kg/m^3). Determine the supply and exhaust airflow rates.

Solution: Using the graph in Figure 27 for $B = 0.576/(2 \times 1.2) = 0.24$, obtain $\overline{V_{min}} = 1$.

From Equations (35) and (36) obtain parameter C and velocity V_{min}:

$$C = \frac{1}{1 + 3.74(0.329/1.2)} = 0.494$$

$$V_{min} = 9.9\sqrt{\frac{2}{0.329}}\left(\frac{\sqrt{1 + 142 \times 0.494^2} - 1}{89 \times 0.494^2}\right) = 5.59 \text{ m/s}$$

Assuming $b = 0.025$ m, calculate supply airflow rate [Equation (37)]:

$$Q_{sup} = 0.435 \times \frac{5.59}{1} \times 1.8\sqrt{0.025 \times 1.2} = 0.76 \text{ m}^3/\text{s}$$

Coefficient K_v accounting for room air movement [Equation (41)]:

$$K_v = 1 + \frac{0.4}{5.59} = 1.07$$

From the graph in Figure 28, $K_1 = 1$.

The exhaust airflow rate [Equation (38)]:

$$Q_{sup} = 0.205 \times \frac{5.59}{1} \times 1.8 \times 1.2 \times 1 \times 1.07 = 2.65 \text{ m}^3/\text{s}$$

Push-Pull Hood above Contaminated Area. A canopy hood with an incorporated slotted nozzle installed around the perimeter of the hood is used to prevent contaminant transfer from contaminated areas, for example, the operating zone of one or several welding robots (Figure 29), where enclosing hoods or other types of nonenclosing hoods are impractical (U.S. Patent). Air supplied through the nozzle creates steady air curtain protection along the contour. Due to the negative pressure created by the hood, the air curtain jet turns at or below the level of the contaminant source toward the center. To minimize the supply airflow rate, the nozzle is equipped with a honeycomb attachment that produces a low-turbulence jet. The width of the nozzle can be determined as follows:

$$b = \frac{A/P}{45\left(\frac{A}{PH}\right)^2\left(0.566\sqrt{\frac{H}{b}} - 1\right)^2 - 0.25\left(0.566\sqrt{\frac{H}{b}} + 1\right)^2} \quad (42)$$

where

b = nozzle width, m
A = hood cross-sectional area, m^2
P = hood perimeter, m
H = height of hood above contaminant source, m

Push-Pull Protection System. These systems are used (Strongin et al. 1986; Strongin and Marder 1988) to prevent contaminant release from process equipment when the process requires that entering and/or exiting apertures remain open (e.g., conveyer painting chambers, cooling tunnels, etc.). The open aperture must be equipped with a tunnel and supply and exhaust air systems (Figure 30). The aperture is protected by the air jet(s) supplied through one or two slots installed along one side or two opposite sides of the tunnel and directed at angle $\alpha = 80$ to 85° to the tunnel cross section. Air supplied through the slot(s) is thus directed toward the incoming room air. Moving along the tunnel, the jet(s) slow down, and their dynamic pressure is converted into static pressure, preventing room air from entering the chamber. After reaching the point with a zero centerline velocity, the jet(s) make a U-turn and redirect into the chamber. The air jet(s) can be supplied vertically (with supply air ducts installed along vertical walls) or horizontally (with supply air ducts installed along horizontal walls). The distance X (Figure 30) from the entrance of a tunnel (with cross-sectional area $B \times H$) to the supply slot location should be greater than or equal to $5B$ with a single vertical jet ($5H$ with a single horizontal jet) and $2.5B$ ($2.5H$) when air is supplied by two jets.

The air supply slot is equipped with diverging vanes (angle β between 30 to 90°) creating an air jet with an increased angle of divergence; the number n of these vanes should be greater than or equal to $\beta/10$. The increased angle of divergence of supply air jets allows a decrease in the distance X between the tunnel entrance and the slot.

Airflow rate supplied by the jet is determined as

$$Q_o^* = \sqrt{\frac{A_o b_o L_o \Delta p}{J}} \tag{43}$$

where

A_o = cross-sectional area of the tunnel, m^2
b_o = supply slot width, m
L_o = supply slot length, m
J = supply jet parameter

$$= \sin\alpha + 2.5\frac{A_o}{A_c}\left[2.13(1+\psi)^2 + \left(\frac{\psi}{1+1/\psi}\right)^2 - \psi^2\right] \tag{44}$$

$$\text{for } \psi = \frac{Q_{exh}}{Q_o}$$

Δp = chamber to room pressure difference, Pa

$$= 0.5gH(\rho_{room} - \rho_c) \tag{45}$$

H = chamber height, m
g = gravitational acceleration, 9.8 m/s^2
ρ_{room} = room chamber air density, kg/m^3
ρ_c = chamber air density, kg/m^3

The minimum airflow rate to be exhausted outside from the chamber and the corresponding amount of outdoor air to be supplied through the slot should dilute the contaminants in the chamber to the desired concentration. In the case of prevention of contaminant release from a drying chamber, the solvent vapor concentration should not exceed 25% of the lower explosive limit $C_{exp(min)}$. In this case, the exhaust airflow rate can be determined as follows:

$$Q_{exh} = \frac{GK}{0.25C_{exp(min)}} \tag{46}$$

where

G = amount of vapor release into the chamber, mg/s
K = coefficient accounting for the nonuniformity of solvent evaporation and other irregularities; typically, $2 \le K \le 5$
$C_{exp(min)}$ = lower explosive limit of pollutant, mg/m^3

OTHER LOCAL EXHAUST SYSTEM COMPONENTS

Duct Design and Construction

Duct Considerations. The second component of a local exhaust ventilation system is the duct through which contaminated air is transported from the hood(s). Round ducts are preferred because they (1) offer a more uniform air velocity to resist settling of material and (2) can withstand the higher static pressures normally found in exhaust systems. When design limitations require rectangular ducts, the aspect ratio (height-to-width ratio) should be as close to unity as possible.

Minimum transport velocity is the velocity required to transport particulates without settling. Table 5 lists some generally accepted transport velocities as a function of the nature of the contaminants (ACGIH 1998). The values listed are typically higher than theoretical and experimental values to account for (1) damage to ducts, which would increase system resistance and reduce volumetric flow and duct velocity; (2) duct leakage, which tends to decrease velocity in the duct system upstream of the leak; (3) fan wheel corrosion or erosion and/or belt slippage, which could reduce fan volume; and (4) reentrainment of settled particulate caused by improper operation of the exhaust system. Design velocities can be higher than the minimum transport velocities but should never be significantly lower.

When particulate concentrations are low, the effect on fan power is negligible. Standard duct sizes and fittings should be used to cut cost and delivery time. Information on available sizes and the cost of nonstandard sizes can be obtained from the contractor(s).

Table 5 Contaminant Transport Velocities

Nature of Contaminant	Examples	Minimum Transport Velocity, m/s
Vapor, gases, smoke	All vapors, gases, smoke	Usually 5 to 10
Fumes	Welding	10 to 13
Very fine light dust	Cotton lint, wood flour, litho powder	13 to 15
Dry dusts and powders	Fine rubber dust, molding powder dust, jute lint, cotton dust, shavings (light), soap dust, leather shavings	15 to 20
Average industrial dust	Grinding dust, buffing lint (dry), wool jute dust (shaker waste), coffee beans, shoe dust, granite dust, silica flour, general material handling, brick cutting, clay dust, foundry (general), limestone dust, asbestos dust in textile industries	18 to 20
Heavy dust	Sawdust (heavy and wet), metal turnings, foundry tumbling barrels and shakeout, sandblast dust, wood blocks, hog waste, brass turnings, cast-iron boring dust, lead dust	20 to 23
Heavy and moist dust	Lead dust with small chips, moist cement dust, asbestos chunks from transite pipe cutting machines, buffing lint (sticky), quicklime dust	23 and up

Source: Adapted from *Industrial Ventilation: A Manual of Recommended Practice* (ACGIH 1998).

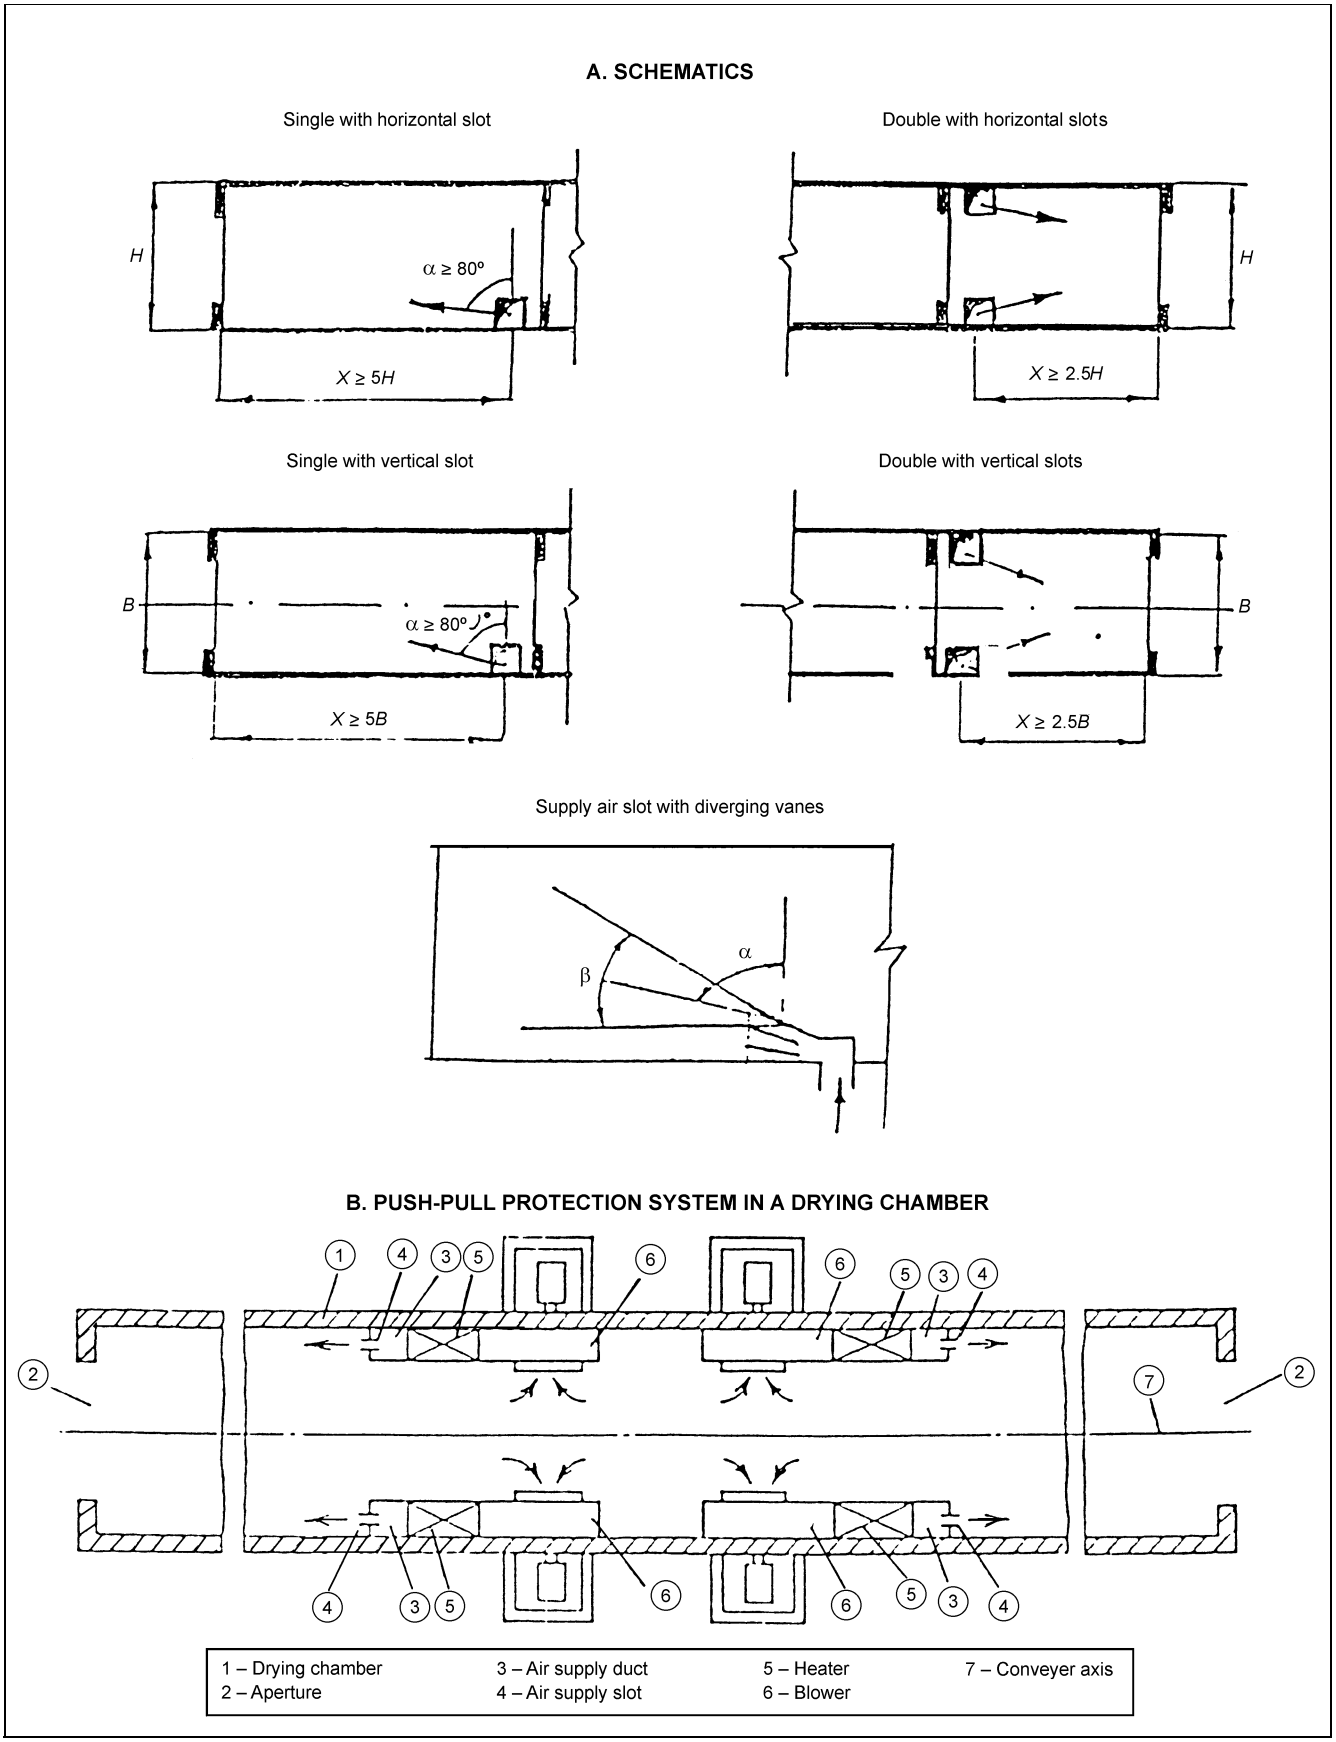

Fig. 30 Push-Pull Protection System

Duct Size Determination. The size of the round duct attached to the hood can be calculated using Equation (1) for the volumetric flow rate and Table 5 for the minimum transport velocity.

Example 5. Suppose the contaminant captured by the hood in Example 1 requires a minimum transport velocity of 15 m/s. What diameter round duct should be specified?

Solution: From Equation (1), the duct area required is

$$A = 0.702/15 = 0.047 \text{ m}^2$$

Generally, the area calculated will not correspond to a standard duct size. The area of the standard size chosen should be less than that calculated. For this example, a 225 mm diameter duct with an area of 0.0398 m^2 should be chosen. The actual duct velocity is then

$$V = 0.702/0.0398 = 17.6 \text{ m/s}$$

Duct Losses. Chapter 32 of the 1997 *ASHRAE Handbook—Fundamentals* covers the basics of duct design and the design of metalworking exhaust systems. The design method presented there is based on total pressure loss, including the fitting coefficients; ACGIH (1998) calculates static pressure loss. Loss coefficients can be found in Chapter 32 of the 1997 *ASHRAE Handbook—Fundamentals* and in the ASHRAE *Duct Fitting Database* (ASHRAE 1994), which runs on a personal computer.

For systems conveying particulates, elbows with a centerline radius-to-diameter ratio (r/D) greater than 1.5 are the most suitable. If $r/D \leq 1.5$, abrasion in dust-handling systems can reduce the life of elbows. Elbows, especially those with large diameters, are often made of seven or more gores. For converging flow fittings, a 30° entry angle is recommended to minimize energy losses and abrasion in dust-handling systems (Fitting ED5-1 in Chapter 32 of the 1997 *ASHRAE Handbook—Fundamentals*).

Where exhaust systems handling particulates must allow for a substantial increase in future capacity, required transport velocities can be maintained by providing open-end stub branches in the main duct. Air is admitted through these stub branches at the proper pressure and volumetric flow rate until the future connection is installed. Figure 31 shows such an air bleed-in. The use of outside air minimizes replacement air requirements. The size of the opening can be calculated by determining the pressure drop required across the orifice from the duct calculations. Then the orifice velocity pressure can be determined from one of the following equations:

$$p_{v,o} = \frac{\Delta p_{t,o}}{C_o} \quad (47)$$

or

$$p_{v,o} = \frac{\Delta p_{s,o}}{C_o + 1} \quad (48)$$

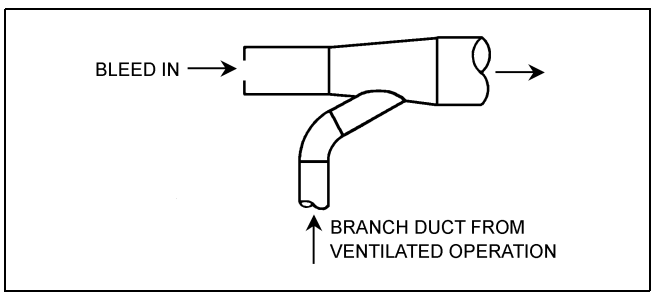

Fig. 31 Air Bleed-In

where

$p_{v,o}$ = orifice velocity pressure, Pa
$\Delta p_{t,o}$ = total pressure to be dissipated across orifice, Pa
$\Delta p_{s,o}$ = static pressure to be dissipated across orifice, Pa
C_o = orifice loss coefficient referenced to the velocity at the orifice cross-sectional area, dimensionless (Figure 15)

Equation (47) should be used if total pressure through the system is calculated; Equation (48) should be used if static pressure through the system is calculated. Once the velocity pressure is known, Equation (15) or (16) can be used to determine the orifice velocity. Equation (1) can then be used to determine the orifice size.

Integrating Duct Segments. Most systems have more than one hood. If the pressures are not designed to be the same for merging parallel airstreams, the system adjusts to equalize pressure at the common point; however, the flow rates of the two merging airstreams will not necessarily be the same as designed. As a result, the hoods can fail to control the contaminant adequately, exposing workers to potentially hazardous contaminant concentrations. Two design methods ensure that the two pressures will be equal. The preferred design self-balances without external aids. This procedure is described in the section on Industrial Exhaust System Duct Design in Chapter 32 of the 1997 *ASHRAE Handbook—Fundamentals*. The second design, which uses adjustable balance devices such as blast gates or dampers, is not recommended, especially when abrasive material is conveyed.

Duct Construction. Elbows and converging flow fittings should be made of thicker material than the straight duct, especially if abrasives are conveyed. In some cases, elbows must be constructed with a special wear strip in the heel. When corrosive material is present, alternatives such as special coatings or different duct materials (fibrous glass or stainless steel) can be used. Industrial duct construction is described in Chapter 16 of the 2000 *ASHRAE Handbook—Systems and Equipment*. Refer to SMACNA (1990) for industrial duct construction standards.

Air Cleaners

Air-cleaning equipment is usually selected to (1) conform to federal, state, or local emissions standards and regulations; (2) prevent reentrainment of contaminants to work areas; (3) reclaim usable materials; (4) permit cleaned air to recirculate to work spaces and/or processes; (5) prevent physical damage to adjacent properties; and (6) protect neighbors from contaminants.

Factors to consider when selecting air-cleaning equipment include the type of contaminant (number of components, particulate versus gaseous, and concentration), the contaminant removal efficiency required, the disposal method, and the air or gas stream characteristics. See Chapters 24 and 25 of the 2000 *ASHRAE Handbook—Systems and Equipment* for information on equipment for removing airborne contaminants. A qualified applications engineer should be consulted when selecting equipment.

The cleaner's pressure loss must be added to overall system pressure calculations. In some cleaners, specifically some fabric filters, the loss increases as operation time increases. The system design should incorporate the maximum pressure drop of the cleaner, or hood flow rates will be lower than designed during most of the duty cycle. Also, fabric collector losses are usually given only for a clean air plenum. A reacceleration to the duct velocity, with the associated entry losses, must be calculated in the design phase. Most other cleaners are rated flange-to-flange with reacceleration included in the loss.

Air-Moving Devices

The type of air-moving device used depends on the type and concentration of contaminant, the pressure rise required, and the allowable noise levels. Fans are usually selected. Chapter 18 of the 2000 *ASHRAE Handbook—Systems and Equipment* describes available

fans and refers the reader to Air Movement and Control Association (AMCA) *Publication* 201, Fans and Systems, for proper connection of the fan(s) to the system. The fan should be located downstream of the air cleaner whenever possible to (1) reduce possible abrasion of the fan wheel blades and (2) create negative pressure in the air cleaner so that air leaks into it and positive control of the contaminant is maintained.

In some instances, however, the fan is located upstream from the cleaner to help remove dust. This is especially true with cyclone collectors, for example, which are used in the woodworking industry. If explosive, corrosive, flammable, or sticky materials are handled, an injector can transport the material to the air-cleaning equipment. Injectors create a shear layer that induces airflow into the duct. Injectors should be the last choice because their efficiency seldom exceeds 10%.

Energy Recovery

The transfer of energy from exhausted air to replacement air may be economically feasible, depending on (1) the location of the exhaust and replacement air ducts, (2) the temperature of the exhausted gas, and (3) the nature of the contaminants being exhausted. The efficiency of heat transfer depends on the type of heat recovery system used. Rotary air-to-air exchangers have the best efficiency, 70-80%. Cross flow fixed-surface plate exchangers and energy recovery loops with liquid coupled coils have efficiencies of 50 and 60% (Aro and Kovula 1992).

If exhausted air contains particulate matter (e.g., dust, lint) or oil mist, the exhausted air should be filtered to prevent fouling the heat exchanger. If the exhausted air contains gaseous and vaporous contaminants such as hydrocarbons and water-soluble chemicals, their effect on the heat recovery device should be investigated (Aro and Kovula 1992).

Exhaust Stacks

The exhaust stack must be designed and located to prevent the reentrainment of discharged air into supply system inlets. The building's shape and surroundings determine the atmospheric airflow over it. Chapter 15 of the 1997 *ASHRAE Handbook—Fundamentals* and Chapter 43 of this volume cover exhaust stack design.

If rain protection is important, stackhead design is preferable to weathercaps. Weathercaps, which are not recommended, have three disadvantages:

1. They deflect air downward, increasing the chance that contaminants will recirculate into air inlets.
2. They have high friction losses.
3. They provide less rain protection than a properly designed stackhead.

Figure 32 contrasts the flow patterns of weathercaps and stackheads. Loss data for weathercaps and stackheads are presented in the ASHRAE *Duct Fitting Database* (ASHRAE 1994). Losses in the straight duct form of stackheads are balanced by the pressure regain at the expansion to the larger-diameter stackhead.

OPERATION

System Testing

After installation, an exhaust system should be tested to ensure that it operates properly with the required flow rates through each hood. If the actual installed flow rates are different from the design values, they should be corrected before the system is used. Testing is also necessary to obtain baseline data to determine (1) compliance with federal, state, and local codes; (2) by periodic inspections, whether maintenance on the system is needed to ensure design operation; (3) whether a system has sufficient capacity for additional airflow; and (4) whether system leakage is acceptable. AMCA *Publication* 203 and Chapter 9 of ACGIH (1998) contain detailed information on the preferred methods for testing systems.

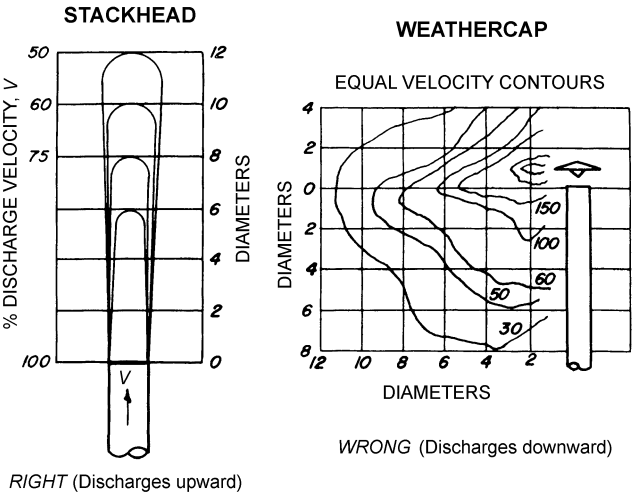

Fig. 32 Comparison of Flow Pattern for Stackheads and Weathercaps

Operation and Maintenance

Periodic inspection and maintenance are required for the proper operation of exhaust systems. Systems are often changed or damaged after installation, resulting in low duct velocities and/or incorrect volumetric flow rates. Low duct velocities can cause the contaminant to settle and plug the duct, reducing flow rates at the affected hoods. Adding hoods to an existing system can change volumetric flow at the original hoods. In both cases, changed hood volumes can increase worker exposure and health risks. The maintenance program should include (1) inspecting ductwork for particulate accumulation and damage by erosion or physical abuse, (2) checking exhaust hoods for proper volumetric flow rates and physical condition, (3) checking fan drives, and (4) maintaining air-cleaning equipment according to manufacturers' guidelines.

CHAPTER 30

KITCHEN VENTILATION

Cooking Effluent 30.1
Exhaust Hoods 30.1
Exhaust Systems 30.6
Replacement (Makeup) Air Systems 30.9
System Integration and Balancing 30.9
Energy Considerations 30.11
Fire Protection 30.12
Operation and Maintenance 30.15
Residential Kitchen Ventilation 30.17

KITCHEN ventilation is a complex application of HVAC systems. System design includes aspects of air conditioning, fire safety, ventilation, building pressurization, refrigeration, air distribution, and food service equipment. Kitchens are in many buildings, including hotels, hospitals, retail malls, single- and multifamily dwellings, and correctional facilities. Each of these building types has special requirements for its kitchens, but many of the basic needs are common to all.

Kitchen ventilation has at least two purposes: (1) to provide a comfortable environment in the kitchen and (2) to enhance the safety of personnel working in the kitchen and of other building occupants. "Comfortable" in this context has different meanings because, depending on the local climate, some kitchens are not air conditioned. Obviously, the kitchen ventilation system can affect temperature and humidity in the kitchen. The ventilation system can also affect the acoustics of a kitchen.

The centerpiece of almost any kitchen ventilation system is an exhaust hood, which is used primarily to remove effluent from kitchens. **Effluent** includes the gaseous, liquid, and solid contaminants produced by the cooking process. These contaminants must be removed for both comfort and safety. Effluent can range from simply annoying to potentially life-threatening and, under certain conditions, flammable. The arrangement of the food service equipment and its coordination with the hood(s) greatly affect the operating costs of the kitchen.

HVAC system designers are most frequently involved in commercial kitchen applications, in which cooking effluent contains large amounts of grease or water vapor. Residential kitchens typically use a totally different type of hood. The amount of grease produced in residential applications is significantly less than in commercial applications, so the health and fire hazard is much lower.

COOKING EFFLUENT

Effluent Generation

Cooking is the process of creating chemical and physical changes in food by applying heat to the raw or precooked food. Cooking improves edibility, taste, or appearance or delays decay. As heat is applied to the food, effluent is released into the surrounding atmosphere. This effluent includes heat that has not transferred to the food, water vapor, and organic material released from the food. The heat source, especially if it involves combustion, may release other contaminants.

All cooking methods release some heat, some of which radiates from all hot surfaces; but most is dissipated by natural convection via a rising **plume** of heated air. Most of the effluent released from the food and the heat source is entrained in this plume, so primary contaminant control should be based on capturing and removing the air and effluent that constitute the plume. A quantitative analysis, or even a relative determination, of plume and combustion product volumetric flow rates is not available at present.

The preparation of this chapter is assigned to TC 5.10, Kitchen Ventilation.

Plume Behavior

The most common method of contaminant control is to install an air inlet device (a **hood**) where the plume can enter it and be conveyed away by an exhaust system. The hood is generally located above or behind the heated surface to intercept the normal upward flow path. Understanding the behavior of the plume is central to designing effective ventilation systems.

Effluent released from a noncooking cold process, such as metal grinding, is captured and removed by placing air inlets so that they catch forcibly ejected material, or by creating airstreams with sufficient velocity to induce the flow of effluent into an inlet. This technique has led to an empirical concept of **capture velocity** that is often misapplied to hot processes. Effluent released from a hot process and contained in a plume may be captured by locating an inlet hood so that the plume flows into it by buoyancy. The hood exhaust rate must equal or slightly exceed the plume flow rate, but the hood need not actively capture the effluent if the hood is large enough at its height above the cooking operation to encompass the plume as it expands during its rise. Additional exhaust airflow may be needed to resist crosscurrents that carry the plume away from the hood.

A plume, in the absence of crosscurrents or other interference, rises vertically. As it rises, it entrains additional air, which causes the plume to enlarge and its average velocity and temperature to decrease. In most cooking processes, the distance between the heated surface and the hood is so short that entrainment is negligible, and the plume loses very little of its velocity or temperature before it reaches the hood. If a surface parallel to the plume centerline (e.g., a back wall) is located nearby, the plume will attach to the surface by the **Coanda effect**. This tendency also directs the plume into the hood.

Appliance Types (Steam, Electric, Solid Fuel, Gas)

The heat source affects the type and quantity of effluent released. When steam is the heat source, it releases no contaminants because it is contained in a closed vessel. Electric heating sources similarly release no significant contaminants.

Solid (wood or charcoal) or gaseous (natural gas or liquefied petroleum gas) fuels are common sources of heat for cooking. Their combustion generates water vapor and carbon dioxide, and it may also generate carbon monoxide and other potentially harmful gases. These effluents must be controlled along with those released from the food. In some cases, the food or its container is directly exposed to the flame; as a result, the combustion effluent and the food effluent are mixed, and a single plume is generated. In other cases, such as ovens, the combustion products are ducted to an outlet adjacent to the plume, and the effluents still mix.

EXHAUST HOODS

The kitchen exhaust hood captures, contains, and evacuates heat, smoke, odor, steam, grease, vapor, and other contaminants generated from cooking in order to provide a safe, healthy, comfortable, and productive work environment for kitchen personnel.

This section discusses all aspects of kitchen hood design; it is based primarily on model codes and standards in the United States.

The design, engineering, construction, installation, and maintenance of commercial kitchen exhaust hoods are controlled by the major nationally recognized standards (e.g., NFPA *Standard* 96) and model codes. In some cases, local codes may prevail. Prior to designing a kitchen ventilation system, the designer should identify governing codes and consult the authority having jurisdiction. Local authorities having jurisdiction may have amendments or additions to these standards and codes.

Hood Types

Many types, categories, and styles of hoods are available, and hood selection depends on many factors. Hoods are classified based on whether they are designed to handle grease. Type I refers to hoods designed for removal of grease and smoke, and Type II refers to all other hoods. The model codes distinguish between grease-handling and non-grease-handling hoods, but not all model codes use Type I/Type II terminology. A Type I hood may be used where a Type II hood is required, but the reverse is not allowed. However, the characteristics of the cooking equipment under the hood, and not the hood type, determine the requirements for the entire exhaust system, including the hood.

A **Type I hood** is used for collection and removal of grease and smoke. It includes (1) listed grease filters, baffles, or extractors for removal of the grease and (2) fire suppression equipment. Type I hoods are required over restaurant equipment, such as ranges, fryers, griddles, broilers, ovens, and steam kettles, that produce smoke or grease-laden vapors.

A **Type II hood** is for collection and removal of steam, vapor, heat, and odors where grease is not present. It may or may not have grease filters or baffles and typically does not have a fire suppression system. It is typically used over dishwashers, steam tables, and so forth. The Type II hood is sometimes used over ovens, steamers, or kettles if they do not produce smoke or grease-laden vapor and if the authority having jurisdiction allows it.

Type I Hoods Categories

Type I hoods fall into two categories. One is the **conventional (nonlisted)** category, which meets the design, construction, and performance criteria of the applicable national and local codes. Conventional (nonlisted) hoods are not allowed to have fire-actuated exhaust dampers.

The second category comprises hoods that are **listed** in Underwriters Laboratories (UL) *Standard* 710. Listed hoods are not generally designed, constructed, or operated in accordance with requirements of the model codes, but are constructed in accordance with the terms of the hood manufacturer's listing. This is allowed because the model codes include exceptions for hoods listed to show equivalency with the safety criteria of the model code requirements.

The two basic subcategories of Type I listed hoods, as defined in UL *Standard* 710, are exhaust hoods without exhaust dampers and exhaust hoods with exhaust dampers. The UL listings do not distinguish between water-wash and dry hoods, except that water-wash hoods with fire-actuated water systems are identified in UL's product directory.

All listed hoods are subjected to electrical tests, temperature tests, and fire and cooking smoke capture tests. The listed exhaust hood with exhaust damper includes a fire-actuated damper, typically located at the exhaust duct collar (and at the replacement air duct collar, depending on the hood configuration). In the event of a fire, the damper closes to prevent fire from entering the duct. Fire-actuated dampers are permitted only as part of a hood listing.

Listed exhaust hoods with fire-actuated water systems are typically water-wash hoods in which the wash system also operates as a fire-extinguishing system. In addition to meeting the requirements of UL *Standard* 710, these hoods are tested under UL *Standard* 300 and may be listed for plenum extinguishment, duct extinguishment, or both.

Type I Hoods—Grease Removal

Most grease removal devices in Type I hoods operate on the same general principle—the exhaust air passes through a series of baffles in which a centrifugal force that throws the grease particles out of the airstream is created as the exhaust air passes around the baffles. The amount of grease removed varies with the design of the baffles, the air velocity, the temperature, the type of cooking, and other factors. A recognized test protocol is not available at present. Mesh filters cannot meet the requirements of UL *Standard* 1046 and therefore cannot be used as primary grease filters. Grease removal devices generally fall into the following categories:

- **Baffle filter.** The baffle filter is a series of vertical baffles designed to capture grease and drain it into a container. The filters are arranged in a channel or bracket for easy insertion and easy removal from the hood for cleaning. Each hood usually has two or more baffle filters. The filters are typically constructed of aluminum, steel, or stainless steel, and they come in various standard sizes. Filters are cleaned by running them through a dishwasher or by soaking and rinsing. NFPA *Standard* 96 requires that grease filters be listed. Listed grease filters are tested and certified by a nationally recognized test laboratory under UL *Standard* 1046.
- **Removable extractor.** Removable extractors are an integral component of listed exhaust hoods designed to use them. They are typically constructed of stainless steel and contain a series of horizontal baffles designed to remove grease and drain it into a container. Removable extractors come in various sizes. They are cleaned by running them through a dishwasher or by soaking and rinsing.
- **Stationary extractor.** The stationary extractor (also called a **water-wash hood**) is an integral component of listed exhaust hoods that use them. They are typically constructed of stainless steel and contain a series of horizontal baffles that run the full length of the hood. The baffles are not removable for cleaning. The stationary extractor includes one or more water manifolds with spray nozzles that, upon activation, wash the grease extractor with hot, detergent-injected water, removing accumulated grease. The wash cycle is typically activated at the end of the day, after the cooking equipment and fans have been turned off; however, it can be activated more frequently. The cycle lasts for 5 to 10 min, depending on the hood manufacturer, the type of cooking, the duration of operation, and the water temperature and pressure. Most water-wash hood manufacturers recommend a water temperature of 55 to 80°C and water pressure of 200 to 550 kPa. Average water consumption varies from 0.1 to 0.3 L/s per linear metre of hood, depending on the hood manufacturer. Most water-wash hood manufacturers provide a manual and/or an automatic means of activating the water-wash system in the event of a fire.

  Some manufacturers of water-wash hoods provide continuous cold water as an option. The cold water runs continuously during cooking and may or may not be recirculated, depending on the manufacturer. Typical cold water usage is 3.5 mL/s per linear metre of hood. The advantage of continuous cold water is that it improves grease extraction and removal, partly through condensation of the grease. Many hood manufacturers recommend continuous cold water in hoods that are located over solid-fuel-burning equipment, as the water also extinguishes hot embers that may be drawn up into the hood and helps cool the exhaust stream.

UL *Standards* 1046 and 710 do not include grease extraction tests because no industry-accepted tests are available at present in the United States. Grease extraction rates published by filter and hood manufacturers are usually derived from tests conducted by

independent test laboratories retained by the manufacturer. Test methods and results therefore vary greatly.

Type I Hoods—Styles

Figure 1 shows the six basic hood styles for Type I applications. These style names are not used universally in all standards and codes but are well accepted in the industry. The styles are as follows:

1. **Wall-mounted canopy.** Used for all types of cooking equipment located against a wall.
2. **Single-island canopy.** Used for all types of cooking equipment in a single-line island configuration.
3. **Double-island canopy.** Used for all types of cooking equipment mounted back-to-back in an island configuration.
4. **Back shelf.** Used for counter-height equipment typically located against a wall, but could be freestanding.
5. **Eyebrow.** Used for direct mounting to ovens and some dishwashers.
6. **Pass-over.** Used over counter-height equipment when pass-over configuration (from the cooking side to the serving side) is required.

Type I Hoods—Sizing

The size of the exhaust hood in relation to cooking appliances is an important aspect of hood performance. Usually the hood must extend beyond the cooking appliances—on all open sides on canopy-style hoods and over the ends on back shelf and pass-over hoods—to capture the expanding thermal currents rising from the appliances. This **overhang** varies with the style of the hood, the distance between the hood and the cooking appliance, and the characteristics of the cooking equipment. With back shelf and pass-over hoods, the front of the hood must be kept behind the front of the cooking equipment (**set back**) to allow head clearance for the cooks. These hoods may require a higher front inlet velocity to catch and contain the expanding thermal currents. All styles may have full or partial side panels to close the area between the appliances and the hood. This may eliminate the overhang requirement and generally reduces the exhaust flow rate requirement.

For conventional hoods, hood size is dictated by the prevailing model code, and for listed hoods, by the terms of the manufacturer's listing. Typically, the overhang requirements applied to listed hoods are similar to those for conventional hoods. General overhang requirements are shown in Table 1.

Type I Hoods—Exhaust Flow Rates

Exhaust flow rate requirements to capture, contain, and remove the effluent vary considerably depending on the hood style, the amount of overhang, the distance from the cooking surface to the hood, the presence and size of side panels, and the cooking equipment and product involved. The hot cooking surfaces and product vapors create thermal air currents that are received or captured by the hood and then exhausted. The velocity of these currents depends largely on the surface temperature and tends to vary from 75 mm/s over steam equipment to 0.75 m/s over charcoal broilers. The actual required flow rate is determined by these thermal currents, a safety allowance to absorb crosscurrents and flare-ups, and a safety factor for the style of hood.

Overhangs, the distance from the cooking surface to the hood, and the presence or absence of side panels all help determine the safety factor for different hood styles. Use of gas-fired cooking equipment may require an additional allowance for the exhaust of combustion products and combustion air. Because it is not practical to place a separate hood over each piece of equipment, general practice is to categorize the equipment into four groups. While published lists vary, and accurate documentation does not yet exist, the following is a consensus opinion list (great variance in product or volume could shift an appliance into another category):

1. Light duty, such as ovens, steamers, and small kettles (up to 200°C)
2. Medium duty, such as large kettles, ranges, griddles, and fryers (up to 200°C)
3. Heavy duty, such as upright broilers, charbroilers, and woks (up to 315°C)
4. Extra heavy duty, such as solid-fuel-burning equipment (up to 370°C)

The exhaust volumetric flow rate requirement is based on the group of equipment under the hood. If there is more than one group, the flow rate is based on the heaviest duty group unless the hood design permits different rates over different sections of the hood.

For areas where model codes or other regional codes have been adopted, the exhaust flow rate requirement for conventional hoods is dictated by the codes; therefore, the manufacturers' calculation methods may not be used without consultation with the authority having jurisdiction. The model code required exhaust flow rates for conventional canopy hoods are typically calculated by multiplying the area A of the hood opening by a given air velocity. Table 2 indicates typical formulas, taken from the model codes, for determining the exhaust flow rate Q for conventional canopy hoods. Some jurisdictions may use the length of the open perimeter of the hood times the vertical height between the hood and the appliance instead of the horizontal hood area.

The *International Mechanical Code* (IMC) and some state codes have alternate formulas that allow lower flow rates for equipment that produces less heat and smoke; however, the IMC does require 1 m^3/s per square metre of hood area for hoods covering charbroilers. Back shelf and pass-over style nonlisted hoods are usually calculated at 0.45 m^3/s per linear metre of exhaust hood.

Listed hoods are allowed to operate at their listed exhaust flow rates by exceptions in the model codes. Most manufacturers of listed hoods verify their listed flow rates by conducting tests per UL *Standard* 710. Typically, the average flow rates are much lower than those dictated by the model codes. It should be noted that these listed values are established under draft-free laboratory conditions. The four categories of equipment groups mentioned are tested and marked according to cooking surface temperature: light and medium duty up to 200°C, heavy duty up to 315°C, and extra heavy duty up to 370°C. Each of these groups has an air quantity factor

Table 1 Typical Overhang Requirements for Both Listed and Conventional (Nonlisted) Type I Hoods

Type of Hood	End Overhang	Front Overhang	Rear Overhang
Wall-mounted canopy	150 mm	300 mm	—
Single-island canopy	300 mm	300 mm	300 mm
Double-island canopy	150 mm	300 mm	300 mm
Eyebrow	0 mm	300 mm	—
Back shelf/Pass-over	0 mm	150 to 300 mm front setback	

Note: The model codes typically require a 150 mm minimum overhang, but most manufacturers design for a 300 mm overhang.

Table 2 Typical Model Code Exhaust Flow Rates for Conventional Type I Hoods

Wall-mounted canopy	$Q = 0.5A$
Single-island canopy	$Q = 0.75A$
Double-island canopy	$Q = 0.5A$
Eyebrow	$Q = 0.5A$
Back shelf/Pass-over	$Q = 0.45 \times$ Length of hood

Note: Q = exhaust flow rate, m^3/s; A = area of hood exhaust aperture, m^2

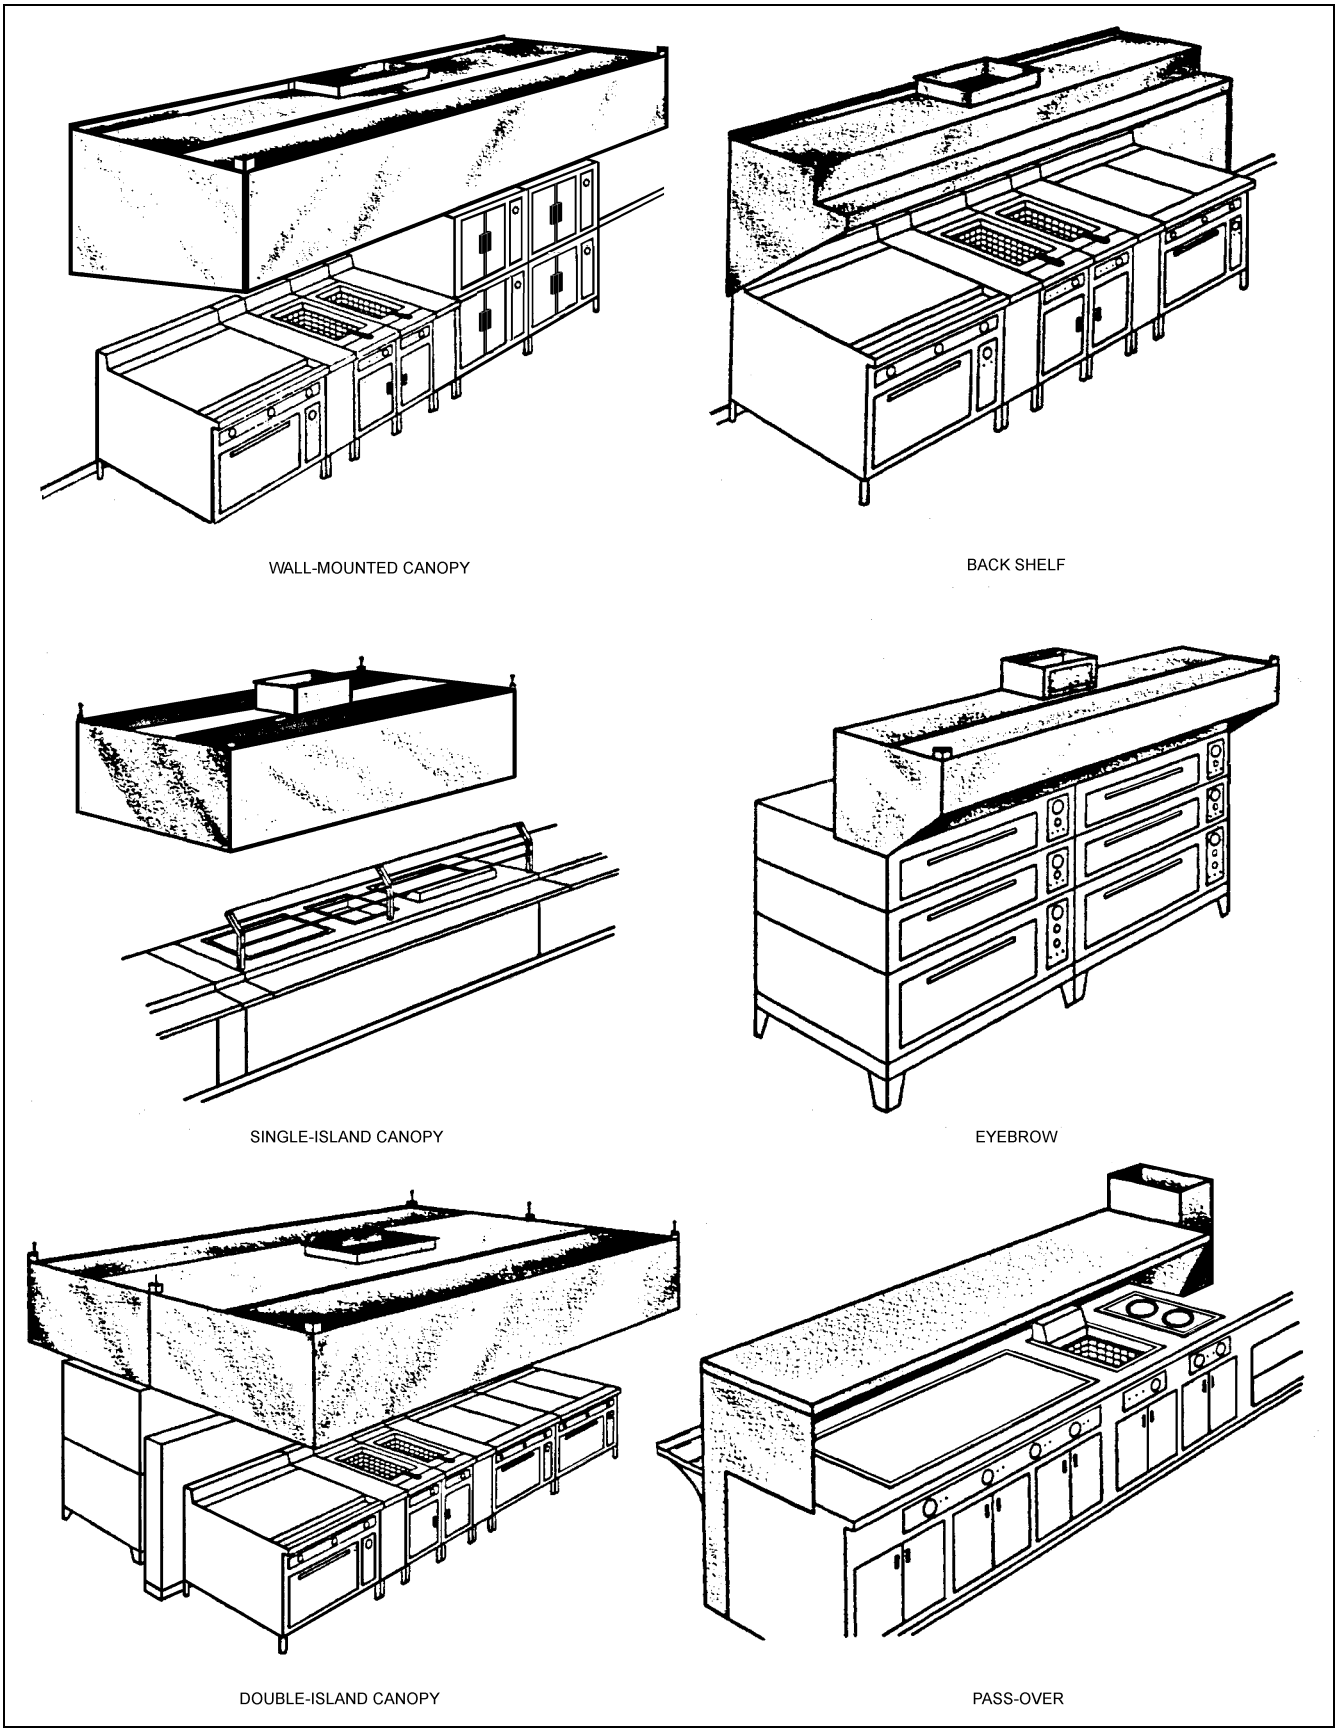

Fig. 1 Styles of Commercial Kitchen Exhaust Hoods

Table 3 Typical Minimum Exhaust Flow Rates for Listed Type I Hoods by Cooking Equipment Type

Type of Hood	Minimum Exhaust Flow Rate, m^3/s per linear metre of hood			
	Light Duty	Medium Duty	Heavy Duty	Extra Heavy Duty
Wall-mounted canopy	0.25 to 0.3	0.35 to 0.45	0.3 to 0.6	0.55+
Single-island	0.4 to 0.45	0.45 to 0.6	0.45 to 0.95	0.85+
Double-island (per side)	0.25 to 0.3	0.3 to 0.45	0.4 to 0.6	0.8+
Eyebrow	0.25 to 0.4	0.25 to 0.4	—	—
Back shelf/ Pass-over	0.15 to 0.3	0.3 to 0.45	0.45 to 0.6	Not recommended

assigned for each style of hood, with the total exhaust flow rate typically calculated by multiplying this factor times the length of the hood.

Minimum exhaust flow rates for listed hoods serving single categories of equipment vary from manufacturer to manufacturer but are generally as shown in Table 3.

Actual exhaust flow rates for hoods with internal short-circuit replacement air are typically higher than those in Table 3, although the net exhaust (actual exhaust less replacement air quantity) may be similar. The specific hood manufacturer should be contacted for exact exhaust and replacement flow rates.

ASTM *Standard* F 1704 details a laboratory flow visualization procedure for determining the capture and containment threshold of an appliance/hood system. This procedure is consistent with the UL *Standard* 710 capture test and can be applied to all hood types and configurations operating over any cooking appliances.

Type I Hoods—Replacement (Makeup) Air Options

Air exhausted from the kitchen space must be replaced. Replacement air can be brought in through the traditional method of **ceiling registers**; however, they must be located so that the discharged air does not disrupt the pattern of air entering the hood. Air should be supplied either (1) as far from the hood as possible or (2) close to the hood and directed away from it or straight down at very low velocity. Exhaust and replacement air fans should be interlocked.

Another way of distributing replacement air is through systems built as an integral part of the hood. Figure 2 shows three available designs for **internal** replacement air. Combinations of these designs are also available. Because the actual flows and percentages vary with all hoods, the manufacturer should be consulted about specific applications. The following are typical descriptions:

Front Face Discharge. This method of introducing replacement air into the kitchen is flexible and has many advantages. Typical supply volume is 70 to 80% of the exhaust, depending on the air balance desired. Supply air temperature should range from 15 to 18°C but may be as low as 10°C, depending on flow rates, distribution, and internal heat load. This air should be directed away from the hood, but the closer the air outlet's lower edge is to the bottom of the hood, the lower the velocity must be to avoid drawing effluent out of the hood.

Down Discharge. This method of introducing replacement air to the kitchen area is typically used when spot cooling of the cooking staff is desired to help relieve the effects of severe radiant heat generated from such equipment as charbroilers. The air must be heated and/or cooled, depending on the climate. Discharge velocities must be carefully selected to avoid air turbulence at the cooking surface, discomfort to personnel, and cooling of food. The amount of supply air introduced may be up to 70% of the exhaust, depending on the cooking equipment involved. Air temperature should be between 10 and 18°C.

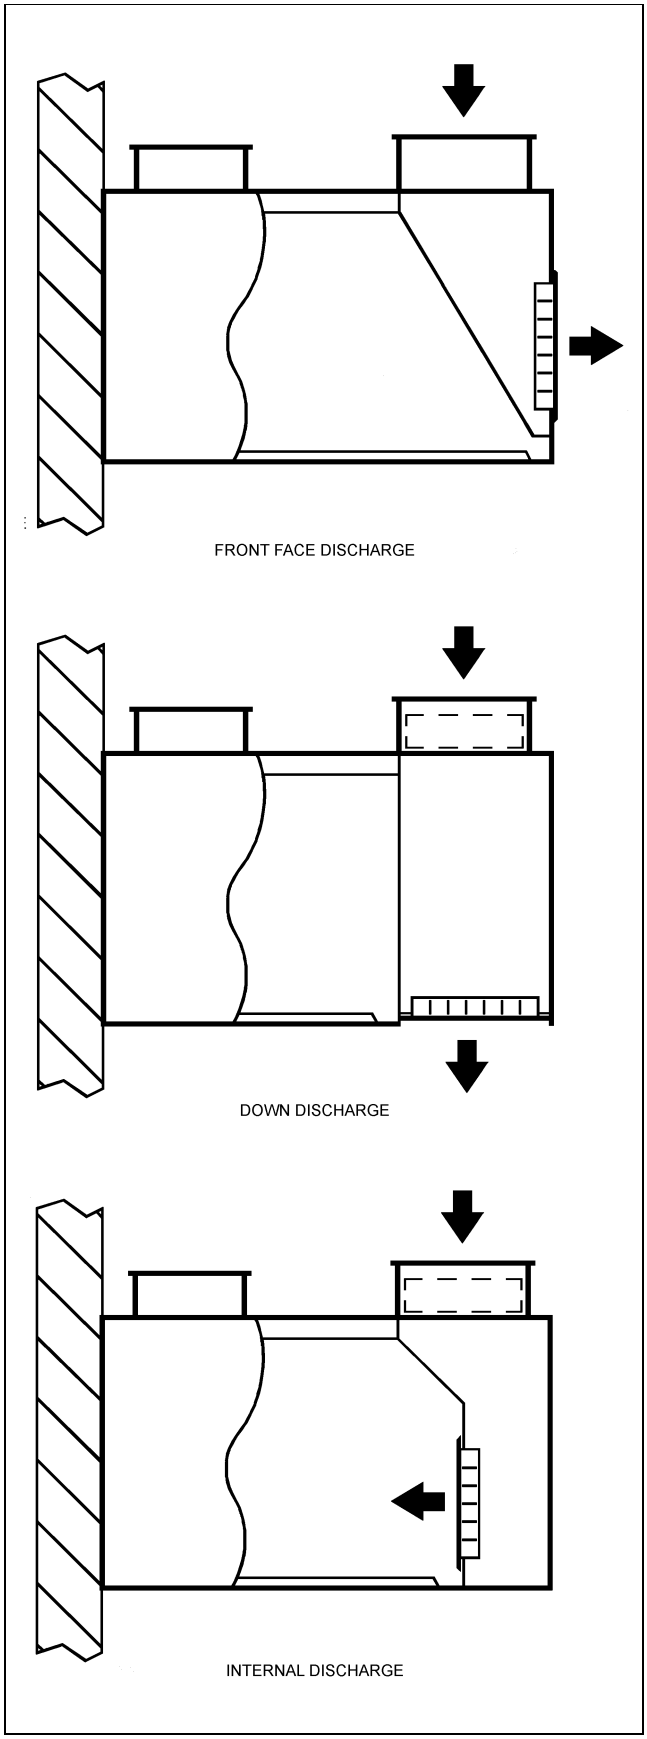

Fig. 2 Internal Methods of Introducing Replacement Air

Table 4 Exhaust Static Pressure Loss for Type I Hoods for Various Exhaust Airflows

Type of Grease Removal Device	Static Pressure Loss, Pa			
	0.25 to 0.4 m^3/s per m	0.4 to 0.55 m^3/s per m	0.55 to 0.7 m^3/s per m	0.8+ m^3/s per m
Baffle filter	60 to 120	120 to 190	190 to 250	250+
Extractor	250 to 340	320 to 420	420+	420+

Internal Discharge. In this method of introducing air into the hood, typically called the **short-circuit or compensating method**, replacement air is introduced inside the hood. This design has limited application, and the amount of supply air that can be introduced varies considerably with the type of cooking equipment and the exhaust flow rate. As noted previously, thermal currents from the cooking equipment create a plume of fumes and vapor of a certain volume that the hood must remove. The hood must therefore draw at least this volume of air from the kitchen, in addition to any short-circuit makeup. If the net exhaust flow rate (total exhaust less short-circuit replacement air) is less than the airflow plume volume created by the cooking equipment, part of the plume will spill out of the hood. The short-circuit replacement air may be untempered in most areas, depending on climatic conditions, manufacturer, and type of cooking equipment. The difference between the quantity of air being introduced and the quantity being exhausted must be supplied through a traditional replacement air system

Some local authorities approve internal discharge hoods, and some do not. The IMC requires that at least 20% of the replacement air come from the kitchen area. In any case, all applicable codes must be consulted to assure that proper criteria are being followed.

Type I Hoods—Static Pressure

The static pressure drop through hoods depends on the type and design of the hood and grease removal devices, the size of duct connections, and the flow rate. Table 4 provides a general guide for determining static pressures. Manufacturers' data should be consulted for actual quantities.

Type II Hoods

Type II hoods (Figure 3) can be divided into the following two application categories:

1. **Condensate hood.** For applications with high-moisture exhaust, condensate forms on interior surfaces of the hood. The hood is designed to direct the condensate toward a perimeter gutter for collection and drainage, allowing none to drip onto the appliance below. Flow rates are typically based on 0.25 to 0.4 m^3/s per square metre of hood opening. Hood material is usually noncorrosive, and filters are usually installed.
2. **Heat/fume hood.** For hoods over equipment producing heat and fumes only, flow rates are typically based on 0.25 to 0.5 m^3/s per square metre of hood opening. Filters are usually not installed.

Recirculating Systems

The recirculating system, sometimes called a **ductless hood**, consists of a cooking appliance/hood assembly designed to remove grease, smoke, and odor and to exhaust the return air directly back into the room. The hood in these systems typically contains the following components in the exhaust stream: (1) a grease removal device such as a baffle filter, (2) a high-efficiency particulate air (HEPA) filter, (3) an electrostatic precipitator (ESP) or water system, (4) some means of odor control such as activated charcoal, and (5) an exhaust fan. NFPA *Standard* 96, Chapter 10, is devoted entirely to recirculating systems and contains specific requirements

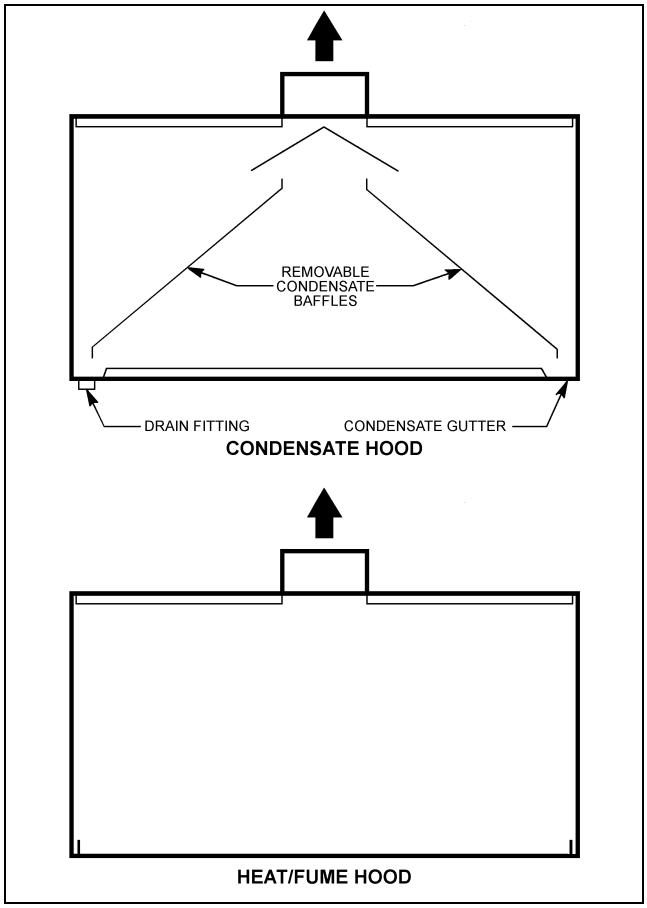

Fig. 3 Type II Hoods

such as (1) design, including interlocks of all critical components to prevent operation of the cooking appliance if any of the components are not operating; (2) fire extinguishment, including specific nozzle locations; (3) maintenance, including a specific schedule for cleaning filters, ESPs, hoods, and blowers; and (4) inspection and testing of the total operation and interlocks. In addition, NFPA *Standard* 96 requires that all recirculating systems be listed with a testing laboratory. The recognized test standard for a recirculating system is UL *Standard* 197. Ductless systems should not be used over gas-fired or solid-fuel-fired equipment, which must be exhausted directly to the outdoors to remove combustion products.

Designers should thoroughly review NFPA *Standard* 96 requirements and contact a manufacturer of recirculating systems to obtain specific information prior to incorporating this type of system into a food service design. It is important to note that recirculating systems discharge the total heat and moisture of the cooking operation back into the kitchen space, adding to the air-conditioning load.

EXHAUST SYSTEMS

Exhaust systems remove effluent from appliances and cooking processes to promote fire and health safety, comfort, and aesthetics. Typical exhaust systems simultaneously incorporate fire prevention designs and fire suppression equipment. In most cases, these functions complement each other, but in other cases they may seem to conflict. Designs must balance the various functions. For example, fire-actuated dampers may be installed to minimize the spread of fire to ducts, but maintaining an open duct might be better for removing the smoke of an appliance fire from the kitchen.

Effluent Control

Effluents generated by the cooking process include grease in the solid, liquid, and vapor states; smoke particles; and volatile organic compounds (VOCs or low-carbon aromatics, commonly referred to as odors). Effluent controls in the vast majority of today's kitchen ventilation systems are limited to the removal of solid and liquid grease particles by grease removal devices located in the hood. With currently available equipment, effluent control is typically a three-stage process: (1) grease removal, (2) smoke removal, and (3) VOC/odor removal.

Grease removal typically starts in the hood with baffle filters or grease removal devices. The more effective devices reduce grease buildup downstream of the hood, lowering the frequency of duct cleaning and reducing the fire hazard. Higher efficiency grease removal devices increase the efficiency of smoke and odor control equipment, if present.

The term grease extraction filters may be a misnomer. These filters are tested and listed not for their grease extraction ability, but for their ability to limit (not totally prevent) flame penetration into the hood plenum and duct. Additionally, research is beginning to indicate that grease particles are generally small, aerodynamic particles that are not easily removed by the centrifugal impingement principle used in most grease extraction devices (Kuehn et al. 1999).

If removal of these small particles is required, the next device is typically a particulate removal unit that removes a large percentage of the grease that was not removed by the grease removal device in the hood and a large percentage of smoke particles.

The following technologies are available today and applied to varying degrees for control of cooking effluent. Following the description of each technology are some qualifications and concerns about its use.

Electrostatic precipitators (ESPs). Particulate removal is by high-voltage ionization, then collection on flat plates.

- In a cool environment, collected grease can block airflow.
- As the ionizer section becomes dirty, efficiency drops because the effective plate surface area is reduced.

Water mist, waterfall, and water bath. Passage of the effluent stream through water mechanically entraps particulates.

- Airflow separates the bath and the waterfall, so they are less effective.
- Bath types have a very high static pressure loss.
- Spray nozzles need much attention. Water may need softening to minimize clogging.
- Drains tend to become blocked.

Pleated or bag filters of fine natural and synthetic fibers. Very fine particulate removal is by mechanical filtration. Some types have an activated carbon face coating for odor control.

- Filters become blocked quickly if too much grease enters.
- Static loss builds quickly with extraction, and airflow drops.
- Almost all filters are disposable and very expensive.

Activated carbon filters. VOC control is through adsorption by fine activated charcoal particles.

- Require a large volume and thick bed to be effective.
- Heavy and can be difficult to replace.
- Expensive to change and recharge. Many are disposable.
- Ruined quickly if they are grease-coated or subjected to water.
- Some concern that carbon is a source of fuel for a fire.

Oxidizing pellet bed filters. VOC and odor control is by oxidation of gaseous effluent into solid compounds.

- Require a large volume and long bed to be effective.
- Heavy to handle and can be difficult to replace.
- Expensive to change.
- Some concern about increased oxygen available in fire.

Incineration. Particulate, VOC, and odor control is by high-temperature oxidation (burning) into solid compounds.

- Must be at system terminus and clear of combustibles.
- Expensive to install with adequate clearances.
- Can be difficult to access for service.
- Very expensive to operate.

Catalytic conversion. A catalytic or assisting material, when exposed to relatively high-temperature air, provides additional heat adequate to decompose (oxidize) most particulates and VOCs.

- Requires high temperature (260°C minimum).
- Expensive to operate due to high temperature requirement.

Duct Systems

The exhaust ductwork conveys the exhaust air from the hood to the outdoors, along with any grease, smoke, VOCs, and odors that are not extracted from the airstream along the way. In addition, this ductwork may be used to exhaust smoke from a fire. To be effective, the ductwork must be greasetight; it must be clear of combustibles, or the combustible material must be protected so that it cannot be ignited by a fire in a duct; and ducts must be sized to convey the volumetric flow of air necessary to remove the effluent. Building codes set the minimum air velocity for exhaust ducts at 7.5 m/s. Maximum velocities are limited by pressure drop and noise and should not exceed 12 m/s. At the present time, 9 m/s is considered the optimum design velocity.

The ductwork should have no traps that can hold grease, which would be an extra fuel source in the event of a fire, and ducts should pitch toward the hood for constant drainage of liquefied grease or condensates. On long duct runs, allowance must be made for possible thermal expansion due to a fire, and the slope back to the hood must be at least 1%.

Single-duct systems carry effluent from a single hood or section of a large hood to a single exhaust termination. In multiple-hood systems, several **branch ducts** carry effluent from several hoods to a single master duct that has a single termination.

For correct flow through the branch duct in multiple-hood systems, the static pressure loss of the branch must match the static pressure loss of the common duct upstream from the point of connection. Any exhaust points subsequently added or removed must be designed to comply with the minimum velocities required by code and to maintain the balance of the remaining system.

Ducts may be constructed of round or rectangular sections. The standards and model codes contain minimum specifications for duct materials, including gage, joining methods, and minimum clearances to combustible materials. UL-listed prefabricated duct systems may also be used. These systems typically allow reductions in the clearance to combustible materials.

Types of Exhaust Fans

Exhaust fans for kitchen ventilation must be capable of handling hot, grease-laden air. The fan should be designed to keep the motor out of the airstream and should be effectively cooled to prevent premature failure. To prevent roof damage, the fan should contain and properly drain all grease removed from the airstream.

The following types of exhaust fans are in common use (all have centrifugal wheels with backward-inclined blades):

- **Upblast.** These fans (Figure 4) are designed for roof mounting directly on top of the exhaust stack, and they discharge upward. Upblast fans are generally aluminum and must be listed for the service. They typically can provide static pressures only up to 250 Pa (gage) but are available with higher pressures. They may

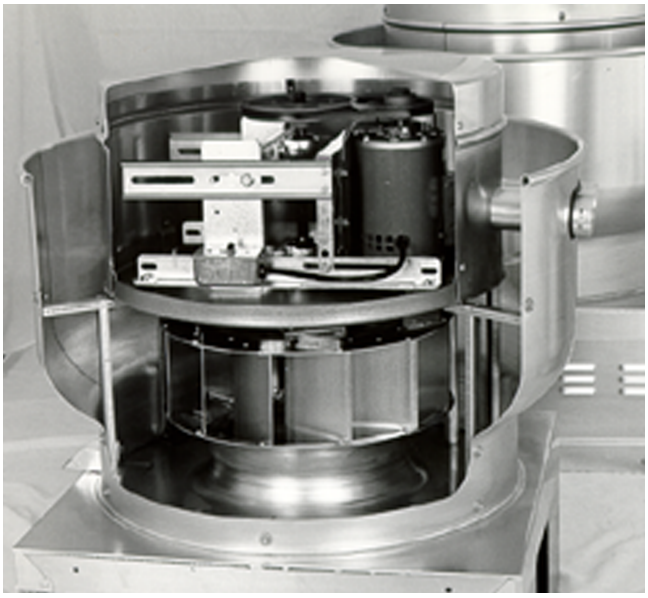

Fig. 4 Upblast Exhaust Fan

have an integral grease drainage path and collection container. These fans allow easy access for duct cleaning because they generally hinge back from the duct.

- **Utility set.** These fans are usually constructed of steel and roof-mounted. The inlet and outlet are at 90° to each other (single width, single inlet), and the outlet can usually be rotated to discharge at many different angles around a vertical circle. They can operate at medium to high and (with special provisions) very high static pressures. Care must be taken to drain the low part of the fan to a safe remote container.
- **Inline.** These fans are typically located in the duct run inside a building where exterior fan mounting is not practical for wall or roof exhaust. They are always constructed of steel. The gasketed flange mounting must be greasetight yet removable for service. A catch pan should be placed under the entire assembly in case of a grease leak at the flanges. If the fan housing is lower than the duct, there must be a drain to a separate collection container.

Exhaust Terminations

Rooftop. Rooftop terminations are preferred because the discharge can be directed away from the building, the fan is at the end of the system, and the fan is accessible. Common concerns with rooftop terminations are as follows:

- The discharge of the exhaust system should be arranged to minimize reentry of effluent into any fresh air intake or other opening to any building. This requires not only separation of the exhaust from intakes, but also knowledge of the direction of the prevailing winds. Some codes specify a minimum distance to air intakes.
- In the event of a fire, neither the flames, nor the radiant heat, nor the dripping grease should be able to ignite the roof or other nearby structures.
- All grease from the fan or the duct termination should be collected and drained to a remote closed container to preclude ignition.
- Rainwater should be kept out of the exhaust system, especially out of the grease container. If this is not possible, then the grease container should be designed to separate the water from the grease and drain the water back onto the roof. Figure 5 shows a rooftop utility set with a stackhead fitting, which directs the exhaust away from the roof and minimizes rain penetration. Discharge caps should not be used because they direct the exhaust back toward the roof and can become grease-fouled.

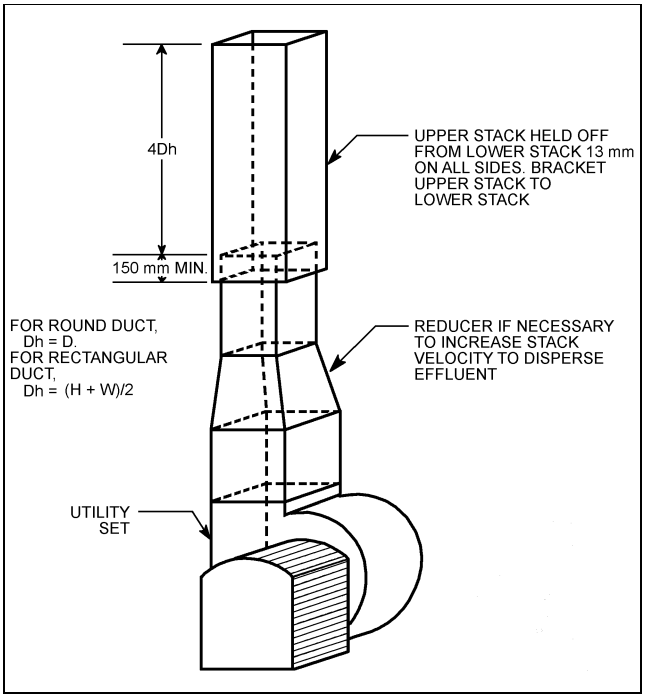

Fig. 5 Rooftop Utility Set with Vertical Discharge

Outside Wall. Wall terminations are less common today but still exist. The fan may or may not be the terminus of the system, located on the outside of the wall. Common concerns with wall terminations are as follows:

- Discharge from the exhaust system should not be able to enter any fresh air intake or other opening to any building.
- Adequate clearance to combustibles must be maintained.
- To avoid having grease drain down the side of the building, duct sections should pitch back to the hood inside, or a grease drain should be provided to drain the grease back into a safe container inside the building.
- The discharge must not be directed downward or toward any pedestrian areas.
- Louvers should be designed to minimize their grease extraction effect and to prevent staining of the building facade.

Recirculating Systems. With these units, it is extremely critical to keep the components in good working order to maintain optimal performance. Otherwise, excessive grease and odor will accumulate in the premises.

As with other terminations, containing and removing the grease and keeping the discharge as far as possible from combustibles are the main concerns. Some units are fairly portable and can readily be set in an unsafe location. The operator should be made aware of the importance of safely locating the unit.

A major concern is system maintenance. If the hood is not properly maintained, it will allow grease, heat, and odors to accumulate in the space. These units are best for large, unconfined areas that have a separate outside exhaust to keep the environment comfortable.

REPLACEMENT (MAKEUP) AIR SYSTEMS

The kitchen air that is exhausted to remove the cooking effluent must be replaced with air from outside the building to avoid excess negative pressure in the space, which may degrade the exhaust system performance. The standards and model codes require 100% replacement (makeup) air. Some manufacturers

offer internal discharge (short-circuit) hoods, which introduce replacement air directly into the hood capture cavity.

Replacement (Makeup) Air Through HVAC System

In many cases, the HVAC system is the ideal means of providing replacement air because the air is comfort conditioned and enhances the kitchen environment. In smaller stand-alone restaurants, rooftop units are typical; they can be obtained with outdoor air dampers that are controlled to automatically open for the proper amount of outside air when the hoods are operational and close when they are turned off. Even better is the use of an enthalpy or temperature control to provide not only the makeup air, but also a degree of free cooling, by keeping the compressors off when outdoor conditions warrant and adjusting the outside and return air dampers. Designers must exercise extreme caution when applying outdoor air economizer cycles to kitchen systems in multiple-occupancy applications because the economizer can upset the air balance between occupancies and cause odor migration.

The amount of air brought in through the HVAC units should be limited so that comfort conditions are maintained. Typically, dining room units should be limited to 25 to 30% outside air to avoid unacceptable variations in discharge temperature. Replacement air through these units must have a ready path to the exhaust hoods. Kitchen units, on the other hand, may be set to bring in up to 50% outside air because temperature swings are less critical. For commercial kitchens where there is no on-site dining (e.g., take-out stores, commissaries, etc.), the entire area can be treated under the kitchen design criteria. Rooftop units are available that deliver 100% outside air with discharge air temperature control on cooling and heating.

Non-HVAC System Replacement (Makeup) Air

In situations where the outside air from the HVAC system is insufficient to replace all the air being drawn from the kitchen, air must be brought directly to the kitchen with limited or no conditioning. In some climates, outdoor conditions may be temperate enough that outside air does not require heating or cooling, particularly if it is mixed with the conditioned air such that comfort is not unduly compromised. In colder climates, it is essential to heat the air at least to a minimal comfort level. This may be done using electric resistance or direct or indirect gas-fired equipment (local codes must be consulted before direct gas-fired equipment is selected). In more arid areas, evaporative cooling can be effective, and direct-expansion HVAC equipment may not be needed in either the kitchen or the dining areas.

Again, replacement air is used primarily for proper operation of the exhaust hoods and not for comfort of the kitchen personnel. Comfort can be achieved through adequate flow of air around the workers, and higher velocity air movement can compensate for higher temperature and humidity, up to a point. Still, a restaurant owner may desire greater comfort for the employees; in this case, comfort becomes an important design concern.

Attempts have been made to temper outside air using heat from the exhaust system itself. However, effective heat transfer from the exhaust stream to the incoming airstream is made difficult by the strict requirements of the exhaust duct design (i.e., cleanability, minimal grease entrapment, etc.). Careful selection of the exhaust hood system to minimize the amount of air exhausted helps minimize both the cost of conditioning the replacement air and the cost of operating the exhaust and replacement air fans.

Replacement (Makeup) Air for Large Buildings

In large buildings with commercial kitchens (e.g., malls, hospitals, supermarkets, schools, etc.), adequate outside air from other parts of the building is generally available to provide replacement air for the hoods. However, in designing such a facility, the kitchen needs should be factored into the outside air provisions even if the amount is a small fraction of the overall requirement. Also, the source of the replacement air must be considered, so that air contaminated with odors, germs, dust, and so forth, is not drawn to the kitchen area, where cleanliness is required. Most malls and multiple-occupancy buildings specify a minimum amount of air to be taken from their space to keep cooking odors in the kitchen, but they also specify a maximum amount that may be taken to hold down the cost of tempering the outside air.

Air Distribution

Outside replacement air should be distributed in the general vicinity of the hoods. It should be delivered so that high velocities, eddies, swirls, or stray currents do not degrade the performance of the hood. Replacement air from any source should be distributed throughout the kitchen with low-velocity diffusers. Some hood manufacturers place diffusers in the face or lower front edge of the canopy to attempt to introduce replacement air into the hood in an effective but nonintrusive manner. The important point is to have replacement air delivered to the hoods (1) with proper velocity and (2) uniformly from all directions to which the hood is open in order to minimize excessive crosscurrents that could cause spillage from the capture area.

Indoor Air Quality

ASHRAE *Standard* 62 requires that 10 L/s outdoor air per person, based on a maximum occupancy of 70 persons per 100 square metres (100 persons per 100 square metres for cafeterias and fast-food restaurants), be brought into the dining area. The requirement is 15 L/s per person in bars/cocktail lounges and 8 L/s per person in kitchens based on 20 persons per 100 square metres. These requirements may be increased or decreased in certain areas by local code, and they sometimes affect the size of an HVAC system more than thermal loading or necessitate the use of another means of introducing outside air. A further requirement of *Standard* 62, that outside air be sufficient to provide for an exhaust rate of at least 7.5 L/s per square metre of kitchen space, is generally easily met.

SYSTEM INTEGRATION AND BALANCING

System integration and balancing bring the many ventilation components together to provide the most comfortable, efficient, and economical performance of each component and of the entire system. In commercial kitchen ventilation, the supply air system (typically referred to as the HVAC system) must integrate and balance with the exhaust system. Optimal performance is achieved more by effective use of components through controls and airflow adjustments than by the selection or design of the system and components. The following fundamentals for restaurants, and kitchens in particular, should be considered and applied within the constraints of the particular location and its equipment and systems.

Principles

Although there are exceptions that will be addressed, the following are the fundamental principles of integrating and balancing restaurant systems for both comfort control and economical operation:

1. In a freestanding restaurant, the overall building should be at all times slightly pressurized compared to the outdoors to minimize the infiltration of untempered air, as well as dirt, dust, and insects, when doors are opened. In multiple-occupancy buildings, a slight negative pressure in the restaurant is desirable to minimize odor migration from the restaurant to other occupancies.
2. Every kitchen should be at all times slightly negative compared to the rooms or areas immediately surrounding it for the following reasons:

- To better contain the unavoidable grease vapors in the kitchen area and limit the extent of cleanup necessary
- To keep cooking odors in the kitchen area
- To prevent the generally hotter and more humid kitchen air from diminishing the comfort level of the adjacent spaces, especially the dining areas

3. Cross-zoning of airflow should be minimal, especially in the temperate seasons, when adjacent zones may be in different modes (e.g., economizer versus air-conditioning or heating). Two situations to consider are the following:
   - In the transitions from winter to spring and from summer to fall, the kitchen zone could be in the economizer mode, or even the mechanical cooling mode, while the dining areas are in the heating mode. Bringing heated dining area supply air into a kitchen that is in the cooling mode only adds to the cooling load. In some areas, this situation is present every day.
   - When all zones are in the same mode, it is more acceptable, and even more economical, to bring dining area air into the kitchen. However, the controls to automatically effect this method of operation are more complex and costly.
4. Typically, no drafts should be noticeable, and temperatures should vary no more than 0.6 K in dining areas and 1.6 K in kitchen areas. These conditions can be achieved with even distribution and thorough circulation of air in each zone by an adequate number of registers sized to preclude high air velocities. If there are noticeable drafts or temperature differences, customers and restaurant personnel will be distracted and will not enjoy dining or working.

Both design concepts and operating principles for proper integration and balance are involved in bringing about the desired results under varying conditions. The same principles are important in almost every aspect of restaurant ventilation.

In designing restaurant ventilation, all the exhaust is assumed to be in operation at one time, and the design replacement air quantity is a maximum requirement because it is for these maximum design conditions that the heating and cooling equipment are sized.

In restaurants with a single large exhaust hood, balancing should be set for this one operation only. In restaurants with multiple exhaust hoods, some may be operated only during heavy business hours or for special menu items. In this case, replacement air must be controlled to maintain minimum building positive pressure and to maintain the kitchen at a negative pressure under all operating conditions. The more variable the exhaust, the more complex the design; the more numerous and smaller the zones involved, the more complex the design. But the overall pressure relationship principles must be maintained to provide optimum comfort, efficiency, and economy.

A different application is a kitchen having one side exposed to a larger building with common or remote dining. Examples are a food court in a mall or a small restaurant in a hospital, airport, or similar building. Pressurizing the kitchen at the front of its space might cause some of the cooking grease, vapor, and odors to spread into the common building space, which would be undesirable. In such a case, the kitchen area is held at a negative pressure relative to other common building areas as well as to its own back room storage or office space.

Air Balancing

Balancing is best performed when the manufacturers of all the various equipment are able to provide a certified reference method of measuring the airflows, rather than depending on generic measurements of duct flows or other forms of measurement in the field. These field measurements can be in error by 20% or more. The manufacturer of the equipment should be able to develop a reference method of measuring airflow in a portion of the equipment that is dynamically stable in the laboratory as well as in the field. This method should relate directly to airflow by graph or formula.

The general steps for air balancing in restaurants are as follows:

1. The exhaust hoods should first be set to their proper flow rates. This should be done with the supply and exhaust fans on.

   Next, the supply air flow rate, whether part of combined HVAC units or separate replacement air units, should be set to the design values through the coils and the design supply flows from each outlet, with the approximate correct settings on the outside air flow rate. Then, the correct outside and return air flow rates should be set proportionately for each unit, as applicable. These settings should be made with the exhaust on, to ensure adequate relief for the outside air.

   Where the outside air and return air flows of a particular unit are expected to modulate, there should ideally be similar static losses through both airflow paths to preclude large changes in total supply air from the unit. Such changes, if large enough, could affect the efficiency of heat exchange and could also change the airflows within and between zones, thereby upsetting the air distribution and balance.
2. Next, outside air should be set with all fans (exhaust and supply) operating.

   The pressure difference between inside and outside should be checked to see that (1) the nonkitchen zones of the building are at a positive pressure compared to outside and (2) the kitchen zone pressure is negative compared to the surrounding zones and negative or neutral compared to outside.

   For applications with modulating exhaust, every step of exhaust and replacement should be shut off, one step at a time. Each combination of operation should be rechecked to be sure that the design pressures and flows are maintained within each zone and between zones. This requires that the replacement airflow rate compensate automatically with each increment of exhaust. It may require some adjustments in controls or in damper linkage settings to get the correct proportional response.
3. When the above steps are complete, the system is properly integrated and balanced. At this time, all fan speeds and damper settings (at all modes of operation) should be permanently marked on the equipment and in the test and balance report. The air balance records of exhaust, supply, return, fresh air, and individual register airflows must also be completed. These records should be kept by the food service facility for future reference.
4. For new facilities, after two or three days in operation (no longer than a week and usually before the facility opens), all belts in the system should be checked and readjusted because new belts wear in quickly and could begin slipping.
5. Once the facility is operational, the performance of the ventilation system should be checked to verify that the design is adequate for the actual operation, particularly at maximum cooking and at outdoor environmental extremes. Any necessary changes should be made, and all the records should be updated to show the changes.

   Rechecking the air balance should not be necessary more than once every 2 years unless basic changes are made in facility operation. If there are any changes, such as a new type of cooking equipment or added or deleted exhaust connections, the system should be modified accordingly.

Multiple-Hood Systems

Kitchen exhaust systems serving more than a single hood present several design challenges not encountered with single-hood systems. One of the main challenges of multiple-hood exhaust systems is air balancing. Because balancing dampers are not permitted in the exhaust ductwork, the system must be balanced by design. Most filters come in varying sizes to allow pressure loss equalization at varying airflows. Some hoods and grease filters have adjustable

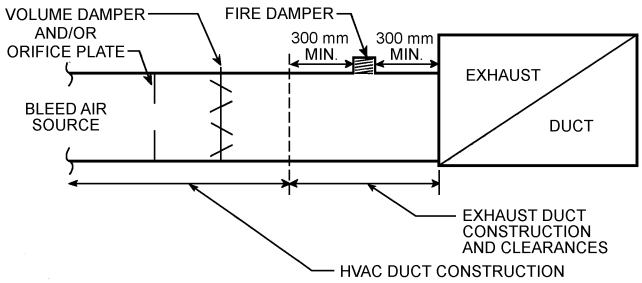

Fig. 6 Method of Introducing Replacement Air Directly into Exhaust Duct

baffles that allow airflow to be adjusted at the hood. These may be helpful for relatively fine balancing, but the system must provide most of the balancing. Adjustable filters should not be used when they can be interchanged between hoods or within the same hood because an interchange could disrupt the previously achieved balance. Balancing can also be accomplished by changing the number and/or the size of filters.

If one designer selects and lays out the entire exhaust system, such as for a large kitchen with several hoods, the ductwork can be designed for controlled pressure loss in all branches. In cases such as master kitchen exhaust systems, which are sometimes used in shopping center food courts, no single group is responsible for the entire design. The base building designer typically lays out the ductwork to (or through) each tenant space, and each tenant selects the hood and lays out the connecting ductwork. Often the base building designer has incomplete information regarding the tenants' exhaust requirements. Therefore, one engineer must be responsible for defining criteria for each tenant's design and for evaluating proposed tenant work to ensure that tenants' designs match the system's capacity as much as possible. The engineer should also evaluate any proposed changes to the system, such as changing tenancy. Rudimentary computer modeling of the exhaust system may be helpful (Elovitz 1992). Given the unpredictability and volatility of tenant requirements, it may not be possible to balance the entire system perfectly. However, without adequate supervision, chances are very good that at least parts of the system will be badly out of balance.

For greatest success with multiple-hood exhaust systems, pressure losses in the ductwork should be minimized by keeping velocities low, minimizing sharp transitions, and using hoods with relatively high pressure drops. When the pressure loss in the ductwork is low compared to the loss through the hood, changes in pressure loss in the ductwork due to field conditions or changes in design airflow will have a smaller effect on total pressure loss and thus on actual airflow.

The minimum, code-required air velocity must be maintained in all portions of the exhaust ductwork at all times. If fewer or smaller hoods are installed than the design anticipated, resulting in low velocity in portions of the ductwork, the velocity must be brought up to the minimum. One way is to introduce air, preferably untempered replacement air, directly into the exhaust duct where it is required (see Figure 6). The bypass duct should connect to the top or sides (at least 50 mm from the bottom) of the exhaust duct to prevent backflow of water or grease through the bypass duct when the fans are off. This arrangement is shown in NFPA *Standard* 96 and should be discussed with the authority having jurisdiction.

A fire damper should be provided in the bypass duct, located close to the exhaust duct. The bypass duct construction should be the same as the exhaust duct construction, including enclosure and clearance requirements, for about a metre beyond the fire damper. Means to adjust the bypass airflow must be provided upstream of the fire damper. All dampers must be in the clean bypass air duct so

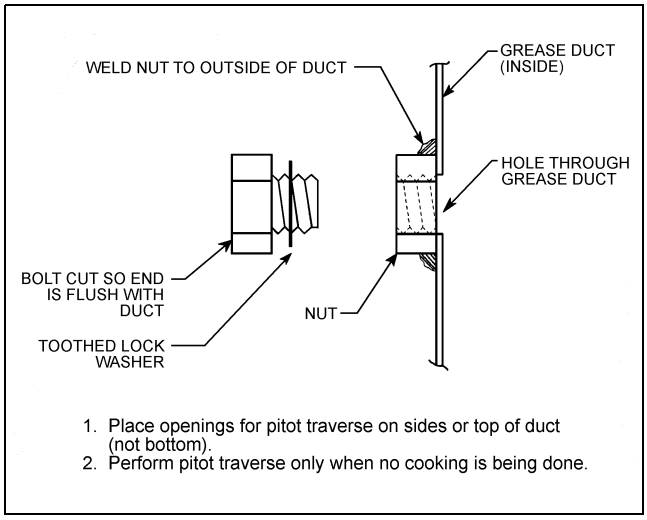

Fig. 7 Metal-to-Metal Seal for Pitot Tube Access Port in Grease Duct

that they are not exposed to grease-laden exhaust air. The difference in pressure between the replacement air and the exhaust air duct may be great; the balancing device must be able to make a fine airflow adjustment against this pressure difference. It is best to provide two balancing devices in series, such as an orifice plate or blast gate for coarse adjustment followed by an opposed-blade damper for fine adjustment.

Direct measurement of air velocities in the exhaust ductwork to assess exhaust system performance may be desirable. **Velocity (pitot-tube) traverses** may be performed in kitchen exhaust systems, but the holes drilled for the pitot tube must be liquidtight to maintain the fire-safe integrity of the ductwork. Figure 7 shows a means of providing a metal-to-metal seal for these holes. Holes should never be drilled in the bottom of a duct, where they may collect grease. Velocity traverses should not be performed when cooking is in progress because grease collects on the instrumentation.

ENERGY CONSIDERATIONS

Energy conservation in restaurants depends on the following variables:

Climate. Average outdoor temperature is the principal predictor of restaurant energy use. Because climatic zones vary dramatically in temperature and humidity, kitchen ventilation conservation designs have widely varying economic recovery periods. In new facilities, the designer can select conservation measures suitable for the climatic zone and the HVAC system to maximize the economic benefits.

Restaurant Type. Claar et al. (1985) defined five restaurant types: fast-food, full-service, coffee shop, pizza, and cafeteria. Restaurant associations identify many additional restaurant types, and energy use varies significantly among the types. As a result, some energy conservation measures work in all restaurants while others may work only in specific types. For simplicity, this discussion classifies restaurants as cafeteria, fast-food, full-menu, and pizza.

Hood Type and Equipment Characteristics. The type of exhaust hood selected depends on such factors as restaurant type, restaurant menu, and food service equipment. Exhaust flow rates are largely determined by the food service equipment and the hood style. The effectiveness of conservation measures, whether in a new design or as a retrofit, is also affected by the type of hood and food service equipment.

Energy Conservation Measures

Energy costs in restaurants vary from 2 to 6% of gross sales. The following major energy conservation measures can reduce commercial kitchen ventilation costs:

- Custom-designed hoods, either listed or approved by the local code official
- Dining room air for kitchen ventilation
- Heat recovery from exhaust hood ventilation air
- Extended economizer operation
- Reduced exhaust and replacement air volumes

Custom-Designed Hoods. A typical cooking lineup combines food service equipment with different thermal updraft characteristics and exhaust flow rate requirements depending on cooking load, cooking temperature, product cooked, fuel source, and so forth. Exhaust hoods are usually sized to handle worst-case cooking requirements, so kitchen exhaust requirements are often overstated.

Custom-designed hoods for each piece of equipment can lower ventilation requirements and, consequently, reduce fan sizes, energy use, and energy costs for all types of restaurants. Hood manufacturers recommend exhaust flow rates based on either thermal current charts or empirical tests. The total flow rate and size of the hood exhaust are determined by summing the individual equipment airflow rate and size requirements for the entire cooking lineup. To operate at flow rates lower than required by code, custom-designed hoods must be either listed or approved by the local code official.

Dining Room Air for Kitchen Ventilation. Most fast-food and pizza restaurants do not physically segregate the kitchen from the dining room, so conditioned air moves from the dining area to the kitchen. Dining room air helps cool the kitchen to some extent and provides some replacement air for the kitchen exhaust.

Full-menu and cafeteria food service facilities are frequently designed so that minimal replacement air transfers between the dining room and the kitchen. This segregation means that the majority of kitchen exhaust must be made up within the kitchen by conditioned or unconditioned air.

In restaurants in which the kitchen and dining room are physically segregated, ducts between the two areas permit conditioned air to flow to the kitchen. This design can reduce replacement air requirements and enhance employee comfort, especially if the kitchen is not air conditioned. Of course, the dining room must have replacement air to replace the air transferred to the kitchen. Also, care must be taken to ensure that enough replacement air is introduced into the kitchen to meet the requirements of applicable codes and standards.

Heat Recovery from Exhaust Hood Ventilation Air. High-temperature effluent, often in excess of 200°C, heats the exhaust air to 40 to 90°C as it travels over the cooking surfaces and areas. It is frequently assumed that this heated exhaust air is suitable for heat recovery; however, smoke and grease in the exhaust air will, with time, cover any heat transfer surface. Under these conditions, the heat exchangers require constant maintenance (e.g., automatic wash-down) to maintain acceptable heat recovery.

Because heat recovery systems are very expensive, only food service facilities with large amounts of cooking equipment and large cooking loads are good candidates for this equipment. Heat recovery may work in full-menu and cafeteria restaurants and in institutional food service facilities such as prisons and colleges. An exhaust hood equipped with heat recovery is more likely to be cost-effective where the climate is extreme, such as the northern tier states or the southern states. A mild climate, such as in California, is not conducive to use of this conservation measure.

Extended Economizer Operation. In most restaurants, the mechanical cooling is called on as soon as someone is too warm in order to keep the staff and customers cool. By operating an economizer system instead, similar cooling can be achieved at less cost because only fans are operated and not compressors. Economizers can be used in lieu of mechanical cooling when the outside temperature (and sometimes humidity) is lower than the return air condition. Economizer systems may be designed to increase ventilation by 25% or less over normal ventilation, or about 50 to 60% of system supply capacity. Yet economizers have the capability of increasing the outside air to 100%. This operation can dramatically extend the time that the mechanical cooling is kept off.

Use of full-capacity economizer operation requires variable rather than one-step control of the exhaust and replacement air. The savings can justify the initial cost, especially in moderate climates where temperatures range between about 25 and 28°C for most of the summer.

To allow economizer operation with canopy hoods, it may be adequate to increase the exhaust at each hood. With back shelf hoods, which are lower than the heads of the crew, it may be better to increase the flow of exhaust from the ceiling of the kitchen in order to lower the upper space temperature.

To take full advantage of maximum economizer operation, the entire food service area, including all cooking and dining zones, must be in the economizer mode. It may be uncomfortable or uneconomical to maximize economizer operation when some zones remain in the heating or mechanical cooling mode.

Reduced Exhaust and Replacement (Makeup) Airflow Rates. The tempering of outdoor replacement air can account for a large part of a food service facility's heating and cooling costs. By reducing the exhaust flow rates (and the corresponding replacement air quantity) when no product is being cooked, the cost of energy can be significantly reduced. Field evaluations by one large restaurant chain suggest that cooking appliances may be at zero load for 75% or more of an average business day (Spata and Turgeon 1995). During these periods when no smoke or grease-laden vapors are being produced, NFPA *Standard* 96 allows reduction of exhaust quantities. The only restriction on the reduced exhaust quantity is that it be "… sufficient to capture and remove flue gases and residual vapors…"

FIRE PROTECTION

The combination of flammable grease and particulates carried by kitchen ventilation systems and the potential of the cooking equipment to be an ignition source creates a higher hazard level than normally found in HVAC systems. The design of an exhaust system serving cooking equipment that may produce grease-laden vapors must provide, at a minimum, a reasonable level of protection for the safety of building occupants and fire fighters. The design can be enhanced to provide extra protection for property.

Replacement air systems, air-conditioning systems serving a kitchen, and exhaust systems serving only cooking equipment that does not produce grease-laden vapor have no specific fire protection requirements beyond those applicable to similar systems not located in kitchens. However, an exhaust system that serves any grease-producing cooking equipment must be considered a grease exhaust system even if it also serves non-grease-producing equipment.

Fire protection starts with proper operation and maintenance of the cooking equipment and the exhaust system. After that, the two primary aspects of fire protection in a grease exhaust system are (1) to extinguish a fire quickly once it has started and (2) to prevent the spread of fire from or to the grease exhaust system.

Fire Suppression

NFPA *Standard* 96 requires that exhaust systems serving grease-producing equipment must include a fire-extinguishing system, except where certain listed grease removal devices or systems are installed. The fire-extinguishing system must protect the cooking surfaces, the hood interior, the hood filters or grease extractors, the ductwork, and any additional grease removal devices in the system.

The most common fire-extinguishing systems are wet chemical and water spray systems.

Operation. Actuation of any fire-extinguishing system should not depend on normal building electricity. If actuation relies on electricity, it should be supplied with standby power.

Any extinguishing system must automatically shut off all supplies of fuel and heat to all equipment protected by that system. Any gas appliance not requiring protection but located under the same ventilating equipment must also be shut off. Upon operation of a wet chemical or water fire-extinguishing system, all electrical sources located under the ventilating equipment, if subject to exposure to discharge from the fire-extinguishing system, must be shut off. If the hood is in a building with a fire alarm system, actuation of the hood extinguishing system should send a signal to the fire alarm.

Dry and Wet Chemical Systems. Wet chemical fire-extinguishing systems are the most common in new construction for the protection of hoods and exhaust systems. Dry chemical systems were popular; however, most manufacturers have removed them from the market because they have not passed UL *Standard* 300. Dry chemical systems are covered in NFPA *Standard* 17, and wet chemical systems are covered in NFPA *Standard* 17A. Both standards provide detailed application information. These systems are tested for their ability to extinguish fires occurring in cooking operations in accordance with UL *Standard* 300. To date, only wet chemical systems are listed to UL *Standard* 300.

Both dry and wet chemicals extinguish a fire by reacting with fats and grease to **saponify**, or form a soapy layer of foam that prevents oxygen from reaching the hot surface. This suppresses the fire and prevents reignition. Saponification is particularly important with deep fat fryers, where the frying medium may be hotter than its autoignition temperature for some time after the fire is extinguished. Should the foam layer disappear or be disturbed before the frying medium has cooled below its autoignition temperature, it could reignite.

Frying media commonly used today have autoignition points of about 360 to 375°C when they are new. Contamination through normal use lowers the autoignition point. The chemical agent that extinguishes the fire also contaminates the frying medium, which can further reduce the autoignition point by 28 to 33 K. One advantage of wet chemical systems over dry chemical systems is that the wet chemical provides extra cooling to the frying medium, so that it falls below the autoignition point more quickly.

For a chemical system protecting the entire exhaust system, fire-extinguishing nozzles are located over the cooking equipment being protected, in the hood to protect the grease removal devices and hood plenum, and at the duct collar (downstream from any fire dampers) to protect the ductwork. The duct nozzle is rated to protect an unlimited length of ductwork, so additional nozzles are not required further downstream in the ductwork. Fire detection is required at the entrance to each duct (or ducts, in hoods with multiple duct takeoffs) and over each piece of cooking equipment that requires protection. The detector at the duct entrance may also cover the piece of cooking equipment directly below it.

Chemical fire-extinguishing systems are available as listed, pre-engineered (packaged) systems. Chemical systems typically consist of one or more tanks of chemical agent (dry or wet), a propellant gas, piping to the suppression nozzles, fire detectors, and auxiliary equipment. The fire detectors are typically fusible links that melt at a set temperature associated with a fire, although electronic devices are also available. Auxiliary equipment may include manual pull stations, gas shutoff valves (spring-loaded or solenoid-actuated), and auxiliary electric contacts.

Actuation of dry and wet chemical suppression systems is typically completely mechanical, requiring no electric power. The fire detectors are typically interconnected with the system actuator by steel cable in tension, so that melting of any of the fusible links releases the tension on the steel cable, causing the actuator to release the propellant and suppressant. The total length of the steel cable and the number of pulley elbows permitted are limited. A manual pull station is typically connected to the system actuator by steel cable. If a mechanical gas valve is used, it is also connected to the system actuator by steel cable. Actuation of the system also switches auxiliary dry electrical contacts, which can be used to shut off electrical cooking equipment, operate an electric gas valve, shut off a replacement air fan, and/or send an alarm signal to the building fire alarm system.

Manual pull stations are generally required to be at least 3 m from the cooking appliance and in a path of egress. Some authorities may prefer that the pull station be installed closer to the cooking equipment, for faster response. However, if the pull station is too close to the cooking equipment, it may not be possible to approach it once a fire has started. Refer to the applicable code requirements for each jurisdiction to determine specific requirements for location and mounting heights of pull stations.

Water Systems. Water can be used for protection of cooking appliances, hoods, and grease exhaust systems. Standard fire sprinklers may be used throughout the system, except over deep fat fryers, where special automatic spray nozzles specifically listed for the application must be used. These nozzles must be aimed properly and be supplied with the correct water pressure. Many hood manufacturers market a pre-engineered water spray system that typically includes a cabinet containing the necessary plumbing and electrical components to monitor the system and initiate fuel shutoff and building alarms. A water system for cleaning or grease removal in a hood can also protect the hood or duct in the case of fire, if the system is listed for this purpose.

Application of standard fire sprinklers for protection of cooking appliances, hoods, and grease exhaust systems is covered by NFPA *Standard* 13. NFPA *Standard* 96 covers maintenance of sprinkler systems serving an exhaust system. The sprinklers must connect to a wet-pipe building sprinkler system installed in compliance with NFPA *Standard* 13.

Water systems can be used to protect cooking equipment if the water spray is a fine mist. The water spray works in two ways to suppress the fire: the mist spray first absorbs heat from the fire, and then it becomes steam, which displaces air and suffocates the fire.

Although standard sprinklers may be used to protect cooking equipment other than deep fat fryers, care must be taken to ensure that sprinklers are properly selected for a fine mist discharge; if the pressure is too high or the spray too narrow, the water spray could push the flames off of the cooking equipment. Most hood manufacturers that use water to protect the cooking equipment use the sprinklers listed for deep fryers over all the cooking equipment.

One advantage of a sprinkler system is that it has virtually unlimited capacity, whereas chemical systems have limited chemical supplies. This can be an advantage in suppressing a serious fire, but all the water must be safely removed from the space. Where sprinklers are used in ductwork, the ductwork should be pitched to drain safely.

When sprinklers are used to protect ductwork, NFPA *Standard* 13 requires that they be installed every 3 m on center in horizontal ductwork, at the top of every vertical riser, and in the middle of any vertical offset. Care must be taken to protect any sprinklers exposed to freezing temperatures.

Hoods that use water either for periodic cleaning (water-wash) or for grease removal (cold water mist) can use this feature as a fire-extinguishing system to protect the hood, grease removal device, and/or ductwork in the event of a fire, if the system has been tested and listed for the purpose. The water supply for these systems may be from the kitchen water supply if flow and pressure requirements are met. These hoods can also act as a fire stop because of their multipass configuration and the fact that the grease extractors are not removable.

Combination Systems. Different system types may protect different parts of the grease exhaust system, as long as the entire

system is protected. Examples include (1) an approved water-wash or water mist system to protect the hood in combination with a dry or wet chemical system to protect the ductwork and the cooking surface or (2) a chemical system in the hood backed up by water sprinklers in the ductwork. Combination systems are more common in multiple-hood systems, where a separate extinguishing system may be used to protect a common duct. If combination systems will discharge their suppressing agents together in the same place, the agents must be compatible.

Multiple-Hood Systems. All hoods connected to a multiple-hood exhaust system must be on the same floor of the building to prevent the spread of fire through the duct from floor to floor. Preferably, there should be no walls requiring greater than a 1 h fire resistance rating between hoods.

The multiple-hood exhaust system must be designed (1) to prevent a fire in one hood or in the duct from spreading through the ductwork to another hood and (2) to protect against a fire starting in the common ductwork. Of course, the first line of protection for the ductwork is to keep it clean. Especially in a multiple-tenant system, a single entity must assume responsibility for cleaning the common ductwork frequently.

Each hood must have its own fire-extinguishing system to protect the hood and cooking surface. A single system could serve more than one hood, but in the event of fire under one hood, the system would discharge its suppressant under all of the hoods served, resulting in unnecessary cleanup expense and inconvenience. A water mist system could serve multiple hoods if the sprinkler heads were allowed to operate independently.

Because of the possibility of a fire spreading through the ductwork from one hood to another, the common ductwork must have its own fire protection system. The appendices of NFPA *Standards* 17 and 17A present detailed examples of how the common ductwork can be protected either by one system or by a combination of separate systems serving individual hoods. Different types of fire-extinguishing systems may be used to protect different portions of the exhaust system; however, in any case where two different types of system can discharge into the common duct at the same time, the agents must be compatible.

As always, actuation of the fire-extinguishing system protecting any hood must shut off fuel or power to all cooking equipment under that hood. When a common duct, or portion thereof, is protected by a chemical fire-extinguishing system, and it activates from a fire in a single hood, NFPA *Standards* 17 and 17A require shutoff of fuel or power to the cooking equipment under every hood served by that common duct, or portion of it protected by the activated system, even if there was no fire in the other hoods served by that duct.

From an operational standpoint, it is usually most sensible to provide one or more fire-extinguishing systems to detect and protect against fire in the common ductwork and a separate system to protect each hood and its connecting ductwork. This (1) prevents a fire in the common duct from causing discharge of fire suppressant under an unaffected hood and (2) allows unaffected hoods to continue operation in the event of a fire under one hood unless the fire spreads to the common duct.

Preventing Fire Spread

The exhaust system must be designed and installed both to prevent a fire starting in the grease exhaust system from spreading to other areas of the building or damaging the building and to prevent a fire in one area of the building from spreading to other parts of the building via the grease exhaust system. This protection has two main aspects: (1) maintaining a clearance from the duct to other portions of the building and (2) enclosing the duct in a fire resistance rated enclosure. Both aspects are sometimes addressed by a single action.

Clearance to Combustibles. A grease exhaust duct fire can generate gas temperatures of 1100°C or greater in the duct. In such a grease fire, heat radiating from the hot duct surface can ignite combustible materials in the vicinity of the duct. Most codes require a minimum clearance of 460 mm from the grease exhaust duct to any combustible material. However, even 460 mm may not be sufficient clearance to prevent ignition of combustibles in the case of a major grease fire, especially in larger ducts.

Several methods to protect combustible materials from the radiant heat of a grease duct fire and permit reduced clearance to combustibles are described in NFPA *Standard* 96. Previous editions required that these protections be applied to the combustible material rather than to the duct, on the theory that if the duct is covered with an insulating material, the duct itself will become hotter than it would if it were free to radiate its heat to the surroundings. The hotter temperatures could result in structural damage to the duct. NFPA *Standard* 96 allows materials to be applied to the actual duct. However, because this edition may not have been accepted by some jurisdictions, the authority having jurisdiction should be consulted before clearances to combustible materials are reduced.

Listed grease ducts, typically double-wall ducts with or without insulation between the walls, may be installed with reduced clearance to combustibles in accordance with manufacturers' installation instructions, which should include specific information regarding the listing. Listed grease ducts are tested under UL *Standard* 1978.

NFPA *Standard* 96 also requires a minimum clearance of 75 mm to "limited combustible" materials (e.g., gypsum wallboard on metal studs). At present, none of the standards and model codes requires any clearance to noncombustible materials except for enclosures.

Enclosures. Normally, when a duct penetrates a fire resistance rated wall or floor, a fire damper is used to maintain the integrity of the wall or floor. Because fire dampers may not be installed in a grease exhaust duct unless specifically approved for such use, there must be an alternate means of maintaining the integrity of rated walls or floors. Therefore, grease exhaust ducts that penetrate a fire resistance rated wall or floor-ceiling assembly must be continuously enclosed in a fire-rated enclosure from the point the duct penetrates the first fire barrier until the duct leaves the building. Listed grease ducts are also subject to these enclosure requirements. The requirements are similar to those for a vertical shaft (typically 1 h rating if the shaft penetrates fewer than three floors, 2 h rating if the shaft penetrates three or more floors), except that the shaft can be both vertical and horizontal. In essence, the enclosure extends the room containing the hood through all the other compartments of the building without creating any unprotected openings to those compartments.

Where a duct is enclosed in a rated enclosure, whether vertical or horizontal, clearance must be maintained between the duct and the shaft. NFPA *Standard* 96 and IMC require minimum 150 mm clearance and that the shaft be vented to the outdoors. IMC requires that each exhaust duct have its own dedicated enclosure.

Some available materials are listed to serve as a fire resistance rated enclosure for a grease duct when used to cover a duct directly with minimal clear space between the duct and the material. These listed materials must be applied in strict compliance with the manufacturer's installation instructions, which may limit the size of duct to be covered and specify required clearances for duct expansion and other installation details. When a duct is directly covered with an insulating material, there is a greater chance of structural damage to the duct due to the heat of a severe fire. The structural integrity of exhaust ducts should be assessed after any serious duct fire.

Insulation materials that have not been specifically tested and approved for use as fire protection for grease exhaust ducts should not be used in lieu of rated enclosures or to reduce clearance to combustibles. Even insulation that is approved for other fire protection applications, such as to protect structural steel, may not be appropriate for grease exhaust ducts because of the high temperatures that may be encountered in a grease fire.

Exhaust and Supply Fire-Actuated Dampers. Because of the risk that the damper may become coated with grease and become a source of fuel in a fire, balancing and fire-actuated dampers are not permitted at any point in a grease exhaust system except where specifically listed for each use or required as part of a listed device or system. Typically, fire dampers are found only at the hood collar and only if provided by the manufacturer as part of a listed hood.

Opinions differ regarding whether any fire-actuated dampers should be provided in the exhaust hood. On one hand, a fire-actuated damper at the exhaust collar may prevent a fire under the hood from spreading to the exhaust duct. However, like anything in the exhaust airstream, the fire-actuated damper and linkage may become coated with grease if not properly maintained, which may impede damper operation. On the other hand, without fire-actuated dampers, the exhaust fan will draw smoke and fire away from the hood. While this cannot be expected to remove all of the smoke from the kitchen in the event of a fire, it can help to contain the smoke in the kitchen and minimize migration of smoke to other areas of the building.

A fire-actuated damper will generally close only in the event of a severe fire; most kitchen fires are extinguished before enough heat is released to trigger the fire-actuated damper. Thus the hood fire-actuated damper remains open during relatively small fires, allowing the hood to remove smoke, but can close in the event of a severe fire, helping to contain the fire in the kitchen area.

Fan Operations. If it is over 1 m^3/s, the replacement air supply to the kitchen is generally required to be shut down in case of fire to avoid feeding air to the fire. However, if the exhaust system is intended to operate during a fire to remove smoke from the kitchen (as opposed to just containing it in the kitchen), the replacement air system must operate as well. If the hood has an integral replacement air plenum, a fire-actuated damper must be installed in the replacement air collar to prevent a fire in the hood from entering the replacement air ductwork. NFPA *Standard* 96 details the instances where fire-actuated dampers are required in a hood replacement air assembly.

Regardless of whether fire-actuated dampers are installed in the exhaust system, NFPA *Standard* 96 calls for the exhaust fan to continue to run in the event of a fire unless fan shutdown is required by a listed component of the ventilating system or of the fire-extinguishing system. Dry and wet chemical fire-extinguishing systems protecting ductwork are tested both with and without airflow; exhaust airflow is not necessary for proper operation.

Special Filtration Systems

Concerns about air quality have emphasized the need for higher efficiency grease extraction from the exhaust airstream than can be provided by filters or grease extractors in the exhaust hoods. Cleaner exhaust discharge to outdoors may be required by increasingly stringent air quality regulations or where the exhaust discharge configuration is such that grease, smoke, or odors in the discharge would create a nuisance. In some cases, the exhaust air is cleaned so that it can be discharged indoors (e.g., through recirculating hoods). Several systems have been developed to clean the exhaust airstream, each of which presents special fire protection risks. These systems are as follows:

- Systems that use one or more stages of filtration to remove the grease from the airstream capture and collect the grease on the filters. In the event of a fire, grease-coated filters may become a source of fuel. Each bank of filters must be protected by an extinguishing system. If filters with deep pleats (e.g., HEPA filters) are used, the extinguishing agent must be able to penetrate deep into the pleats to extinguish the fire.
- Systems that use **electrostatic precipitators** (ESPs) to clean the exhaust stream must also have appropriate fire protection. ESPs use electricity, which could be a source of ignition. ESPs in grease ducts should use self-limiting (cold spark) transformers to minimize the possibility of electrical fire. ESP plates must be cleaned frequently to prevent grease buildup and to maintain operating efficiency. ESPs are available with automatic washdown features that simplify the task of keeping the plates clean.

Where odor control is required in addition to grease removal, activated charcoal or other oxidizing bed filters are typically used downstream of the grease filters. Because much of the cooking odor is gaseous, and therefore not removed by air filtration, the filtration upstream of the charcoal filters must remove virtually all of the grease in the airstream in order to prevent grease buildup on the charcoal filters. However, charcoal filters themselves are flammable and must be protected from fire.

OPERATION AND MAINTENANCE

Operation and maintenance are closely related; operation creates the need for maintenance, and maintenance permits continued operation.

Operation

All components of the ventilation system are designed to operate in balance with each other, even under variable loads, to properly capture, contain, and remove the cooking effluent and heat and maintain proper temperature control in the spaces in the most efficient and economical manner. Deterioration in any of these components unbalances the system, affecting one or more of its design concepts. The system design intent should be fully understood by the operator so that any deviations in the operation can be noted and corrected. In addition to creating health and fire hazards, normal cooking effluent deposits can also unbalance the system, so they must be regularly removed.

All the various components of the exhaust and replacement air systems affect proper capture, containment, and removal of the cooking effluent. In the exhaust system, this includes the cooking equipment itself, the exhaust hood, all filtration devices, the ductwork, the exhaust fan, and any dampers in the exhaust system. In the replacement air system, this includes the air-handling unit(s) with the intake louvers, dampers, filters, fan wheels, heating and cooling coils, ductwork, and supply registers. In systems that obtain their replacement air from the general HVAC system for the space, this also includes the return air registers and ductwork.

When the system is first set up and balanced in new condition, these components are set to optimum efficiency. In time, all components become dirty; filtration devices, dampers, louvers, heating and cooling coils, and ducts become restricted; fan blades change shape as they accumulate dirt and grease; and fan belts loosen. In addition, dampers can come loose and change position, even closing, and ductwork can develop leaks or be shut off when internal insulation sheets fall down.

All these changes deteriorate the performance of the system. The operator should know how the system performed when it was new, in order to better recognize when it is no longer performing the same way. This knowledge allows problems to be found and corrected sooner and the peak efficiency and safety of the system operation to better be maintained.

Maintenance

Maintenance may be classified as preventive or emergency (breakdown). **Preventive maintenance** keeps the system operating at the smallest deviation from optimal performance. Preventive maintenance allows continued optimal performance of the system, including the maximum production and least shutdown. It is the most effective maintenance and is preferred.

Preventive maintenance is able to prevent most emergency shutdowns and emergency maintenance. Preventive maintenance has a

modest ongoing cost and fewer unexpected costs. It is clearly the lowest cost maintenance in the long run because it keeps the system components in peak condition, which extends the operating life of all components.

Emergency maintenance must be applied when a breakdown occurs. Sufficient staffing and money must be applied to the situation to bring the system back on line in the shortest possible time. Such emergencies can be of almost any nature. They are impossible to predict or address in advance, except to presume the type of component failures that could shut the system down and keep spares of these components on hand, or readily accessible, so they can be quickly replaced. Preventive maintenance, which includes regular inspection of critical system components, is the most effective way to avoid emergency maintenance.

Following are brief descriptions of typical operations of various components of kitchen ventilation systems and the type of maintenance and cleaning that would be applied to the abnormally operating system to bring it back to normal. Many nontypical operations are not listed here.

Cooking Equipment

Normal Operation. Produces properly cooked product, of correct temperature, within expected time period. Minimum smoke during cooking cycles.

Abnormal Operation. Produces undercooked product, of lower temperature, with longer cooking times. Increased amount of smoke during cooking cycles.

Cleaning/Maintenance. Clean solid cooking surfaces between each cycle if possible, or at least once a day. Baked-on product insulates and retards heat transfer. Filter frying medium daily and change it on schedule recommended by supplier. Check that (1) fuel source is at correct rating, (2) thermostats are correctly calibrated, and (3) conditioned air is not blowing on cooking surface.

Exhaust Systems

Normal Operation. All cooking vapors are readily drawn into the exhaust hood, where they are captured and removed from the space. The environment immediately around the cooking operation is clear and fresh.

Abnormal Operation. Many cooking vapors do not enter the exhaust hood at all, and some that enter subsequently escape. The environment around the cooking operation, and likely in the entire kitchen, is contaminated with cooking vapors.

Cleaning/Maintenance. Clean all grease removal devices in the exhaust system. Hood filters should be cleaned at least daily. For other devices, follow the minimum recommendations of the manufacturer; even these may not be adequate at very high flow rates or with products producing large amounts of effluent. Check that (1) all dampers are in their original position, (2) fan belts are properly tensioned, (3) the exhaust fan is operating at the proper speed and turning in the proper direction, (4) the exhaust duct is not restricted, and (5) the fan blades are clear.

NFPA *Standard* 96 design requirements for access to the system should be followed to facilitate cleaning of the exhaust hood, ductwork, and fan. If the cleaner cannot get to parts of the system, these parts will not be cleaned. Cleaning should be done before the grease has built up to 6 mm in any part of the system. Cleaning should be by a method that cleans to bare metal, and the metal should be left clean. Cleaning agents should be thoroughly rinsed off, and all loose grease particles should be removed, as they can ignite more readily. Agents should not be added to the surface after cleaning, as their textured surfaces merely collect more grease more quickly. Fire-extinguishing systems may need to be disarmed prior to cleaning to prevent accidental discharge and then reset by authorized personnel after cleaning. All access panels removed must be reinstalled after cleaning, with the proper gasketing in place to prevent grease leaks and escape of fire.

Supply, Replacement, and Return Air Systems

Normal Operation. The environment in the kitchen area is clear, fresh, comfortable, and free of drafts and excessive air noise.

Abnormal Operation. The kitchen is smoky, choking, hot, and humid, and perhaps very drafty with excessive air noise.

Cleaning/Maintenance. Check that the replacement air system is operating and that it is providing the correct amount of air to the space. If it is not, the exhaust system cannot operate properly. Check that the dampers are set correctly, the filters and exchangers are clean, the belts are tight, the fan is turning in the correct direction, and the supply and return ductwork and registers are open with the supply air discharging in the correct direction and pattern. If drafts persist, the system may need to be rebalanced. If noise persists in a balanced system, system changes may be required.

Filter cleaning or changing frequency varies widely depending on the quantity of airflow and the contamination of the local air. Once determined, the cleaning schedule must be maintained.

With replacement air systems, the air-handling unit, coils, and fan are usually cleaned in spring and fall, at the beginning of the seasonal change. More frequent cleaning or better quality filtering may be required in some contaminated environments. Duct cleaning for the system is on a much longer cycle, but local codes should be checked as stricter requirements are invoked. Ventilation systems should be cleaned by professionals to ensure that none of the expensive system components are damaged. Cleaning companies should be required to carry adequate liability insurance. The International Kitchen Exhaust Cleaning Association (IKECA) and the National Air Duct Cleaners Association (NADCA), both located in Washington, D.C., can provide descriptions of proper cleaning and inspection techniques and lists of their members.

Control Systems (Operation and Safety)

Normal Operation. Control systems should not permit the cooking equipment to operate unless both the exhaust and replacement air systems are operating and the fire suppression system is armed. With multiple exhaust and replacement air systems, the controls maintain the proper balance as cooking equipment is turned on and off. In the event that a fire suppression system operates, the energy source for the cooking equipment it serves is shut off. On ducted systems, the exhaust fan usually keeps running to remove fire and smoke from building. On ductless systems, the fan may or may not keep running, but a discharge damper closes to keep the flames away from the ceiling. The replacement air system may continue to run, or it may be shut off by a separate local area fire and smoke sensor. If the control system does not operate in this way, changing to this operation should be considered.

Abnormal Operation. The cooking equipment can operate when the exhaust and supply are turned off, perhaps because the fire suppression system is unarmed or has been bypassed. When extra cooking systems are turned on or off, the operator must remember to manually turn the exhaust and replacement air fans on or off as well.

When the exhaust and replacement air systems are not interlocked, the system can be out of balance. This can cause many of the kinds of abnormal operation described for the other systems. With gas-fired cooking equipment, the fire suppression system may have a false discharge if the exhaust system is not operating. If cooking is permitted when the fire suppression system inoperable, there is a great chance of a serious fire, and the operator is liable because insurance usually does not cover this situation.

Cleaning/Maintenance. Cleaning is usually restricted to the mechanical operators and electrical sensors in the fire suppression system and within the hood that are exposed to grease. If they

become excessively coated with grease, mechanical operators cannot move and sensors cannot sense. The result is decreased control and safety. The mechanical operators should be cleaned as often as required to maintain free movement. Fire suppression system operators may need to be changed annually rather than cleaned. Check with a local fire suppression system dealer before attempting to clean any of these components.

Maintenance of control systems (presuming they were properly designed) is mostly a matter of checking the performance of the entire system regularly (minimum every three months) to be sure it is still performing as designed. Mechanical linkages on dampers and cleanliness of sensors should be checked regularly (minimum once a month). All electrical screw terminals in the components should be checked for tightness, relay contacts should be checked for cleanliness, and all exposed conducting surfaces should be checked for corrosion on an annual basis.

RESIDENTIAL KITCHEN VENTILATION

Although commercial and residential cooking processes are similar, ventilation requirements and procedures for the two are different. Differences include exhaust airflow rate and installation height. In addition, residential kitchen ventilation has no replacement air requirement, and energy consumption is insignificant due to lower airflow, smaller motors, and intermittent operation.

Residential Cooking Equipment and Processes

Although the physics of the cooking process and the resulting effluent are about the same, residential cooking is done more conservatively. Equipment such as upright broilers and solid-fuel-burning equipment, described in the section on Exhaust Hoods as Group 3 (heavy duty) and Group 4 (extra heavy duty), is not used. Therefore, the high ventilation rates and ventilation equipment associated with these rates are not found in residential kitchens. On the other hand, cooking effluent and by-products of open flame combustion must be more closely controlled in a residence than in a commercial kitchen because any escaping effluent is dispersed throughout a residence whereas a commercial kitchen is negative compared to surrounding spaces. A residence also has a much lower background ventilation rate, so escaping contaminant is more persistent. This situation presents a different challenge because it is not possible to overcome problems by simply increasing the ventilation rate at the cooking process.

Residential cooking always produces a convective plume that carries upward with it both cooking effluent and any by-products of combustion. Sometimes there is spatter as well, but those particles are so large that they are not removed by ventilation. Residential kitchen hoods depend almost entirely on buoyancy capture.

Hoods and Other Residential Kitchen Ventilation Equipment

Most residential kitchens are ventilated by wall-mounted, conventional range hoods. Overall, they do the best job at the lowest installed cost. A variation is the deep decorative canopy hood, which is usually chosen for aesthetic reasons. The canopy hood is significantly more costly, but somewhat more effective. **Downdraft range-top ventilators** are currently popular in higher priced homes. These are an exception because they are designed to capture the contaminants by producing velocities over the cooking surface greater than those of the convective plume. With sufficient velocity, their operation can be satisfactory; however, with gas cooking, velocity is limited to prevent an adverse effect on the flame.

Kitchen exhaust fans were more widely used in the past, but they are still used and probably will be for several years. Mounted in the wall or ceiling, they ventilate the kitchen generally rather than at the source of contaminant. For general ventilation in all possible kitchen arrangements, 15 air changes per hour are typical; for ceiling-mounted fans, this is usually sufficient, but for wall-mounted fans, it may be marginal.

Continuous low-level ventilation throughout the house is used increasingly as houses are built with greater airtightness and public awareness of the importance of good indoor air quality grows. This continuous ventilation is for a distinctly different purpose than kitchen ventilation. ASHRAE *Standard* 62 recommends 0.35 air changes per hour but not less than 8 L/s per person. Some installations with equipment for continuous ventilation use that same equipment for kitchen ventilation by intermittently boosting the flow to a considerably higher level or by simply running longer to achieve the needed reduction in effluent concentration. These dual-purpose systems require good design for satisfactory operation and seldom achieve the results of a conventional range hood. If kitchen exhaust is introduced into a general ventilation system, bionutrients must be removed.

Differences Between Commercial and Residential Equipment

Residential hoods usually meet UL *Standard* 507 requirements. Fire-actuated dampers are never part of the hood and are almost never used. Grease filters in residential hoods are much simpler; grease collection through channels is undesirable because inadequate maintenance could allow grease to pool, creating a fire and health hazard.

Conventional residential wall hoods are usually produced with standard height (from 150 to 230 mm or 300 mm) and standard depth (430 to 560 mm). Width is usually the same as the cooking surface; 760 mm is almost a standard in the United States. The current HUD Manufactured Home Construction and Safety Standards call for 75 mm overhang per side.

Mounting height is usually 460 to 610 mm, with some mounted even higher at a sacrifice in collection efficiency. The lower the hood, the more effective the capture; the velocity of the convective plume is not great, and the plume is easily disrupted by air currents and disturbances. Studies show that 460 mm is the minimum height for suitable access to the cooking surface. Some codes call for a minimum of 760 mm from the cooking surface to combustible cabinets. In that case, the bottom of a 150 mm hood can be 610 mm above the cooking surface.

A minimum flow rate (exhaust capacity) of 60 L/s per linear metre of hood width is recommended by the Home Ventilating Institute (HVI 1998). Informal tests were conducted in which hood users were told to keep adjusting the variable speed control on the hood until it was running slow enough to minimize the sound level while still maintaining good performance. After a trial period, the chosen setting was evaluated; most users had selected a speed providing flow within 15% of the recommended minimum 60 L/(s·m). Although these tests were too few to be statistically valid and were quite informal, the outcome was predicted. Additional capacity, with speed control, is desirable for handling unusually vigorous cooking and cooking mistakes. The airflow can be increased for a brief period to clear the air.

Exhaust Systems

Residential hoods offer little opportunity for custom design of an exhaust system. A duct connector is built into the hood, and the installation should use the same size duct. A hood includes either an axial or a centrifugal fan. The centrifugal fan has higher pressure capabilities, but the axial fan is usually adequate for low-volume hoods. Virtually all residential hoods on the market in the United States have HVI-certified airflow performance.

Replacement (Makeup) Air

The exhaust rate of residential hoods is generally low enough to avoid the need for replacement air systems, so hoods rely on natural

infiltration. This may cause slight negative pressurization of the residence, but it is usually less than that caused by other equipment such as the clothes dryer. Still, the penalties for backdrafts through the flue of a combustion appliance are high. If the residence has a gas furnace and water heater, the flue should be checked for adequate flow with all exhaust devices turned on unless the furnace and water heater are of the sealed combustion type.

Sometimes commercial-style cooking equipment approved for residential use, with its associated higher ventilation requirements, is installed in residences. In such cases, designers should refer to the earlier sections of this chapter, possibly including the section on Replacement (Makeup) Air Systems.

Energy Conservation

The energy cost of residential hoods is quite low because of the few hours of running time and the low rate of exhaust. For example, it typically costs less than $10 per heating season in Chicago to run a hood and heat the replacement air, based on running at 70 L/s for an hour a day and using gas heat.

Fire Protection for Residential Hoods

Residential hoods must be installed with metal (preferably steel) duct, and the duct should be positioned to prevent pooling of grease. Residential hood exhaust ducts are almost never cleaned, and there is no evidence that this causes fires. Several attempts have been made to make fire extinguishers available in residential hoods, but none has met with broad acceptance. In contrast, residential grease fires on the cooking surface are still a problem. Although the fires always ignite at the cooking surface when cooking grease is left unattended and overheats, the hood is sometimes blamed. That problem is not solved with fire-extinguishing equipment.

Maintenance of Residential Kitchen Ventilation Equipment

All UL-listed hoods and kitchen exhaust fans are designed for simple cleaning, which should be done at intervals consistent with the cooking practices of the user. Although cleaning is often thought to be for fire prevention only, it also benefits health by removing nutrients available for the growth of organisms.
